Theorem 17 (Angluin) *For any polynomial $q(\cdot)$ there exist constants t_0 and s_0 and a strategy for the oracle $\mathfrak{O}$ to answer equivalence queries posed by a learning algorithm in such a way that for sufficiently large n any learning algorithm that asks at most $q(n)$ equivalence queries, each bounded in size by $q(n)$, cannot exactly identify elements of $M(n, t_0, s_0)$.*

To employ Theorem 17, we associate with every monotone DNF formula $\phi = \bigvee_{i=1}^{t}(x^i_1 \wedge \dots \wedge x^i_{s^i})$ with variables $x_1, \dots, x_n$ a DL-Lite$^{\exists}_{\mathcal{R}}$ TBox $\mathcal{T}_\phi$ as follows. With each conjunct $x^i_1 \wedge \dots \wedge x^i_{s^i}$ we associate a concept $C_i := \exists\rho^i_1.\exists\rho^i_2.\dots.\exists\rho^i_n.\top$ where $\rho^i_j = r$ if x_j occurs in $x^i_1 \wedge \dots \wedge x^i_{s^i}$ and $\rho^i_j = \bar{r}$ otherwise (r and $\bar{r}$ are role names). Let A be a concept name and set

$$\mathcal{T}_\phi = \{A \sqsubseteq \textstyle\bigsqcap_{i=1}^{t} C_i, \quad \bar{r} \sqsubseteq r\}.$$

For example, for $n = 4$ and $\phi = (x_1 \wedge x_4) \vee x_2$ we have

$$\mathcal{T}_\phi = \{A \sqsubseteq \exists r.\exists\bar{r}.\exists\bar{r}.\exists r.\top,\ A \sqsubseteq \exists\bar{r}.\exists r.\exists\bar{r}.\exists\bar{r}.\top,\ \bar{r} \sqsubseteq r\}.$$

A truth assignment I (for the variables $x_1 \dots, x_n$) also corresponds to a concept $C_I := \exists\rho^i_1.\exists\rho^i_2.\dots.\exists\rho^i_n.\top$, where $\rho^i_j = r$ if I makes x_j true and $\rho^i_j = \bar{r}$ otherwise. Then $I \models \phi$ iff $\mathcal{T}_\phi \models A \sqsubseteq C_I$ holds for all truth assignments I.

Note that $\bar{r}$ represents that a variable is false and r that a variable is true. Thus, the role inclusion $\bar{r} \sqsubseteq r$ captures the monotonicity of the DNF formulas considered. For any fixed values n, s and t, we set $T(n, t, s) = \{\mathcal{T}_\phi \mid \phi \in M(n, t, s)\}$.

Theorem 18 *The class of DL-Lite$^{\exists}_{\mathcal{R}}$ TBoxes is not polynomial time learnable using equivalence queries.*

Proof. We sketch the proof for the case when the TBoxes $\mathcal{H}$ from any equivalence query represent a monotone DNF formula in the variables $x_1, \dots, x_n$, that is, if all equivalence queries $\mathcal{H}$ are of the form

$$\{A \sqsubseteq \textstyle\bigsqcap_{\rho_1 \cdots \rho_n \in \Gamma} \exists\rho_1.\exists\rho_2.\dots.\exists\rho_n.\top, \quad \bar{r} \sqsubseteq r\},$$

for some $\Gamma \subseteq \{r, \bar{r}\}^n$. Arbitrary DL-Lite$^{\exists}_{\mathcal{R}}$ TBoxes in equivalence queries are considered in the appendix.

For a proof by contradiction, suppose that the running time of a learning algorithm $\mathfrak{A}$ for DL-Lite$^{\exists}_{\mathcal{R}}$ TBoxes in $\Sigma = \{A, r, \bar{r}\}$ is bounded at every stage of computation by a polynomial $p(x, y)$, where x is the size of the target TBox, and y is the maximal size of a counterexample returned by the oracle up to the current stage of computation. Let $q(n) = p(n^2, 4n + 2)$, and let t_0 and s_0 be the constants from the strategy of the oracle in Theorem 17. Let n be sufficiently large so that the claim of Theorem 17 holds.

Consider the oracle $\mathfrak{O}'$ that responds to every equivalence query $\mathcal{H}$ that represents a monotone DNF-formula ψ in n variables by returning the counterexample $A \sqsubseteq C_I$ corresponding to the truth assignment I that $\mathfrak{O}$ would return for the equivalence query ψ. We show that $\mathfrak{A}$ cannot distinguish between certain TBoxes in $T(n, t_0, s_0)$ and thus obtain a contradiction.

The largest counterexample returned by $\mathfrak{O}'$ is of the form $A \sqsubseteq \exists\rho_1.\dots\exists\rho_n.\top$, so for sufficiently large n the maximal size of any counterexample returned by $\mathfrak{O}'$ in any run of the algorithm is bounded by $4n + 2$. Similarly, the size of every potential target TBox $\mathcal{T}_\phi \in T(n, t_0, s_0)$ does not exceed $t_0 \cdot (4n + 2)$ and, as t_0 is a constant, for sufficiently large n it is bounded by n^2. Thus, for sufficiently large n the total running time of $\mathfrak{A}$ for any target TBox in $T(n, t_0, s_0)$ is bounded by $p(n^2, 4n + 2)$. So, the size of a monotone DNF equivalence query forwarded to the strategy $\mathfrak{O}$ is bounded by $q(n)$, and there will be at most $q(n)$ queries forwarded. But then $\mathfrak{O}$ returns answers such that some ϕ and ψ from $M(n, t_0, s_0)$ are not distinguished. It remains to observe that $\mathfrak{A}$ does not distinguish $\mathcal{T}_\phi$ and $\mathcal{T}_\psi$. ❑

Future Work

We have presented the first study of learnability of DL TBoxes in Angluin et al's framework of learning via queries. Many research questions remain to be explored. An immediate question is whether acyclic $\mathcal{EL}$ TBoxes can be learned in polynomial time using queries and counterexamples of the form $A \equiv C$ and $A \sqsubseteq C$ only. Note that our non-learnability result for acyclic $\mathcal{EL}$ TBoxes relies heavily on counterexamples that are not of this form. Another immediate question is whether the extension of $\mathcal{EL}_{\mathsf{lhs}}$ with inverse roles (which is a better approximation of OWL2 RL than $\mathcal{EL}_{\mathsf{lhs}}$ itself) can still

be learned in polynomial time. Other interesting research directions are non-polynomial time learning algorithms for $\mathcal{EL}$ TBoxes and the admission of different types of membership queries and counterexamples in the learning protocol. For example, one could replace concept inclusions as counterexamples with interpretations. In an OBDA context, one could allow membership queries that speak about certain answers to queries over an ABox and relative to the target TBox. Our results provide a good starting point for studying such variations.

Nominal Schemas in Description Logics: Complexities Clarified

Markus Krötzsch and **Sebastian Rudolph**
Technische Universität Dresden, Germany
{*markus.kroetzsch,sebastian.rudolph*}*@tu-dresden.de*

Abstract

Nominal schemas extend description logics (DLs) with a restricted form of variables, thus integrating rule-like expressive power into standard DLs. They are also one of the most recently introduced DL features, and in spite of many works on algorithms and implementations, almost nothing is known about their computational complexity and expressivity. We close this gap by providing a comprehensive analysis of the reasoning complexities of a wide range of DLs—from $\mathcal{EL}$ to $\mathcal{SROIQ}$—extended with nominal schemas. Both combined and data complexities increase by one exponential in most cases, with the one previously known case of $\mathcal{SROIQ}$ being the main exception. Our proofs employ general modeling techniques that exploit the power of nominal schemas to succinctly represent many axioms, and which can also be applied to study DLs beyond those we consider. To further improve our understanding of nominal schemas, we also investigate their semantics, traditionally based on finite grounding, and show that it can be extended to infinite sets of individuals without affecting reasoning complexities. We argue that this might be a more suitable semantics when considering entailments of axioms with nominal schemas.

1 Introduction

The fruitful integration of reasoning on both schema and instance level poses a continued challenge to knowledge representation and reasoning. While description logics (DLs) excel at the former task, rule-based formalisms are often more adequate for the latter. An established and highly productive strand of research therefore continues to investigate ways of reconciling both paradigms.

A practical breakthrough in this area was the discovery of *DL-safe rules*, which ensure decidability of reasoning by restricting the applicability of rules to a finite set of elements that are denoted by an individual name (Motik, Sattler, and Studer 2005). As of today, DL-safe rules are the most widely used DL-rule extension, supported by several mainstream reasoners (Kolovski, Parsia, and Sirin 2006; Motik, Shearer, and Horrocks 2009).

More recently, *nominal schemas* have been proposed as an even tighter integration of "DL-safe" instance reasoning with DL schema reasoning (Krötzsch et al. 2011). A *nominal* is a DL concept expression $\{a\}$ that represents a singleton set containing only (the individual denoted by) a. Nominal schemas replace a by a variable x that ranges over all individual names, so that it might represent arbitrary nominals $\{a\}$, where all occurrences of $\{x\}$ in one axiom represent the same nominal. For example,

$$\exists \texttt{hasFather}.\{x\} \sqcap \exists \texttt{hasMother}.(\{y\} \sqcap \exists \texttt{married}.\{x\})$$

represents the set of all individuals whose father (x) and mother (y) are married to each other, where the parents must be represented by individual names. No standard DL can express this in such a concise way. The interplay with other DL features also makes nominal schemas more expressive than the combination of DLs and DL-safe rules (cf. Sect. 8).

Nominal schemas have thus caused significant research interest, and several reasoning algorithms that exploit this succinct representation have been proposed (Krisnadhi and Hitzler 2012; Wang and Hitzler 2013; Steigmiller, Glimm, and Liebig 2013; Martínez, Wang, and Hitzler 2013). Most recently, Steigmiller, Glimm, and Liebig (2013) demonstrated that such algorithms can even outperform other systems for reasoning with DL-safe rules.

Surprisingly and in sharp contrast to these successes, many basic questions about the expressivity and complexity of nominal schemas have remained unanswered. A naive reasoning approach is based on replacing nominal schemas by nominals in all possible ways, which leads to complexity upper bounds one exponential above the underlying DL. The only tight complexity result so far is that the N2ExpTime combined complexity of reasoning in the DL $\mathcal{SROIQ}$ is not affected by nominal schemas—a result that reveals almost nothing about the computational or expressive impact of nominal schemas in general (Krötzsch et al. 2011). Beyond this singular result, it is only known that nominal schemas can simulate Datalog rules of any arity using $\exists$, $\sqcap$, and the universal role U (Knorr, Hitzler, and Maier 2012).

In this paper, we give a comprehensive account of the reasoning complexities of a wide range of DLs, considering both combined complexities (w.r.t. the size of the given knowledge base) and data complexities (w.r.t. the size of the ABox only). Figure 1 summarizes our results for combined complexities for DLs with nominal schemas (right; marked by the letter $\mathcal{V}$) in comparison with known complexities of DLs with nominals (left). It turns out that $\mathcal{SROIQ}$ is an exception, while most other DLs experience exponential complexity increases due to nominal schemas.

The effects on the data complexity are even more striking. The data complexity of standard DLs is either in P (for $\mathcal{EL}$ and Horn-DLs, which restrict the use of $\sqcup$ and $\neg$) or in NP. In contrast, the data complexities for all nominal-schema DLs in Fig. 1 are only one exponential below their combined complexity, i.e., ExpTime or NExpTime for most cases.

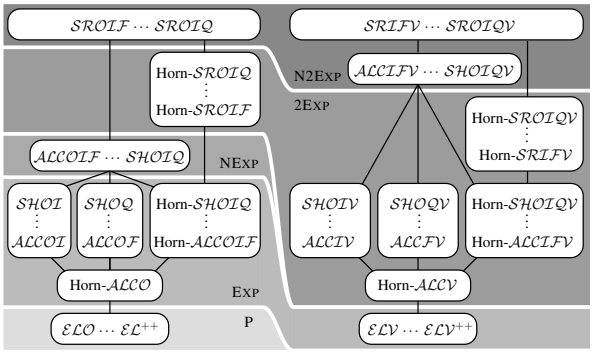

Figure 1: Combined complexities for DLs with nominals compared to DLs with nominal schemas

To obtain these results, we identify general modeling techniques that use nominal schemas to express complex schema information very succinctly. Two fundamental techniques provide the basis for most of our hardness proofs:

- **TBox-to-ABox Internalization** A TBox is replaced by a small set of "template axioms" with nominal schemas, and the original TBox is expressed with ABox assertions.
- **GCI Iterators** Templates of TBox axioms (general concept inclusions, short GCIs) are instantiated by replacing placeholder concepts by concepts from an exponentially long list of "indexed" concept names.

TBox-to-ABox internalization explains why the data complexity of most DLs with nominal schemas agrees with the combined complexity of their underlying standard DL. $\mathcal{SROIQV}$ is a noteworthy exception where the internalization is not possible. GCI iterators are a kind of generalized TBox axiom that can be used to encode exponentially large TBoxes polynomially using nominal schemas. This technique can be applied to TBoxes from known hardness proofs to boost complexities by one exponential. Both techniques provide concrete illustrations for the expressive power of nominal schemas and outline ways to obtain results for DLs that we did not consider.

After establishing these results, we revisit the formal semantics of nominal schemas. Normally, nominal schemas are considered to represent a finite set of nominals, based on individuals that either occur in the knowledge base or are part of some finite signature. This can lead to unintuitive effects, since entailments may become invalid when adding more individuals. We thus study the semantics obtained when using an infinite set of individual names instead. This makes it impossible to replace nominal schemas by nominals in all possible ways to decide entailment. Surprisingly, reasoning is still decidable with the same complexity results. Indeed, the consequences of both approaches turn out to agree under some mild assumptions.

2 Standard Description Logics

The DLs we consider are based on the well-known DL $\mathcal{SROIQ}$ (Horrocks, Kutz, and Sattler 2006). The precise syntax and semantics that we adhere to is explained in detail in the freely available DL Primer (Krötzsch, Simančík, and Horrocks 2012), so we will not repeat it here. We also consider Horn-DLs, which, in essence, forbid $\sqcup$ and $\neg$, and restrict the use of $\forall$ (Krötzsch, Rudolph, and Hitzler 2013).

Our results apply to many DLs. The smallest DL we consider is $\mathcal{EL}$, allowing only $\sqcap$, $\exists$, and $\top$. We do not consider variants of DL-Lite, since these DLs typically exclude nominals, and are therefore no natural candidates for extension with nominal schemas. We also exclude lightweight approaches like DLP, pD*, and OWL RL, since the rule-like expressiveness of these DLs is subsumed completely by nominal schemas (see Section 4). We thus use the term *standard description logic* to mean a DL $\mathcal{L}$ with $\mathcal{EL} \subseteq \mathcal{L} \subseteq \mathcal{SROIQ}$. Our complexity results refer to standard reasoning tasks, and this is what the term *reasoning* will refer to. Formally, a *standard reasoning problem* of $\mathcal{L}$ is any problem that can be polynomially reduced to checking if an $\mathcal{L}$ knowledge base KB entails a fact $A(a)$ (note that $\mathcal{EL}$ consistency checking is trivial). Nondeterminstic complexity classes may occur in two versions, e.g., NExpTime and co-NExpTime, depending on the exact reasoning task.

Two knowledge bases are semantically equivalent if they have the same models. This is often too restrictive, since many "essentially equivalent" transformations make use of auxiliary symbols that affect the set of models. A useful way to describe that a knowledge base faithfully captures the semantics of another one is to use *conservative extensions*.

Definition 1. *Consider a knowledge base* KB *over a signature* Σ*, and a knowledge base* KB$'$ *over a signature* Σ' *that extends* Σ*. Then* KB$'$ *is a* (model-)conservative extension *of* KB *if (a) every model of* KB$'$ *is a model of* KB*, and (b) every model of* KB *can be extended to a model of* KB$'$ *by adding suitable interpretations for additional signature symbols. Note that we do not require* KB $\subseteq$ KB$'$.

Essentially all mainstream DLs allow axioms to be normalized. We exploit this in some of our proofs.

Definition 2. *A DL* $\mathcal{L}$ *is called normalizable, if there is a finite set* $\{\alpha_1, \ldots, \alpha_k\}$ *of* $\mathcal{L}$ *axioms and a polynomially computable function* τ *that maps* $\mathcal{L}$ *knowledge bases to* $\mathcal{L}$ *knowledge bases such that for every* $\mathcal{L}$ *knowledge base* KB

- τ(KB) *is a conservative extension of* KB*, and*
- *every axiom of* τ(KB) *can be obtained from some* $\alpha \in \{\alpha_1, \ldots, \alpha_k\}$ *by renaming signature symbols.*

3 Nominal Schemas: Syntax and Semantics

Recall that a $\mathcal{SROIQ}$ knowledge base is based on a signature consisting of finite sets N_I of individual names, N_C of concept names, and N_R of role names. To define nominal schemas, we extend signatures by an additional finite set N_V of variable names. A nominal schema is a concept of the form $\{x\}$ with $x \in \mathsf{N}_V$, which can be used in axioms and complex concept expressions like any other $\mathcal{SROIQ}$ concept. DLs with nominal schemas are denoted by their standard name extended by $\mathcal{V}$ as in $\mathcal{SROIQV}$ or $\mathcal{ELV}$.

The semantics of nominal schemas are defined by *grounding*. For a $\mathcal{SROIQV}$ axiom α, ground(α) is the set of all $\mathcal{SROIQ}$ axioms obtained from α by uniformly replacing all variables in α by individual names in N_I in all

possible ways. The grounding of a knowledge base KB is $\mathsf{ground}(\mathrm{KB}) := \bigcup_{\alpha \in \mathrm{KB}} \mathsf{ground}(\alpha)$. Note that $\mathsf{ground}(\mathrm{KB})$ is finite, since N_I is finite. An interpretation satisfies a $\mathcal{SROIQV}$ knowledge base KB if it satisfies $\mathsf{ground}(\mathrm{KB})$, and satisfiability and entailment are defined accordingly.

The semantics of nominal schemas depends on the set N_I of individual names in the given signature. For example,

$$\{a\} \sqsubseteq \{b\} \models \{a\} \sqsubseteq \{x\} \tag{1}$$

is a valid entailment in a signature with $\mathsf{N}_I = \{a,b\}$, but not in one with $\mathsf{N}_I = \{a,b,c\}$. However, the choice of N_I (as long as it is non-empty) is only relevant when asking if axioms with nominal schemas are entailed but not for standard reasoning problems, such as instance or subsumption checking. Hence we often do not mention N_I explicitly, though, in general, always assume that the signature is given. Moreover, instances of entailment problems are always considered in the context of a single signature that covers all involved axioms.

One could take other approaches, which are worth mentioning. First, instead of using N_I, one could define nominal schemas to refer to all individual names that occur in the knowledge base. This raises questions when considering entailment problems (Which of the knowledge bases? Both?), and it leads to a kind of non-monotonicity, where $\{a\} \sqsubseteq \{x\}$ follows from $\{a\} \sqsubseteq \{b\}$, while the logically weaker axiom $\{a\} \sqsubseteq \{x\} \sqcup \{c\}$ does not (since it extends the range of $\{x\}$). Secondly, to overcome this problem, one could restrict the range of each nominal schema explicitly by requiring additional syntax. The original formulation of DL-safe rules, e.g., requires each rule variable x to appear in an atom of the form $O(x)$ in the premise, and O was defined in the ABox (Motik, Sattler, and Studer 2005). For DL axioms, however, such restrictions would unduly clutter the syntax. Finally, instead of considering N_I to be variable and finite, one could consider an infinite signature used by all knowledge bases. Grounding is no longer possible in this approach, and it is not the semantics that was assumed in previous works. We study this approach in Section 8, and find that it leads to mostly the same results as the traditional formulation.

Regarding reasoning complexity, it is important that we do not assume N_I to be fixed. Rather, the signature is part of the problem instance of an entailment problem. Therefore, the *size of a problem* always includes the size of the signature. Analogously, *data complexity* refers to the complexity of a problem under the assumption that the size of TBox and RBox is bounded by a constant, while the ABox *and* the signature can vary. When speaking of the size of a knowledge base or of an ABox, we always assume that the size of the signature is included.

Since the size of $\mathsf{ground}(\mathrm{KB})$ is exponential in the size of KB and polynomial in the size of the ABox (where the number of variables per TBox axiom is bounded), we obtain some general upper bounds for the complexity of reasoning.

Theorem 1. *Consider a DL $\mathcal{L}$. The combined complexity of $\mathcal{LV}$ is at most exponentially higher than that of $\mathcal{LO}$. If the combined complexity of $\mathcal{LO}$ is in a complexity class* C *that subsumes* P*, then the data complexity of $\mathcal{LV}$ is in* C *as well.*

4 Expressiveness of Nominal Schemas

We now take a closer look at the expressive power of nominal schemas, and draw some first conclusions about the complexity of reasoning. It was immediately observed that nominal schemas can be used to encode DL-safe rules (Krötzsch et al. 2011), and this result has later been extended to show that they can express extended DL-safe rules with predicates of any arity (Knorr, Hitzler, and Maier 2012). The universal role U was used in both encodings. However, it is easy to see that we can remove this requirement. To represent a first-order logic atom $p(t_1,\ldots,t_n)$, where $t_i \in \mathsf{N}_I \cup \mathsf{N}_V$, we use a fresh concept A_p and auxiliary roles $\mathtt{atom}$, $\mathtt{arg}_1$, …, $\mathtt{arg}_n$. We define $\mathsf{enc}(p(t_1,\ldots,t_n))$ to be the formula

$$\exists \mathtt{atom}.(A_p \sqcap \exists \mathtt{arg}_1.\{t_1\} \sqcap \ldots \sqcap \exists \mathtt{arg}_n.\{t_n\}). \tag{2}$$

A rule $B_1 \wedge \ldots \wedge B_\ell \rightarrow H$, where $B_1,\ldots,B_\ell,H$ are first-order atoms, can now be encoded by the DL axiom

$$\mathsf{enc}(B_1) \sqcap \ldots \sqcap \mathsf{enc}(B_\ell) \sqsubseteq \mathsf{enc}(H) \tag{3}$$

(as usual, the left-hand side is $\top$ if $\ell = 0$). It is easy to see that this captures the semantics of an arbitrary set of function-free Horn rules (a.k.a. Datalog). Hence, the simple DL $\mathcal{ELV}$ can already capture Datalog and thus inherits its ExpTime complexity (Dantsin et al. 2001). The matching upper bound follows from Theorem 1 and the polynomial combined complexity of $\mathcal{EL}$ (Baader, Brandt, and Lutz 2005).

Theorem 2. *Standard reasoning in $\mathcal{ELV}$ is* ExpTime*-complete for combined complexity.*

Note that the encoding of rules does not provide any interaction between unary and binary rule predicates and DL concepts and roles, respectively. We could add this using axioms like $\exists \mathtt{atom}.(A_r \sqcap \exists \mathtt{arg}_1.\{x\} \sqcap \exists \mathtt{arg}_2.\{y\}) \sqsubseteq \exists \mathtt{aux}.(\{x\} \sqcap \exists r.\{y\})$. However, some DL knowledge bases may interfere with the correctness of the encoding if they restrict the overall domain size. We address this issue in the next section.

In addition to the above, it is intuitively clear that nominal schemas are at least as expressive as nominals. The next definition provides a suitable construction. As before, we only need features of $\mathcal{EL}$.

Definition 3. *Let* KB *be a knowledge base. The knowledge base* $\mathsf{nomelim}(\mathrm{KB})$ *is obtained from* KB *as follows:*

- *replace all occurrences of $\{a\}$ in* KB *by O_a, where O_a is a fresh concept name,*
- *add an ABox axiom $O_a(a)$ for all $a \in \mathsf{N}_I$ in* KB*,*
- *add the axiom $\top \sqsubseteq \exists \mathtt{somenom}.\{x\}$, where* somenom *is a fresh role name, and*
- *add the axiom $O_a \sqcap \exists \mathtt{somenom}.(\{x\} \sqcap O_a) \sqsubseteq \{x\}$ for each of the fresh O_a.*

Essentially this procedure installs atomic concepts O_a which are axiomatized to have the same extension as the nominals they substitute. It is clear that one can compute $\mathsf{nomelim}(\mathrm{KB})$ in polynomial time. Moreover, $\mathsf{nomelim}(\mathrm{KB})$ is a conservative extension of KB. Part (a) of Definition 1 is straightforward since $\{a\} \equiv O_a$ is a direct consequence of $\mathsf{nomelim}(\mathrm{KB})$ for every nominal $\{a\}$ of KB. For (b) we enrich any model $\mathcal{I}$ of KB by $O_a^{\mathcal{I}} = \{a^{\mathcal{I}}\}$ and $\mathtt{somenom}^{\mathcal{I}} = \Delta^{\mathcal{I}} \times \{a^{\mathcal{I}} \mid a \text{ individual in KB}\}$ to find a model of $\mathsf{nomelim}(\mathrm{KB})$. This leads to the following general result.

Theorem 3. *For any DL $\mathcal{L}$ with $\mathcal{EL} \subseteq \mathcal{L}$, the combined and data complexities of standard reasoning in $\mathcal{LO}$ are lower bounds for the respective complexities of $\mathcal{LV}$.*

Nominal schemas thus generalize the expressiveness of nominals, DL-safe rules, and (DL-safe) Datalog. Nevertheless, using grounding, all of these can be expressed with nominals already, though an exponential loss in efficiency is unavoidable in general. DL-safe rules, in contrast, cannot even express nominals. The Datalog encoding (3) illustrates a type of expression that is not expressible in DLs extended with DL-safe rules. Indeed, if we consider all rules and axioms as first-order logic formulae, then the existential quantifiers in the conclusion of (3) occur in the scope of (i.e., "depend on") an arbitrary number of nominal schema assignments. In contrast, existential quantifiers in DLs (with or without DL-safe rules) occur only in axioms that share exactly one variable between the left and right formula. In other words, using Skolemization to eliminate quantifiers, one only needs unary Skolem functions in standard DLs, but Skolem functions of arbitrary arity with nominal schemas.

A related property of DLs with nominal schemas is that they cannot be normalized in the sense of Definition 2. Our complexity results allow us to show the following theorem at the end of Section 7; the case of $\mathcal{SROIQ}$ remains open.

Theorem 4. *No DL $\mathcal{LV}$ with $\mathcal{ELV} \subseteq \mathcal{LV} \subseteq \mathcal{SHOIQV}$ is normalizable.*

5 Domain Size Matters

Several of our results are based on transforming a knowledge base by using fresh individuals to represent classes. For example, for a concept `Car`, we can introduce an individual $c_{\texttt{Car}}$ and express a fact $\texttt{Car}(a)$ as $\texttt{type}(a, c_{\texttt{Car}})$. However, DLs that support nominals can interfere with this encoding.

Example 1. *Consider a knowledge base* KB *containing the TBox axiom $\top \sqsubseteq \{a,b\}$ and the ABox axioms $A(a), \neg B(a), \neg A(b), B(b), C(a), C(b)$. Clearly,* KB *is satisfiable. If we represent classes by individuals as above, we obtain the knowledge base* KB$'$ *with ABox axioms $\texttt{type}(a,c_A), \neg\texttt{type}(a,c_B), \neg\texttt{type}(b,c_A), \texttt{type}(b,c_B), \texttt{type}(a,c_C), \texttt{type}(b,c_C)$. Since every model $\mathcal{I}$ of* KB$'$ *has to map any of c_A, c_B, c_C to either $a^{\mathcal{I}}$ or $b^{\mathcal{I}}$,* KB$'$ *is unsatisfiable.*

To address this obstacle, we show how an $\mathcal{L}$ reasoning problem can be transformed in such a way that it is legitimate to focus attention on models with unbounded domains. The following notion will come handy for this.

Definition 4. *We call a knowledge base* KB unbounded *if, for every model $\mathcal{I}$ of* KB*, there is a model $\mathcal{J}$ of* KB *with infinite domain such that $\mathcal{I} \models \alpha$ iff $\mathcal{J} \models \alpha$ for every atomic concept assertion α.*

Unboundedness is guaranteed in some situations. For example, every $\mathcal{SRIQ}$ knowledge base not using the universal role is unbounded (Mehdi and Rudolph 2011, Lemma 1), and every Horn-$\mathcal{SROIQ}$ knowledge base that has a model with a domain size > 1 is unbounded as well. In the remainder of this section, we show how to transform bounded knowledge bases into unbounded ones. We can then focus on unbounded knowledge bases in the rest of the paper.

Concept expressions of the form $\forall U.C$ complicate the conversion of a knowledge base into an unbounded one, especially if the availability of other modeling features cannot be assumed. However, one can remove such expressions in a way that (next to using the universal role U which is present anyway) only requires features of $\mathcal{EL}$.

Definition 5. *Let* $\mathsf{remuniv}(\text{KB})$ *be the knowledge base obtained from* KB *by performing the following steps for each concept expression of the form $\forall U.C$ contained in* KB*, where $A_{\forall U.C}$ and $Aux_{\forall U.C}$ are fresh concept names:*

- *substitute all occurrences of $\forall U.C$ by $A_{\forall U.C}$*
- *add the following axioms to* KB*:*

$$\exists U.A_{\forall U.C} \sqsubseteq C \tag{4}$$

$$\top \sqsubseteq \exists U.Aux_{\forall U.C} \tag{5}$$

$$\exists U.(Aux_{\forall U.C} \sqcap C) \sqsubseteq A_{\forall U.C} \tag{6}$$

Lemma 5. $\mathsf{remuniv}(\text{KB})$ *is a conservative extension of* KB.

Proof. First, we show that every model of $\mathsf{remuniv}(\text{KB})$ is a model of KB by observing that $\mathsf{remuniv}(\text{KB}) \models A_{\forall U.C} \equiv \forall U.C$ for all the replaced expressions $\forall U.C$. To this end, we make a detour via first-order logic. We start with the Axiom (4) and obtain $\exists U.A_{\forall U.C} \sqsubseteq C \Rightarrow \forall x.(\exists y.(A_{\forall U.C}(y)) \rightarrow C(x)) \Rightarrow (\exists y.(A_{\forall U.C}(y)) \rightarrow \forall x.C(x)) \Rightarrow \forall y.(A_{\forall U.C}(y) \rightarrow \forall x.C(x)) \Rightarrow A_{\forall U.C} \sqsubseteq \forall U.C$.

For the other direction, we start from Axiom (6), $\exists U.(Aux_{\forall U.C} \sqcap C) \sqsubseteq A_{\forall U.C}$, translate it into first-order logic: $\forall x.(\exists y.(Aux_{\forall U.C}(y) \wedge C(y)) \rightarrow A_{\forall U.C}(x))$, transform it into $\forall x.(\forall y.(\neg Aux_{\forall U.C}(y) \vee \neg C(y)) \vee A_{\forall U.C}(x))$, and further into $\forall y.(\neg Aux_{\forall U.C}(y) \vee \neg C(y) \vee \forall x.(A_{\forall U.C}(x)))$ to finally arrive at $\forall y.(Aux_{\forall U.C}(y) \rightarrow (\neg C(y) \vee \forall x.(A_{\forall U.C}(x))))$. Since the FOL version of Axiom (5) is simply $\exists y.Aux_{\forall U.C}(y)$, we can use this to instantiate the premise of the last rule and thus obtain: $\exists y.(\neg C(y) \vee \forall x.(A_{\forall U.C}(x))) \Rightarrow \forall x.(\exists y.(\neg C(y)) \vee A_{\forall U.C}(x)) \Rightarrow \forall x.(\neg \forall y.(C(y)) \vee A_{\forall U.C}(x)) \Rightarrow \forall x.(\forall y.(C(y)) \rightarrow A_{\forall U.C}(x)) \Rightarrow \forall U.C \sqsubseteq A_{\forall U.C}$.

Next, we have to show that every model $\mathcal{I}$ of KB can be extended to a model $\mathcal{J}$ of $\mathsf{remuniv}(\text{KB})$ by providing appropriate extensions for the fresh concept names. This can be achieved via $A^{\mathcal{J}}_{\forall U.C} := (\forall U.C)^{\mathcal{I}}$ and by letting $Aux^{\mathcal{J}}_{\forall U.C} := \top^{\mathcal{I}}$ if $(\neg C)^{\mathcal{I}} = \emptyset$ and $Aux^{\mathcal{J}}_{\forall U.C} := (\neg C)^{\mathcal{I}}$ otherwise. □

Since remuniv is clearly polynomial, we do not have to consider expressions $\forall U.C$ below. Our next transformation to produce an unbounded knowledge base is reminiscent of a technique used to allow the introduction of new individuals for metamodeling (Glimm, Rudolph, and Völker 2010).

Definition 6. *Let* KB *be an $\mathcal{L}$ knowledge base for a standard DL $\mathcal{L}$, without expressions of the form $\forall U.C$. We define* $\mathsf{unbound}(\text{KB})$ *as follows, where* `Top` *is a fresh concept:*

1. *Recursively, outside-in, we replace all concept subexpressions C in all axioms by $\texttt{Top} \sqcap C$.*
2. *If $\mathcal{L}$ allows for universal quantification, we add a GCI $\top \sqsubseteq \forall r.\texttt{Top}$ for every (possibly inverse) role $r \neq U$ in* KB*.*
3. *For every individual name a in* KB*, we add $\texttt{Top}(a)$; if no individual occurs, we introduce a fresh one a_{new}.*

Example 2. *Consider our knowledge base* KB *from Example 1;* $\mathsf{unbound}(\mathrm{KB})$ *contains the axioms* $\mathtt{Top} \sqsubseteq \mathtt{Top} \sqcap \{a,b\}$, $\mathtt{Top}(a)$, $\mathtt{Top}(b)$, $\mathtt{Top} \sqcap A(a)$, $\mathtt{Top} \sqcap \neg(\mathtt{Top} \sqcap B)(a)$, $\mathtt{Top} \sqcap \neg(\mathtt{Top} \sqcap A)(b)$, $\mathtt{Top} \sqcap B(b)$, $\mathtt{Top} \sqcap C(a)$, $\mathtt{Top} \sqcap C(b)$.

Obviously, the described transformation can be computed in polynomial time and outputs a knowledge base of polynomial size. Moreover, for any standard DL $\mathcal{L}$, and any $\mathcal{L}$ knowledge base, $\mathsf{unbound}(\mathrm{KB})$ is an $\mathcal{L}$ knowledge base.

Lemma 6 (Properties of $\mathsf{unbound}$**).**

1. *For any knowledge base* KB *and any model* $\mathcal{J}$ *of* $\mathsf{unbound}(\mathrm{KB})$*, there is a model* $\mathcal{I}$ *of* KB *such that* $\mathcal{I} \models A(a)$ *if and only if* $\mathcal{J} \models \mathtt{Top} \sqcap A(a)$ *for every atomic concept assertion* $A(a)$.
2. *For any model* $\mathcal{I}$ *of a knowledge base* KB*, there is a model* $\mathcal{J}$ *of* $\mathsf{unbound}(\mathrm{KB})$ *with an infinite domain such that* $\mathcal{I} \models A(a)$ *if and only if* $\mathcal{J} \models \mathtt{Top} \sqcap A(a)$ *for every atomic concept assertion* $A(a)$.
3. $\mathsf{unbound}(\mathrm{KB})$ *is unbounded.*
4. $\mathrm{KB} \models A(a)$ *if and only if* $\mathsf{unbound}(\mathrm{KB}) \models \mathtt{Top} \sqcap A(a)$.

Proof. Claim (1). We provide a construction of $\mathcal{I}$. Given a model $\mathcal{J} = (\Delta^{\mathcal{J}}, \cdot^{\mathcal{J}})$ of $\mathsf{unbound}(\mathrm{KB})$ we define $\mathcal{I} = (\Delta^{\mathcal{I}}, \cdot^{\mathcal{I}})$ as follows: $\Delta^{\mathcal{I}} := \mathtt{Top}^{\mathcal{J}}$ (note that nonemptyness is guaranteed since $\mathtt{Top}^{\mathcal{J}}$ contains at least one named individual by definition of $\mathsf{unbound}$), $a^{\mathcal{I}} := a^{\mathcal{J}}$ for all $a \in \mathsf{N}_I$, $A^{\mathcal{I}} := A^{\mathcal{J}} \cap \Delta^{\mathcal{I}}$ for $A \in \mathsf{N}_C$, and $r^{\mathcal{I}} := r^{\mathcal{J}} \cap (\Delta^{\mathcal{I}} \times \Delta^{\mathcal{I}})$ for $r \in \mathsf{N}_R$. We can now show by induction on the structure of the concept expressions that $C^{\mathcal{I}} = \mathsf{topbound}(C)^{\mathcal{J}}$ for any concept expression C occurring in KB, where $\mathsf{topbound}(C)$ denotes the result of replacing, recursively and outside-in, all concept subexpressions D of C (including C itself) by $\mathtt{Top} \sqcap D$. Base cases and induction steps are straightforward for all cases except for universal quantification.

Thus, consider $C = \forall r.D$, with $\mathsf{topbound}(C) = \mathtt{Top} \sqcap \forall r.\mathsf{topbound}(D)$ and assume $D^{\mathcal{I}} = \mathsf{topbound}(D)^{\mathcal{J}}$ holds by induction hypothesis. Since C occurs in KB, the latter must be formulated in a DL supporting universal quantification, thus $\mathsf{unbound}(\mathrm{KB})$ must by definition contain the axiom $\top \sqsubseteq \forall r.\mathtt{Top}$. Hence $y \in \mathtt{Top}^{\mathcal{J}}$ for all $\langle x,y\rangle \in r^{\mathcal{J}}$. Now we observe equivalence of the following statements: $x \in C^{\mathcal{I}} \iff x \in (\forall r.D)^{\mathcal{I}} \iff x \in \Delta^{\mathcal{I}}$ and $\forall y$ with $\langle x,y\rangle \in r^{\mathcal{I}}$ holds $y \in D^{\mathcal{I}} \iff x \in \mathtt{Top}^{\mathcal{J}}$ and $\forall y$ with $\langle x,y\rangle \in r^{\mathcal{J}} \cap (\Delta^{\mathcal{I}} \times \Delta^{\mathcal{I}})$ holds $y \in \mathsf{topbound}(D)^{\mathcal{J}} \iff x \in \mathtt{Top}^{\mathcal{J}}$ and $\forall y$ with $\langle x,y\rangle \in r^{\mathcal{J}} \cap (\mathtt{Top}^{\mathcal{J}} \times \mathtt{Top}^{\mathcal{J}})$ holds $y \in \mathsf{topbound}(D)^{\mathcal{J}} \iff x \in \mathtt{Top}^{\mathcal{J}}$ and $\forall y$ with $\langle x,y\rangle \in r^{\mathcal{J}}$ holds $y \in \mathsf{topbound}(D)^{\mathcal{J}} \iff x \in (\mathtt{Top} \sqcap \forall r.\mathsf{topbound}(D))^{\mathcal{J}} \iff x \in \mathsf{topbound}(C)^{\mathcal{J}}$.

Having established that $C^{\mathcal{I}} = \mathsf{topbound}(C)^{\mathcal{J}}$, we can show that satisfaction of all axioms from $\mathsf{unbound}(\mathrm{KB})$ in $\mathcal{J}$ directly ensures satisfaction of all axioms from KB in $\mathcal{I}$. We also find, for any individual name a and concept name A, that: $\mathcal{I} \models A(a) \iff a^{\mathcal{I}} \in A^{\mathcal{I}} \iff a^{\mathcal{I}} \in A^{\mathcal{J}} \cap \Delta^{\mathcal{I}} \iff a^{\mathcal{J}} \in A^{\mathcal{J}} \cap \mathtt{Top}^{\mathcal{J}} \iff \mathcal{J} \models \mathtt{Top} \sqcap A(a)$ as claimed.

Claim (2). We assume a model $\mathcal{I} = (\Delta^{\mathcal{I}}, \cdot^{\mathcal{I}})$ of KB and construct $\mathcal{J} = (\Delta^{\mathcal{J}}, \cdot^{\mathcal{J}})$ as follows: $\Delta^{\mathcal{J}} := \Delta^{\mathcal{I}} \cup \mathbb{N}$; $a^{\mathcal{J}} := a^{\mathcal{I}}$ for all $a \in \mathsf{N}_I$, where $a^{\mathcal{J}}_{\text{new}} \in \Delta^{\mathcal{I}}$ if a_{new} has been introduced in $\mathsf{unbound}(\mathrm{KB})$; $A^{\mathcal{J}} := A^{\mathcal{I}}$ for all $A \in \mathsf{N}_C$ interpreted by $\mathcal{I}$; $\mathtt{Top}^{\mathcal{J}} := \Delta^{\mathcal{I}}$; and $r^{\mathcal{J}} := r^{\mathcal{I}}$ for $r \in \mathsf{N}_R$. Again, we can use induction to show that the correspondence $C^{\mathcal{I}} = \mathsf{topbound}(C)^{\mathcal{J}}$ holds and conclude that all axioms from $\mathsf{unbound}(\mathrm{KB})$ are valid in $\mathcal{J}$. Clearly, $\mathcal{J}$ has an infinite domain. We also obtain for any concept name A and individual name a the following equivalence: $\mathcal{J} \models \mathtt{Top} \sqcap A(a) \iff a^{\mathcal{J}} \in A^{\mathcal{J}} \cap \mathtt{Top}^{\mathcal{J}} \iff a^{\mathcal{I}} \in A^{\mathcal{I}} \cap \Delta^{\mathcal{I}} \iff \mathcal{I} \models A(a)$.

Claim (3). This is a direct consequence of the preceding two. For an arbitrary model $\mathcal{J}$ of $\mathsf{unbound}(\mathrm{KB})$ we create the model $\mathcal{I}$ of KB as in the proof of Claim (1). From $\mathcal{I}$, we then construct a model $\mathcal{J}'$ of $\mathsf{unbound}(\mathrm{KB})$ as in the proof of Claim (2). Then we know that $\mathcal{J}$ and $\mathcal{J}'$ satisfy the same atomic concept assertions and $\mathcal{J}'$ has an infinite domain.

Claim (4). This is equivalent to the statement that $\mathrm{KB} \not\models A(a)$ iff $\mathsf{unbound}(\mathrm{KB}) \not\models \mathtt{Top} \sqcap A(a)$. This can be easily shown by seeing that any model of KB not satisfying $A(a)$ can be turned into a model of $\mathsf{unbound}(\mathrm{KB})$ not satisfying $\mathtt{Top} \sqcap A(a)$ (by Claim (2)) and vice versa (by Claim (1)). □

Example 3. *Referring to Example 2, we find that* $\mathsf{unbound}(\mathrm{KB})$ *is satisfiable and, unlike* KB*, it even has a model* $\mathcal{J}$ *with infinite domain* $\Delta^{\mathcal{J}} = \{a^{\mathcal{J}}, b^{\mathcal{J}}\} \cup \mathbb{N}$*. Moreover we find, e.g., the correspondence between* KB *entailing* $A \sqsubseteq C$ *and* $\mathsf{unbound}(\mathrm{KB})$ *entailing* $\mathtt{Top} \sqcap A \sqsubseteq \mathtt{Top} \sqcap C$.

6 Data Complexities

From Theorem 1 and the known complexity results for various DLs, we obtain the following upper bounds for the data complexity: P for $\mathcal{EL}\mathcal{V}^{++}$ (Baader, Brandt, and Lutz 2005), ExpTime for $\mathcal{SHOIV}$, $\mathcal{SHOQV}$, and Horn-$\mathcal{SHOIQV}$ (Hladik 2004; Glimm, Horrocks, and Sattler 2008; Ortiz, Rudolph, and Simkus 2010), NExpTime for $\mathcal{SHOIQV}$ (Tobies 2001), 2ExpTime for Horn-$\mathcal{SROIQV}$ (Ortiz, Rudolph, and Simkus 2010), and N2ExpTime for $\mathcal{SROIQV}$ (Kazakov 2008).[1] We can obtain matching hardness results in many cases, even for much simpler DLs.

Theorem 7. *1. The data complexity of* $\mathcal{ELV}$ *is* P*-hard.*

2. *The data complexity of Horn-*$\mathcal{ALCV}$ *is* ExpTime*-hard.*
3. *The data complexity of* $\mathcal{ALCIFV}$ *is* (co)NExpTime*-hard.*

For $\mathcal{ELV}$, this already follows from the hardness of data complexity for $\mathcal{EL}$. To prove the other cases, we apply a generic method of expressing TBoxes as ABoxes.

Definition 7. *Consider a DL* $\mathcal{L}$ *with* $\mathcal{EL} \subseteq \mathcal{L} \subseteq \mathcal{SROIQ}$ *and an* $\mathcal{L}$ *TBox axiom* $\alpha = C \sqsubseteq D$*. The* template *for* α*, denoted* $\mathsf{tmpl}(\alpha)$*, is defined as follows. Let* $\sigma_1, \ldots, \sigma_n$ *be a list of all individual names and concept names in* α*. Let* A_α *be a fresh concept name, and let* $\mathtt{gci}$, $\mathtt{type}$*, and* $\mathtt{symb}_i$ $(1 \le i \le n)$ *be fresh role names. Then* $\mathsf{tmpl}(\alpha)$ *is the* $\mathcal{LV}$ *axiom*

$$\exists \mathtt{gci}.(A_\alpha \sqcap \exists \mathtt{symb}_1.\{x_1\} \sqcap \ldots \sqcap \mathtt{symb}_n.\{x_n\}) \sqcap C' \sqsubseteq D'$$

where C' *and* D' *are obtained from* C *and* D*, respectively, by replacing each concept name* σ_i *by* $\exists \mathtt{type}.\{x_i\}$ *and each individual name* σ_j *by* x_j.

[1] Most complexity upper bounds for DLs above $\mathcal{ALCOIN}$ are only known to hold when assuming unary coding of numbers; our results inherit this restriction.

The template instance for α, *denoted* $\mathsf{tins}(\alpha)$, *is the following set of ABox assertions:*

$$\{A_\alpha(c_\alpha), \mathtt{symb}_1(c_\alpha, c_{\sigma_1}), \ldots, \mathtt{symb}_n(c_\alpha, c_{\sigma_n})\}$$

where c_α *and* $c_{\sigma_1}, \ldots, c_{\sigma_n}$ *are fresh individual names.*

We extend temp *and* tins *to sets of axioms by taking the union of the results, and to ABox axioms* $A(c)$ *and* $r(c,d)$ *by expressing them as TBox axioms* $\{c\} \sqsubseteq A$ *and* $\{c\} \sqsubseteq \exists r.\{d\}$, *respectively. For an unbounded knowledge base* KB *with ABox* $\mathcal{A}$, *TBox* $\mathcal{T}$, *and RBox* $\mathcal{R}$, *we define* $\mathsf{tt}(\mathrm{KB})$ *as the set* $\{\top \sqsubseteq \exists \mathtt{gci}.\{x\}\} \cup \mathsf{temp}(\mathcal{A} \cup \mathcal{T}) \cup \mathsf{tins}(\mathcal{A} \cup \mathcal{T}) \cup \mathcal{R}$, *where we assume that the same individuals* c_σ *for representing a symbol* σ *in any translation.*

It is easy to verify the following correctness property, where the axiom $\top \sqsubseteq \exists \mathtt{gci}.\{x\}$ ensures that the template instantiation individuals c_α are universally reachable via gci.

Lemma 8. $\mathrm{KB} \models A(c)$ *iff* $\mathsf{tt}(\mathrm{KB}) \models \exists \mathtt{type}.\{c_A\}(c)$.

This yields a polynomial reduction from one reasoning problem to another. We can improve this to obtain a reduction where the size of the TBox of $\mathsf{tt}(\mathrm{KB})$ is not affected by the size of N_I, N_C, or the TBox of KB. Indeed, since $\mathsf{tmpl}(\alpha)$ contains only role names and variable names, we only need one template for each variant of α obtained by uniformly renaming concepts and individuals. In particular, if the given DL admits a finite number of normal forms, then it is enough to include one template for each axioms that can be obtained by uniform renaming of roles in some normal form. If N_R is fixed, this yields a fixed TBox and also a fixed RBox (since a fixed N_R only allows for a bounded number of RBox axioms in normal form). Summing up, all standard reasoning problems for a normalizable DL $\mathcal{L}$ that can be expressed with a fixed, finite set of role names N_R can be expressed in $\mathcal{LV}$ using a fixed, finite TBox and RBox.

Lemma 9. *Let* $\mathcal{L}[\mathsf{N}_R]$ *be the DL* $\mathcal{L}$ *restricted to signatures that use a fixed, finite set* N_R *of role names. If* $\mathcal{L}[\mathsf{N}_R]$ *is normalizable using only roles from* N_R, *and its combined complexity is hard for a complexity class* C *that includes* P, *then so is the data complexity of* $\mathcal{LV}$.

This allows us to show Theorem 7. Indeed, the known hardness proofs for Horn-$\mathcal{ALC}$ (Krötzsch, Rudolph, and Hitzler 2013) and $\mathcal{ALCOIF}$ (Tobies 2000) are based on constructing a sequence of knowledge bases that use a fixed, finite set of role names. Hence, the respective complexities are the claimed lower bounds for the data complexities of Horn-$\mathcal{ALCV}$ and $\mathcal{ALCIFV}$.

Interestingly, Lemma 9 is not applicable to $\mathcal{SROIQV}$, since the known N2ExpTime-hardness proof for $\mathcal{SROIQ}$ relies on an unbounded set of role names (Kazakov 2008). Indeed, it turns out that our N2ExpTime upper bound for the data complexity of $\mathcal{SROIQV}$ can be improved to NExpTime, which is tight according to Theorem 7. With a very similar argument one can establish an ExpTime upper bound for data complexity of Horn-$\mathcal{SROIQV}$.

Theorem 10. *The data complexity of* $\mathcal{SROIQV}$ *is in* NExpTime, *assuming unary coding of numbers. The data complexity of Horn-*$\mathcal{SROIQV}$ *is in* ExpTime.

Proof. In order to show our claim, we deploy a two-step reduction and analyze its effects on the knowledge base. Starting from the $\mathcal{SROIQV}$ knowledge base $\mathrm{KB} = (\mathcal{A}, \mathcal{T}, \mathcal{R})$, we obtain the $\mathcal{SROIQ}$ knowledge base $\mathrm{KB}' = (\mathcal{A}, \mathcal{T}', \mathcal{R})$ by grounding KB. Next, we obtain the $\mathcal{ALCHOIQ}$ knowledge base $\mathrm{KB}'' = (\mathcal{A}, \mathcal{T}'', \emptyset)$ by applying the RBox removal transformation introduced by Kazakov (2008). Analyzing the grounding step, we find that $size(\mathcal{T}') \leq size(\mathcal{T}) + size(\mathcal{A})^{size(\mathcal{T})}$. Moreover, for the RBox removal step, we obtain $size(\mathcal{T}'') \leq 2^{size(\mathcal{R})} \cdot size(\mathcal{T}')$. Therefore we get $size(\mathrm{KB}'') = size(\mathcal{A}) + size(\mathcal{T}'') \leq size(\mathcal{A}) + 2^{size(\mathcal{R})} \cdot size(\mathcal{T}') \leq size(\mathcal{A}) + 2^{size(\mathcal{R})} \cdot (size(\mathcal{T}) + size(\mathcal{A})^{size(\mathcal{T})})$. Since $\mathcal{T}$ and $\mathcal{R}$ are fixed, we find that KB'' is polynomial in the size of $\mathcal{A}$. Since the combined complexity of standard reasoning in $\mathcal{ALCHOIQ}$ is in NExpTime for unary coding of numbers (Tobies 2001), we have proven our claim. The same size argument as above holds for the transformation of Horn-$\mathcal{SROIQV}$ into Horn-$\mathcal{SROIQ}$ (via grounding) and further into Horn-$\mathcal{ALCHOIF}b$, which has a combined complexity of ExpTime (Ortiz, Rudolph, and Simkus 2010). This shows the claim for Horn-$\mathcal{SROIQ}$. □

7 Combined Complexities

We already know the combined complexities of $\mathcal{ELV}$ (ExpTime, cf. Section 4) and $\mathcal{SROIQV}$ (N2ExpTime). The N2ExpTime argument for $\mathcal{SROIQV}$ (Krötzsch et al. 2011) can be directly applied to Horn-$\mathcal{SROIQV}$ (Ortiz, Rudolph, and Simkus 2010) to establish 2ExpTime combined complexity. From Theorem 1 and the known complexity results we further obtain that the upper bound for the combined complexity of $\mathcal{SHOIV}$, and $\mathcal{SHOQV}$ is 2ExpTime (Hladik 2004; Glimm, Horrocks, and Sattler 2008). The upper bounds Theorem 1 yields for $\mathcal{SHOIQV}$ and Horn-$\mathcal{SHOIQV}$ coincide with those of $\mathcal{SROIQV}$ and Horn-$\mathcal{SROIQV}$, respectively. It turns out that these bounds are tight: reasoning in DLs above Horn-$\mathcal{ALCV}$ is 2ExpTime-hard, and reasoning in DLs above $\mathcal{ALCIFV}$ is (co)N2ExpTime-hard.

To show these results, we employ a general technique of encoding "axiom templates" that can encode an exponential number of concept inclusion axioms in polynomial space. We call this expressive feature *GCI iterator* since it iterates over a list of indexed concept names to produce concrete axioms. For example, the GCI iterator $A[\mathtt{i}] \sqsubseteq A[\mathtt{i}+1]$ $[\mathtt{i} = 1, \ldots, n]$ encodes n axioms of the form $A_i \sqsubseteq A_{i+1}$. We will show that GCI iterators can be expressed polynomially using nominal schemas, even when assuming binary coding of the number n. This allows us to encode exponentially large knowledge bases using polynomially many axioms with nominal schemas. In particular, we will do this for the specific knowledge bases that have been used to show the known hardness results for Horn-$\mathcal{ALC}$ and $\mathcal{ALCOIF}$, thus boosting the complexity by one exponential.

Definition 8. *Consider a DL signature* $\langle \mathsf{N}_I, \mathsf{N}_C, \mathsf{N}_R \rangle$. *A* GCI iterator *over this signature is an expression*

$$C \sqsubseteq D \; [\mathtt{i} = 1, \ldots, n]$$

where $n \geq 1$ *and* $C \sqsubseteq D$ *is a general concept inclusion over*

$\langle \mathsf{N}_I, \mathsf{N}_C \cup \{A[1],\dots,A[n+1],A[\mathtt{i}],A[\mathtt{i}+1] \mid A \in \mathsf{N}_C\}, \mathsf{N}_R\rangle$. *Note that* $\mathtt{i}$ *is a literal part of the syntax, not a placeholder for a specific number. The additional concept names* $A[\dots]$ *are assumed to be distinct from all concepts in* N_C.

The expansion *of a GCI iterator is the set of GCIs over* $\langle \mathsf{N}_I, \mathsf{N}_C \cup \{A[1],\dots,A[n+1] \mid A \in \mathsf{N}_C\}, \mathsf{N}_R\rangle$ *obtained by replacing, for each* $i \in \{1,\dots,n\}$*, all concepts* $A[\mathtt{i}]$ *by* $A[i]$*, and all concepts* $A[\mathtt{i}+1]$ *by* $A[i+1]$.

For a DL $\mathcal{L}$*, we let* $\mathcal{L}_{\mathrm{GI}}$ *be* $\mathcal{L}$ *extended by GCI iterators as axioms. The semantics of an* $\mathcal{L}_{\mathrm{GI}}$ *knowledge base* KB *is given by the translation into* $\mathcal{L}$ *through replacing all GCI iterators by their expansions, denoted* $\mathsf{expand}(\mathrm{KB})$.

Note that, assuming binary encoding of the value n, GCI iterators allow for an exponentially more succinct representation of their expansion.

Next, we will show that standard reasoning in a DL $\mathcal{L}_{\mathrm{GI}}$ without nominal schemas can be polynomially reduced to standard reasoning in $\mathcal{LV}$. We restrict attention to the case where the upper bound n in all GCI iterators is of the form 2^ℓ for some $\ell \geq 1$. Arbitrary n could be supported with some additional effort, but this is not relevant for our proofs.

Definition 9. *Consider* $\ell \geq 1$*, role names* $\mathtt{bit}_1,\dots,\mathtt{bit}_\ell$*, and individual names* 0 *and* 1*. For a list* $b_1,\dots,b_\ell$ *with* $b_i \in \{0,1\} \cup \mathsf{N}_V$*, we define* $\mathit{Bits}(b_1,\dots,b_\ell) := \prod_{i=1}^{\ell} \exists \mathtt{bit}_i.\{b_i\}$*. Consider additional role names* $\mathtt{num}$*,* $\mathtt{this}$*, and* $\mathtt{next}$*.* $\mathrm{KB}_{\mathrm{num}}$ *consists of the following axioms, for all* $1 \leq i \leq \ell$*:*

$$\top \sqsubseteq \exists \mathtt{num}.\exists \mathtt{this}.\mathit{Bits}(0,\dots,0)$$
$$\exists \mathtt{this}.\mathit{Bits}(x_1,\dots,x_i,0,1,\dots,1) \equiv \exists \mathtt{next}.\mathit{Bits}(x_1,\dots,x_i,1,0,\dots,0)$$
$$\exists \mathtt{num}.\exists \mathtt{next}.\mathit{Bits}(x_1,\dots,x_\ell) \equiv \exists \mathtt{num}.\exists \mathtt{this}.\mathit{Bits}(x_1,\dots,x_\ell)$$

Given a GCI iterator γ *of the form* $C \sqsubseteq D \;\; [\mathtt{i}=1,\dots,2^\ell]$*, we define* $\mathsf{vexpand}(\gamma)$ *to be the axiom* $N \sqcap C' \sqsubseteq D'$*, where* $N = \exists \mathtt{num}.(\exists \mathtt{this}.\mathit{Bits}(x_1,\dots,x_\ell) \sqcap \exists \mathtt{next}.\mathit{Bits}(y_1,\dots,y_\ell))$ *and* C' *and* D' *are obtained from* C *and* D*, respectively, by the following replacements:*

- $A[\mathtt{i}]$ *is replaced by* $\exists \mathtt{type}.(A' \sqcap \mathit{Bits}(x_1,\dots,x_\ell))$*,*
- $A[\mathtt{i}+1]$ *is replaced by* $\exists \mathtt{type}.(A' \sqcap \mathit{Bits}(y_1,\dots,y_\ell))$*,*
- $A[k]$ *is replaced by* $\exists \mathtt{type}.(A' \sqcap \mathit{Bits}(b_1,\dots,b_\ell))$ *where* $b_1,\dots,b_\ell$ *is the binary encoding of* k*,*

where A' *is a fresh concept name for each* $A \in \mathsf{N}_C$.

For an unbounded $\mathcal{L}_{\mathrm{GI}}$ *knowledge base* $\mathrm{KB} = \langle \mathcal{A}, \mathcal{T}, \mathcal{R}\rangle$ *where all GCI iterators range from* 1 *to* 2^ℓ*, the* $\mathcal{LV}$ *knowledge base* $\mathsf{itov}(\mathrm{KB})$ *is obtained by adding the axioms* $\mathrm{KB}_{\mathrm{num}}$ *and replacing each GCI iterator* $\gamma \in \mathrm{KB}$ *with* $\mathsf{vexpand}(\gamma)$.

Theorem 11. *For any DL* $\mathcal{L}$*,* itov *provides a polytime reduction from standard reasoning in* $\mathcal{L}_{\mathrm{GI}}$ *to standard reasoning in* $\mathcal{LV}$*: for every unbounded* $\mathcal{L}_{\mathrm{GI}}$ *knowledge base* KB *and* $\mathcal{L}$ *axiom* $A(c)$*, we have* $\mathrm{KB} \models A(c)$ *iff* $\mathsf{itov}(\mathrm{KB}) \models \mathsf{itov}(A(c))$.

Proof. We write $\mathsf{bin}(k)$ for the list of ℓ bits of a number $k < 2^\ell$ in binary encoding. The minimal model for $\mathrm{KB}_{\mathrm{num}}$ is one where every individual has one $\mathtt{num}$-successor in concept $\exists \mathtt{this}.\mathit{Bits}(\mathsf{bin}(k))$ for each number $0 \leq k < 2^\ell$. Moreover, if $k < 2^\ell - 1$ (i.e., $\mathsf{bin}(k)$ contains a 0), the corresponding successor also is in the class $\exists \mathtt{next}.\mathit{Bits}(\mathsf{bin}(k+1))$.

Now every model $\mathcal{I} \models \mathsf{expand}(\mathrm{KB})$ with $\mathcal{I} \not\models A(c)$ can be transformed into a model $\mathcal{I}' \models \mathsf{itov}(\mathrm{KB})$ with $\mathcal{I}' \not\models \mathsf{itov}(A(c))$. By unboundedness, we can assume that the domain of $\mathcal{I}$ contains infinitely many individuals. We can thus find distinct individuals to represent bits and numbers, and we interpret $\mathtt{num}$, $\mathtt{this}$, $\mathtt{next}$, and $\mathtt{bit}_i$ according to the minimal model. Moreover, for all $A \in \mathsf{N}_C$ and $0 \leq k < 2^\ell$, we add an element $\delta_{A[k]}$ with $\delta_A \in (A' \sqcap \mathit{Bits}(\mathsf{bin}(k)))^{\mathcal{I}'}$, and we set $\langle \delta, \delta_{A[k]}\rangle \in \mathtt{type}$ iff $\delta \in A[k]^{\mathcal{I}}$. Roles and concepts that are not of the form $B[k]$ are interpreted as in $\mathcal{I}$. It is easy to see that $\mathcal{I}'$ has the claimed properties. For the converse, note that the minimal model of $\mathrm{KB}_{\mathrm{num}}$ is indeed found in every model of $\mathsf{itov}(\mathrm{KB})$. Thus, if $\mathcal{I}' \models \mathsf{itov}(\mathrm{KB})$ with $\mathcal{I}' \not\models \mathsf{itov}(A(c))$, then there is more general interpretation $\mathcal{I}'' \models \mathsf{itov}(\mathrm{KB})$ with $\mathcal{I}'' \not\models \mathsf{itov}(A(c))$ where $\mathrm{KB}_{\mathrm{num}}$ is interpreted as in the minimal model. Using similar correspondences as before, we can construct a suitable model $\mathcal{I} \models \mathsf{expand}(\mathrm{KB})$ with $\mathcal{I} \not\models A(c)$. □

We now use Theorem 11 to show additional hardness results by using GCI iterators to re-encode known hardness proofs for exponentially large knowledge bases.

Theorem 12. *The combined complexity of Horn-*$\mathcal{ALCV}$ *is* 2ExpTime*-hard.*

Proof. The known ExpTime-hardness result for Horn-$\mathcal{ALC}$ is based on reducing the problem of deciding if a word w is accepted by an alternating Turing machine (ATM) in polynomial space to the problem if a Horn-$\mathcal{ALC}$ knowledge base entails a GCI, where both knowledge base and GCI are of polynomial size w.r.t. $|w|$ (Krötzsch, Rudolph, and Hitzler 2013). One can generalize this construction to arbitrary (possibly non-polynomial) space bounds s, leading to knowledge base of size polynomial in s. We modify the encoding to be able to express this knowledge base in Horn-$\mathcal{ALC}_{\mathrm{GI}}$, so that the resulting knowledge base is logarithmic in the size of s. Thus, we can simulate exponential space ATM runs with a polynomial Horn-$\mathcal{ALC}_{\mathrm{GI}}$ knowledge base.

Let s be an arbitrary space bound. To encode an s-space ATM $\langle Q, \Sigma, \Delta, q_0\rangle$, the original encoding uses the following concept names: A_q for $q \in Q$ (ATM is in state q), H_i for $i = 1,\dots,s$ (ATM head is at position i), $C_{\sigma,i}$ with $\sigma \in \Sigma$ and $i = 1,\dots,s$ (tape position i contains symbol σ), and A (ATM accepts this configuration). Accordingly, we use concepts A_q, $H[i]$, $C_\sigma[i]$, and A. Roles S_δ encode δ-successor configurations. The original encoding of ATM transitions $\delta = \langle q, \sigma, q', \sigma', r\rangle$ can then be expressed as follows:

$$A_q \sqcap H[\mathtt{i}] \sqcap C_\sigma[\mathtt{i}] \sqsubseteq \exists S_\delta.(A_{q'} \sqcap H[\mathtt{i}+1] \sqcap C'_\sigma[\mathtt{i}]) \; [\mathtt{i}=1,\dots,s]$$

Transitions with leftwards head movement are expressed analogously. To apply Theorem 11, we use the same range for all GCI iterators. This has the side effect that the tape has cells $1,\dots,s+1$, while $\mathtt{i}$ ranges over $1,\dots,s$ and $\mathtt{i}+1$ ranges over $2,\dots,s+1$; thus, when using $\mathtt{i}$ in axioms that refer to all tape positions, we generally assume that there is also one one more axiom for covering $s+1$ as well.

The accepting conditions are modelled by $A_q \sqcap \exists S_\delta.A \sqsubseteq A$ (for existential states q) and $A_q \sqcap H[\mathtt{i}] \sqcap C_\sigma[\mathtt{i}] \sqcap \bigsqcap_{\delta \in \bar{\Delta}} (\exists S_\delta.A) \sqsubseteq A$ $[\mathtt{i}=1,\dots,s]$ (for universal states q with

possible transitions $\tilde{\Delta}$ for symbol σ). To ensure preservation of the ATM memory between configurations, the original proof uses axioms $H_j \sqcap C_{\sigma,i} \sqsubseteq \forall S_\delta.C_{\sigma,i}$ for all $i \neq j$. This cannot be expressed with GCI iterators. Instead, we introduce new concepts $L[i]$ (cell i is left of the head) and $R[i]$ (cell i is right of the head), which we can axiomatize using GCI iterators $H[\mathtt{i}] \sqsubseteq R[\mathtt{i}+1]$, $R[\mathtt{i}] \sqsubseteq R[\mathtt{i}+1]$, $H[\mathtt{i}+1] \sqsubseteq L[\mathtt{i}]$, and $L[\mathtt{i}+1] \sqsubseteq L[\mathtt{i}]$, all with the same range as before. The rules of memory preservation can now be expressed with the GCI iterators $L[\mathtt{i}] \sqcap C_\sigma[\mathtt{i}] \sqsubseteq \forall S_\delta.C_\sigma[\mathtt{i}]$ and $R[\mathtt{i}] \sqcap C_\sigma[\mathtt{i}] \sqsubseteq \forall S_\delta.C_\sigma[\mathtt{i}]$, for all $\delta \in \Delta$ and $\sigma \in \Sigma$.

Finally, the initialization of the tape in the original proof simply defines the tape contents for each position. To initialize the $s-|w|$ many blank cells after the input word, we use concepts $B[i]$ and axioms $B[\mathtt{i}] \sqsubseteq B[\mathtt{i}+1]$ and $B[\mathtt{i}] \sqsubseteq C_\square[\mathtt{i}]$. The initial configuration is now described with the concept

$$I_w := A_{q_0} \sqcap H_1 \sqcap C_{\sigma_1}[1] \sqcap \ldots \sqcap C_{\sigma_{|w|}}[|w|] \sqcap B[|w|+1].$$

Let $\mathrm{KB}_{\mathcal{M},w}$ be the knowledge base that contains all of the above GCIs. It is a direct consequence from (Krötzsch, Rudolph, and Hitzler 2013) that $\mathrm{KB}_{\mathcal{M},w} \models I_w \sqsubseteq A$ if the ATM $\mathcal{M}$ accepts w in space s. Since GCI iterators can encode the range $[\mathtt{i}{=}1,\ldots,s]$ in space logarithmic in s, reasoning with a polynomially large $\mathrm{KB}_{\mathcal{M},w}$ can solve the word problem of exponential space ATMs, which is 2ExpTime-hard. The claim thus follows from Theorem 11. □

Theorem 13. *The combined complexity of $\mathcal{ALCIFV}$ is* (co)N2ExpTime*-hard.*

Proof. We proceed with the case of $\mathcal{ALCOIF}$. We build on the proof of Tobies (2000), which reduced the tiling problem for exponential grids to $\mathcal{ALCOIF}$ consistency checking. To construct an exponential grid, one encodes coordinates of tiles in binary numbers, represented by concept names $X_1,\ldots,X_\ell$ (horizontal position) and $Y_1,\ldots,Y_\ell$ (vertical position), respectively. We will express these by indexed concepts $X[i]$ and $Y[i]$. Horizontal neighbours are connected by a role h, vertical ones by a role v. Functionality restrictions and inverse functionality restrictions on h and v ensure uniqueness of neighbours. The concept with the maximal coordinates (right upper corner) is subsumed by a nominal, ensuring that the potentially diverging structure of h and v successors collapses into one grid.

We need to express that the encoded position of the right (and upper) neighbour is the successor. For numbers of linear length, this can be done as in Definition 9; to allow for numbers of exponential length, we use auxiliary concepts $\hat{X}[i]$ to express that all bits up to position $i-1$ are set to true, i.e., that the conjunction $\prod_{j=1}^{i-1} X[j]$ holds. $\hat{Y}[i]$ plays the same role for vertical positions. The propagation of X-coordinates can now be expressed with the following GCI iterators, all of which we assume to have range $[\mathtt{i}=1,\ldots,\ell]$ for some ℓ:

$$\top \sqsubseteq \exists h.\top \sqcap \leqslant 1\, h.\top \sqcap \leqslant 1\, h^-.\top \tag{7}$$

$$\top \sqsubseteq \hat{X}[1] \qquad \hat{X}[\mathtt{i}] \sqcap X[\mathtt{i}] \equiv \hat{X}[\mathtt{i}+1] \tag{8}$$

$$\hat{X}[\mathtt{i}] \sqsubseteq (X[\mathtt{i}] \sqcap \forall h.\neg X[\mathtt{i}]) \sqcup (\neg X[\mathtt{i}] \sqcap \forall h.X[\mathtt{i}]) \tag{9}$$

$$\neg\hat{X}[\mathtt{i}] \sqsubseteq (X[\mathtt{i}] \sqcap \forall h.X[\mathtt{i}]) \sqcup (\neg X[\mathtt{i}] \sqcap \forall h.\neg X[\mathtt{i}]) \tag{10}$$

$$X[\mathtt{i}] \sqsubseteq \forall v.X[\mathtt{i}] \qquad \neg X[\mathtt{i}] \sqsubseteq \forall v.\neg X[\mathtt{i}] \tag{11}$$

Axiom (7) ensures a chain of h successors. Axioms (8) express the relation of $\hat{X}[i]$ and $X[i]$ explained above. Axioms (9) and (10) characterize the binary increment of numbers. Axioms (11) ensure that horizontal positions are preserved among vertical neighbours. We assume the same formulation for the vertical propagation, swapping h with v and X with Y, respectively. Note that $\mathtt{i}+1$ only occurs in (8); indeed, the bits $X[\ell+1]$ and $Y[\ell+1]$, which exist due to our uniform choice of range, have no significance in our modelling. To "start" the grid, we assert that there is a lower left corner: $\{a\} \sqsubseteq \neg X[i] \sqcap \neg Y[i]$. To "close" the grid, we add a nominal to the upper right corner: $\hat{X}[\ell+1] \sqcap \hat{Y}[\ell+1] \sqsubseteq \{o\}$. Note that the grid will continue to have successors beyond this point, due to axiom (7), but these do not need to form a grid and will not affect whether the tiling problem has a solution (one can always ensure that there are tiles to continue in non-grid structures only).

Formally, a tiling problem is given by a set of tiles $\mathcal{D} = \{D_1,\ldots,D_n\}$ together with horizontal and vertical compatibility relations $V,H \subseteq \mathcal{D} \times \mathcal{D}$. Using concept names D_i (which are not iterated over), we can axiomatize correct tilings by the axioms $\top \sqsubseteq \bigsqcup_{1\leq i\leq d} \left(D_i \sqcap \prod_{j\neq i} \neg D_j\right)$, $D_i \sqsubseteq \forall v. \bigsqcup_{\langle D_i,D_j\rangle \in V} D_j$, and $D_i \sqsubseteq \forall h. \bigsqcup_{\langle D_i,D_j\rangle \in H} D_j$. It is easy to see that this construction reduces the tiling problem on a grid of size $2^\ell \times 2^\ell$ to checking the consistency of an $\mathcal{ALCOIF}_{\mathrm{GI}}$ knowledge base of size polynomial in $\log(\ell)$ (since ℓ is encoded in binary in GCI iterators). Since the double-exponential tiling problem is N2ExpTime-hard, the claim follows from Theorem 11. □

Proof of Theorem 4. As the number of nominal schemas in normalized axioms is bounded, a normalized knowledge base can be grounded polynomially. Thus, the combined complexity of any normalizable DL $\mathcal{LV}$ coincides with the combined complexity of $\mathcal{L}$. It is known that P $\subsetneq$ ExpTime $\subsetneq$ 2ExpTime and that NExpTime $\subsetneq$ N2ExpTime. Together with our previous results, this shows the claim. □

8 An Alternative Semantics

As discussed in Section 3, our semantics of nominal schemas depends on the given set N_I of individual names. If we allow N_I to be empty, then this can even affect the entailment of standard DL axioms. For example, $\top \sqsubseteq \exists r.\{x\} \not\models \top \sqsubseteq \exists r.\top$ if $\mathsf{N}_I = \emptyset$. However, in most cases, only entailments of axioms with nominal schemas are affected, as discussed for (1) in Section 3. Such a dependence on the set of "known" symbols might be considered to be in conflict with the open-world assumption. The ontology language OWL considers a potentially infinite signature of URIs (W3C OWL Working Group 27 October 2009).[2]

To address this problem, one could modify the semantics of nominal schemas by assuming the set N_I to be infinite and fixed. A severe practical consequence of this suggestion is that $\mathsf{ground}(\alpha)$ and $\mathsf{ground}(\mathrm{KB})$ become infinite if they contain any nominal schemas. While this does not pose problems for any of the definitions as such, we seem to lose

[2] On the other hand, OWL also provides ways to explicitly declare a finite set of signature symbols in an ontology.

the upper complexity bounds of Theorem 1. However, we will show that the alternative semantics does not actually affect reasoning complexities, and in fact agrees with the standard semantics in many cases.

In the rest of this section, we assume N_I to be infinite, and use $\bar{\mathsf{N}}$ for a set $\bar{\mathsf{N}} \subseteq \mathsf{N}_I$ that corresponds to our earlier finite signature. We use $\models_{\bar{\mathsf{N}}}$ to denote standard entailment w.r.t. $\bar{\mathsf{N}}$, and $\models_\infty$ to denote entailment w.r.t. the infinite N_I.

Theorem 14. *For any standard DL $\mathcal{L}$, any $\mathcal{LV}$ knowledge base* KB*, any $\mathcal{LV}$ axiom and any finite set* $\bar{\mathsf{N}}$ *which contains more individual names than the sum of the number of individual names used in* $\mathrm{KB} \cup \alpha$ *and the number of variable names in α, we have* $\mathrm{KB} \models_{\bar{\mathsf{N}}} \alpha$ *iff* $\mathrm{KB} \models_\infty \alpha$.

Proof. "If." Assume $\mathrm{KB} \models_\infty \alpha$. We pick a function $\psi : \mathsf{N}_I \to \bar{\mathsf{N}}$ such that $\psi(a) = a$ for all $a \in \bar{\mathsf{N}}$. Note that such a ψ always exists since $\bar{\mathsf{N}}$ is nonempty by assumption. Lifting ψ to concept expressions, axioms and sets of axioms in the usual way, we observe that $\psi(\mathsf{ground}_\infty(\mathrm{KB})) = \mathsf{ground}_{\bar{\mathsf{N}}}(\mathrm{KB})$, as well as $\psi(\mathsf{ground}_\infty(\alpha)) = \mathsf{ground}_{\bar{\mathsf{N}}}(\alpha)$. Moreover, from $\mathsf{ground}_\infty(\mathrm{KB}) \models \beta$ follows that $\psi(\mathsf{ground}_\infty(\mathrm{KB})) \models \psi(\beta)$ for all $\beta \in \psi(\mathsf{ground}_\infty(\alpha))$. Hence we obtain $\mathsf{ground}_{\bar{\mathsf{N}}}(\mathrm{KB}) \models \mathsf{ground}_{\bar{\mathsf{N}}}(\alpha)$ and therefore $\mathrm{KB} \models_{\bar{\mathsf{N}}} \alpha$.

"Only if." Assume $\mathrm{KB} \models_{\bar{\mathsf{N}}} \alpha$. Let $V = \{x_1, \ldots x_n\}$ be the set of nominal variables occurring in α. Then, by assumption, we find n distinct individuals $\{a_1, \ldots, a_n\} \subseteq \bar{\mathsf{N}}$ not occurring in $\mathrm{KB} \cup \alpha$. Let $\alpha' = \alpha[x_1/a_1, \ldots, x_n/a_n]$. Clearly $\mathrm{KB} \models_{\bar{\mathsf{N}}} \alpha'$. Then also $\mathrm{KB} \models_\infty \alpha'$, since the grounding of KB with individuals from $\bar{\mathsf{N}}$ is contained in the grounding of KB with all individuals. In order to show $\mathsf{ground}_\infty(\mathrm{KB}) \models \alpha$, we will show that $\mathsf{ground}_\infty(\mathrm{KB}) \models \beta$ for all $\beta \in \mathsf{ground}_\infty(\alpha)$. So, given such a β and the variable assignment *val* of $V = \{x_1, \ldots x_n\}$ to N_I that produces β from α, we pick a surjective mapping $\varphi : \mathsf{N}_I \to \mathsf{N}_I$ such that $\varphi(a) = a$ for every individual name mentioned in $\mathrm{KB} \cup \alpha$ and $\varphi(a_i) = \mathit{val}(x_i)$ (this is possible since N_I is infinite). Lifting φ to concept expressions, axioms and sets of axioms in the usual way, it is obvious that $\mathrm{KB} \models_\infty \alpha' \implies \mathsf{ground}_\infty(\mathrm{KB}) \models \alpha' \implies \varphi(\mathsf{ground}_\infty(\mathrm{KB})) \models \varphi(\alpha') \implies \mathsf{ground}_\infty(\mathrm{KB}) \models \varphi(\alpha') \implies \mathsf{ground}_\infty(\mathrm{KB}) \models \beta \implies \mathrm{KB} \models_\infty \beta$. Note that $\varphi(\mathsf{ground}_\infty(\mathrm{KB})) = \mathsf{ground}_\infty(\mathrm{KB})$ by construction. □

The previous proof requires that the unique name assumption (UNA) is not made, as is standard for all DLs considered in this paper. Moreover, imposing the unique name assumption in our setting would enforce all models to have an infinite domain, which makes domain-restricting axioms such as $\top \sqsubseteq \{a, b, c\}$ unsatisfiable.

Theorem 14 asserts that the two semantics coincide whenever the finite individual set is "large enough" for the considered knowledge base and tested consequence. For the special case of entailment of axioms without nominal schemas, it suffices if there is at least one individual name.

Corollary 15. *For any standard DL $\mathcal{L}$, $\mathcal{LV}$-reasoning complexities (both data and combined) for $\models$ and $\models_\infty$ coincide.*

We have shown that entailment checking w.r.t. $\models_\infty$ can be reduced to entailment checking w.r.t. $\models_{\bar{\mathsf{N}}}$ for a suitable $\bar{\mathsf{N}}$. On the other hand, any such reasoning task w.r.t. $\models_{\bar{\mathsf{N}}}$ can be reduced to reasoning w.r.t. $\models_\infty$ if disjunction is available, since $\mathrm{KB} \models_{\bar{\mathsf{N}}} \alpha$ iff $\mathrm{KB} \cup \{\{x\} \sqsubseteq \bigsqcup_{a \in \bar{\mathsf{N}}} \{a\}\} \models_\infty \alpha$.

The alternative semantics also comes handy when analyzing expressivity, since one cannot finitely express nominal schemas using grounding. We can use this to show that $\mathcal{LV}$ is generally more expressive than $\mathcal{L}$ extended with DL-safe rules. Consider the axiom

$$\{x\} \sqsubseteq \exists r.\exists r.\exists r.\{x\}. \tag{12}$$

Now, suppose there exists a $\mathcal{SROIQ}$ knowledge base KB and a set RB of DL-safe rules (where w.l.o.g. all used concept expressions are concept names) such that $\mathrm{KB} \cup \mathrm{RB}$ is a conservative extension of the above axiom. Now we pick an individual name a not mentioned in $\mathrm{KB} \cup \mathrm{RB}$ and define two interpretations $\mathcal{I} = (\Delta^{\mathcal{I}}, \cdot^{\mathcal{I}})$ and $\mathcal{J} = (\Delta^{\mathcal{J}}, \cdot^{\mathcal{J}})$ as follows: $\Delta^{\mathcal{I}} = \Delta^{\mathcal{J}} = \{b_1, b_2, b_3 \mid b \in \mathsf{N}_I\} \cup \mathbb{N}$, $b^{\mathcal{I}} = b^{\mathcal{J}} = b_1$ for all $b \in \mathsf{N}_I$, $r^{\mathcal{I}} = \{(b_1, b_2), (b_2, b_3), (b_3, b_1) \mid b \in \mathsf{N}_I\}$, and $r^{\mathcal{J}} = r^{\mathcal{I}} \setminus \{(a_1, a_2), (a_2, a_3), (a_3, a_1)\}$. Note that $\mathcal{I}$ is a model of the above axiom while $\mathcal{J}$ is not. Consequently, by assumption there must be an extension $\mathcal{I}'$ of $\mathcal{I}$ satisfying $\mathrm{KB} \cup \mathrm{RB} \models \mathcal{I}'$ but any extension $\mathcal{J}'$ of $\mathcal{J}$ must not be a model of $\mathrm{KB} \cup \mathrm{RB}$. Now we pick a bijective function $\varphi : \mathsf{N}_I \setminus \{a\} \to \mathsf{N}_I$ with $\varphi(b) = b$ for all b mentioned in $\mathrm{KB} \cup \mathrm{RB}$ and use it to define a renaming ρ of $\Delta^{\mathcal{I}'}$ as follows: $\rho(b_i) := c_i$ with $c = \varphi(b)$ for all $b \in \mathsf{N}_I \setminus \{a\}$ and $i \in \{1, 2, 3\}$, $\rho(a_i) := i$ for all $i \in \{1, 2, 3\}$ and $\rho(i) := i + 3$ for all $i \in \mathbb{N}$. Now let $\mathcal{K}$ be the interpretation obtained from $\mathcal{I}'$ via the renaming ρ. It is easy to check that $\mathcal{K}$ is an extension of $\mathcal{J}$. We also find that $\mathcal{K}$ must be a model of KB since $\mathcal{K}$ and $\mathcal{I}'$ are isomorphic as far as the used signature is concerned. Moreover, $\mathcal{K}$ is a model of RB since assuming, for a rule $R \in \mathrm{RB}$, a violating variable assignment *var*, $\varphi^- \circ \mathit{var}$ would be a violating assignment for $\mathcal{I}'$. Thus we have found an extension of $\mathcal{J}$ that is a model of $\mathrm{KB} \cup \mathrm{RB}$, which contradicts our initial assumption. Therefore, the above axiom cannot be expressed by $\mathcal{SROIQ}$ extended by DL-safe rules.

9 Conclusion and Future Work

We have clarified the data and combined complexities for nominal-schema-extensions of all DLs between $\mathcal{EL}$ and $\mathcal{SROIQ}$. The techniques developed for this purpose (TBox-to-ABox internalization and GCI iterators) are generic and directly applicable to DLs outside this range. For example, it is an obvious consequence of our findings and the results from (Rudolph, Krötzsch, and Hitzler 2008b) that adding arbitrary Boolean role constructors on simple roles to any DL above $\mathcal{ALCIFV}$ does not increase data or combined complexity; the same holds if conjunctions on simple roles are added to $\mathcal{ELV}^{++}$. Adding the concept product $\times$ (Rudolph, Krötzsch, and Hitzler 2008a) does not impact complexities either. Likewise, it is trivial to establish ExpTime completeness (data) and 2ExpTime completeness (combined) for $\mathcal{ZOQV}$ and $\mathcal{ZOIV}$ (Calvanese, Eiter, and Ortiz 2009).

The most obvious avenue for future work is the investigation of the complexities for conjunctive query answering.

Abstract

We develop a clausal resolution-based approach for computing uniform interpolants of TBoxes formulated in the description logic $\mathcal{ALC}$ when such uniform interpolants exist. We also present an experimental evaluation of our approach and of its application to the logical difference problem for real-life $\mathcal{ALC}$ ontologies. Our results indicate that in many practical cases uniform interpolants exist and that they can be computed with the presented algorithm.

Introduction

Ontologies or *TBoxes* expressed in Description Logics (DL) provide a common vocabulary for a domain of interest together with a description of the meaning of the terms built from the vocabulary and of the relationships between them. Modern applications of ontologies, especially in the biological, medical, or healthcare domain, often demand large and complex ontologies; for example, the National Cancer Institute ontology (NCI) consists of more than 60 000 term definitions. For developing, maintaining, and deploying such large-scale ontologies it can be advantageous for ontology engineers to concentrate on specific parts of an ontology and ignore or *forget* the rest. Ignoring parts of an ontology can be formalised with the help of *predicate forgetting* and its dual *uniform interpolation*, which have both been extensively studied in the AI and DL literature (ten Cate et al. 2006; Eiter et al. 2006; Herzig and Mengin 2008; Konev, Walther, and Wolter 2009; Wang et al. 2008; 2010; 2012; Lutz and Wolter 2011).

Forgetting parts of an ontology can be used, for example, in the following practical scenarios. *Exhibiting hidden relations*: in addition to the explicitly stated connections between terms, additional relations can also be derived from ontologies with the help of reasoners. Such inferred connections are often harder to understand or debug. By forgetting everything but a handful of terms of interest, it then becomes possible to exhibit inferred relations that were hidden initially, potentially simplifying the understanding of the ontology structure. *Ontology obfuscation*: in software engineering, obfuscation (Collberg, Thomborson, and Low 1998) transforms a given program into a functionally equivalent one that is more difficult to read and understand for humans for the purpose of preventing reverse engineering. Forgetting can provide a similar function in the context of ontology engineering. Terms are often defined with the help of auxiliary terms which give structure to TBox inclusions. However, such a structure might be considered proprietary knowledge that should not be exposed, or it could simply be of little interest for ontology users. By forgetting these intermediate auxiliary terms, we obtain an ontology that is functionally equivalent, yet harder to read, understand, and modify by humans. Further applications of forgetting can be found in (Konev, Walther, and Wolter 2009; Lutz, Seylan, and Wolter 2012).

A promising and important application area of forgetting is the computation of the *logical difference* between ontology versions. Determining whether two versions of a document have differences is a standard task in information technology, and finding differences is particularly relevant for text processing and software development. Already in these areas, it is important to be able to identify which changes are *significant* and which are not (e.g., a software developer might want to ignore changes in the formatting style of the code such as the number of indentation spaces). Detecting significant changes is even more important in the setting of Knowledge Representation, where differences in the knowledge captured by ontologies are often more relevant than syntactic changes. Arguably, one of the most important concerns of an ontology engineer when modifying an existing ontology is to ensure that the introduced changes do not interfere with the meaning of the terms outside the fragment under consideration. Notice that neither the version comparison based on the syntactic form of the documents representing ontologies (Conradi and Westfechtel 1998) nor methods based on the structural transformations of ontology statements (Noy and Musen 2002; Klein et al. 2002; Jiménez-Ruiz et al. 2011) can be used to identify changes to the logical meaning of terms in every situation. However, such a correctness guarantee can be achieved by checking the equivalence of the ontologies resulting from forgetting the terms under consideration before and after the changes occurred.

In this paper we develop an algorithm based on clausal resolution for computing uniform interpolants of TBoxes formulated in the description logic $\mathcal{ALC}$ which can preserve all the consequences which do not make use of some given *concept names* and which have a quantifier nesting level limited to some given depth. Subsequently, we present an experimental evaluation of our approach which demonstrates that in many practical cases uniform interpolants (without limitations on the quantifier nesting depth) exist and that they can be computed with our algorithm. We also apply our prototype tool to compute the logical difference between versions of ontologies from the biomedical domain.

The material presented here extends earlier work (Ludwig and Konev 2013). All the missing proofs can be found in the full version of this paper.[1]

Related work. Until recently research on uniform interpolation and forgetting in the setting of DL mainly has concentrated on theoretical foundations of forgetting. This could be partly explained by the high computational complexity of this task and by the fact that uniform interpolants do not always exist. The notion of forgetting has been introduced by Reiter and Lin (1994). Konev, Walther, and Wolter (2009) prove tractability of uniform interpolation for $\mathcal{EL}$ TBoxes of a specific syntactic form. Uniform interpolation for general $\mathcal{EL}$-TBoxes has been investigated by Nikitina and Rudolph (2012).

Wang et al. (2008; 2010; 2012) have developed algorithms for forgetting in expressive description logics. A tight 2-ExpTime-complete bound on the complexity for deciding the existence of a Σ-uniform interpolant in $\mathcal{ALC}$ and a worst-case triple-exponential procedure for computing a Σ-uniform interpolant if it exists, have been given by Lutz and Wolter (2011). Koopmann and Schmidt (2013) have introduced a two-stage resolution-based algorithm for computing uniform interpolants. As outcome of the first stage, a representation of the uniform interpolant in a description logic with fixpoint operators is computed (such a representation always exists) Then in the second stage an attempt is made to eliminate the newly-introduced fixpoints (which may not succeed). In contrast to this approach, our algorithm has one stage and it can be guaranteed that a uniform interpolant of bounded depth is returned.

The notion of the logical difference has been introduced by Konev, Walther, and Wolter (2008) as a way of capturing the difference in the meaning of terms that is independent of the representation of ontologies.

Preliminaries

We start with introducing the description logic $\mathcal{ALC}$. Let $\mathsf{N_C}$ and $\mathsf{N_R}$ be countably infinite and mutually disjoint sets of *concept names* and *role names*. *$\mathcal{ALC}$-concepts* are built according to the following syntax rule

$$C ::= \quad A \quad | \quad \top \quad | \quad \neg C \quad | \quad \exists r.C \quad | \quad C \sqcap D,$$

where $A \in \mathsf{N_C}$ and $r \in \mathsf{N_R}$. As usual, other $\mathcal{ALC}$ concept constructors are introduced as abbreviations: $\bot$ stands for $\neg\top$, $C \sqcup D$ stands for $\neg(\neg C \sqcap \neg D)$ and $\forall r.C$ stands for $\neg\exists r.\neg C$. An $\mathcal{ALC}$-TBox $\mathcal{T}$ is a finite set of $\mathcal{ALC}$-inclusions of the form $C \sqsubseteq D$, where C and D are $\mathcal{ALC}$-concepts. A concept equation $C \equiv D$ is an abbreviation for the two inclusions $C \sqsubseteq D$ and $D \sqsubseteq C$. An $\mathcal{ALC}$-TBox $\mathcal{T}$ is *acyclic* if all its inclusions are of the form $A \sqsubseteq C$ and $A \equiv C$, where $A \in \mathsf{N_C}$ and C is an $\mathcal{ALC}$-concept, such that no concept name occurs more than once on the left-hand side and $\mathcal{T}$ contains no cycle in its definitions, i.e., it does not contain inclusions $A_1 \bowtie C_1, \ldots, A_k \bowtie C_k$, where $\bowtie \in \{\sqsubseteq, \equiv\}$, such that A_{i+1} occurs in C_i, for $i = 1, \ldots, k-1$ and $A_k = A_1$.

A signature Σ is a finite subset of $\mathsf{N_C} \cup \mathsf{N_R}$. The signature of a concept C, denoted by $\mathsf{sig}(C)$, is the set of concept and role names that occur in C. If $\mathsf{sig}(C) \subseteq \Sigma$, we call C a Σ-concept. We assume that the two previous definitions also apply to concept inclusions/equations $C \bowtie D$ with $\bowtie \in \{\sqsubseteq, \equiv\}$ and to TBoxes $\mathcal{T}$. The size of a concept C is the length of the string that represents it, where concept names and role names are considered to be of length one. The size of an inclusion/equation $C \bowtie D$ with $\bowtie \in \{\sqsubseteq, \equiv\}$ is the sum of the sizes of C and D plus one. The size of a TBox $\mathcal{T}$ is the sum of the sizes of its inclusions.

The semantics of $\mathcal{ALC}$ is given by *interpretations* $\mathcal{I} = (\Delta^{\mathcal{I}}, \cdot^{\mathcal{I}})$, where the *domain* $\Delta^{\mathcal{I}}$ is a non-empty set, and $\cdot^{\mathcal{I}}$ is a function mapping each concept name A to a subset $A^{\mathcal{I}}$ of $\Delta^{\mathcal{I}}$, each role name r to a binary relation $r^{\mathcal{I}} \subseteq \Delta^{\mathcal{I}} \times \Delta^{\mathcal{I}}$. The *extension* $C^{\mathcal{I}}$ of a concept C is defined by induction as follows:

$$\begin{array}{lcl} \top^{\mathcal{I}} & := & \Delta^{\mathcal{I}} \\ (\neg C)^{\mathcal{I}} & := & \Delta^{\mathcal{I}} \setminus C^{\mathcal{I}} \\ (\exists r.C)^{\mathcal{I}} & := & \{\, d \in \Delta^{\mathcal{I}} \mid \exists\, e \in C^{\mathcal{I}} : (d, e) \in r^{\mathcal{I}} \,\} \\ (C \sqcap D)^{\mathcal{I}} & := & C^{\mathcal{I}} \cap D^{\mathcal{I}}. \end{array}$$

Then $\mathcal{I}$ *satisfies* a concept inclusion $C \sqsubseteq D$, in symbols $\mathcal{I} \models C \sqsubseteq D$, if $C^{\mathcal{I}} \subseteq D^{\mathcal{I}}$.

We say that an interpretation $\mathcal{I}$ is a *model of a TBox* $\mathcal{T}$ if $\mathcal{I} \models C \sqsubseteq D$ for all $C \sqsubseteq D \in \mathcal{T}$. An $\mathcal{ALC}$-inclusion $C \sqsubseteq D$ *follows from* (or is *entailed by*) a TBox $\mathcal{T}$ if every model of $\mathcal{T}$ is a model of $C \sqsubseteq D$, in symbols $\mathcal{T} \models C \sqsubseteq D$. We use $\models C \sqsubseteq D$ to denote that $C \sqsubseteq D$ follows from the empty TBox. Finally, a TBox $\mathcal{T}'$ *follows from* (or is *entailed by*) a TBox $\mathcal{T}$ if every model of $\mathcal{T}$ is a model of $\mathcal{T}'$, in symbols $\mathcal{T} \models \mathcal{T}'$.

We now introduce the main notion that we study in this paper.

Definition 1. *Let $\mathcal{T}$ be an $\mathcal{ALC}$-TBox and let $\Sigma \subseteq \mathsf{sig}(\mathcal{T})$ be a signature. We say that an $\mathcal{ALC}$-TBox $\mathcal{T}_\Sigma$ is a* Σ-uniform interpolant *of the TBox $\mathcal{T}$ iff $\mathsf{sig}(\mathcal{T}_\Sigma) \subseteq \Sigma$, $\mathcal{T} \models \mathcal{T}_\Sigma$, and for every $\mathcal{ALC}$ Σ-concept inclusion $C \sqsubseteq D$ with $\mathcal{T} \models C \sqsubseteq D$ it holds that $\mathcal{T}_\Sigma \models C \sqsubseteq D$.*

Uniform interpolation can be seen as the dual notion of *forgetting*: a TBox $\mathcal{T}_\Upsilon$ is the result of forgetting about a signature Υ in a TBox $\mathcal{T}$ iff $\mathcal{T}_\Upsilon$ is a uniform interpolant of $\mathcal{T}$ w.r.t. $\Sigma = \mathsf{sig}(\mathcal{T}) \setminus \Upsilon$. As the following example shows, uniform interpolants of $\mathcal{ALC}$-TBoxes do not always exist.

Example 2. *Let $\mathcal{T} = \{A \sqsubseteq B,\ B \sqsubseteq C \sqcap \exists r.B\}$ and $\Sigma = \{A, C, r\}$. Then there does not exist a Σ-uniform inter-*

[1] Available from http://lat.inf.tu-dresden.de/~michel/publications/

polant of $\mathcal{T}$ as (in particular) the infinite number of consequences of the form $A \sqsubseteq \exists r.C$, $A \sqsubseteq \exists r.\exists r.C, \ldots$ cannot be captured by an $\mathcal{ALC}$-TBox $\mathcal{T}'$ with $\mathsf{sig}(\mathcal{T}') \subseteq \Sigma$. On the other hand, for $\mathcal{T}' = \{A \sqsubseteq B,\ B \sqsubseteq C \sqcap \exists r.B,\ D \equiv B\}$ and $\Sigma' = \{A, C, D, r\}$, a Σ'-uniform interpolant of $\mathcal{T}'$ is $\{A \sqsubseteq D,\ D \sqsubseteq C \sqcap \exists r.D\}$.

Uniform interpolation is also related to the notion of logical difference between ontologies.

Definition 3. *The Σ-logical difference between $\mathcal{ALC}$-TBoxes $\mathcal{T}_1$ and $\mathcal{T}_2$ is the set $\mathsf{Diff}_\Sigma(\mathcal{T}_1, \mathcal{T}_2)$ of all $\mathcal{ALC}$-concept inclusions $C \sqsubseteq D$ such that $\mathsf{sig}(C \sqsubseteq D) \subseteq \Sigma$, $\mathcal{T}_1 \models C \sqsubseteq D$, and $\mathcal{T}_2 \not\models C \sqsubseteq D$.*

It is easy to see that $\mathsf{Diff}_\Sigma(\mathcal{T}_1, \mathcal{T}_2) = \emptyset$ if, and only if, $\mathcal{T}_2 \models \mathcal{T}_1^{(\Sigma)}$ where $\mathcal{T}_1^{(\Sigma)}$ is a Σ-uniform interpolant of $\mathcal{T}_1$. Moreover, if $\mathcal{T}_2 \not\models \mathcal{T}_1^{(\Sigma)}$, every inclusion $C \sqsubseteq D \in \mathcal{T}_1^{(\Sigma)}$ with $\mathcal{T}_2 \not\models C \sqsubseteq D$ can be regarded as a *witness* of $\mathsf{Diff}_\Sigma(\mathcal{T}_1, \mathcal{T}_2)$.

With the exception of acyclic $\mathcal{EL}$-TBoxes, checking whether the logical difference between two ontologies is nonempty is at least one exponential harder than reasoning (Konev et al. 2012). Additionally, if the set $\mathsf{Diff}_\Sigma(\mathcal{T}_1, \mathcal{T}_2)$ is nonempty, it is typically infinite. Therefore, in practice, the notion of logical difference is primarily used as a theoretical underpinning of its *approximations* that limit the choice of inclusions $C \sqsubseteq D$ in Definition 3 to Σ-inclusions constructed according to some syntactic rules, see e.g. (Jiménez-Ruiz et al. 2009), (Gonçalves, Parsia, and Sattler 2012).

Computing Uniform Interpolants by $\mathcal{ALC}$-Resolution

The aim of our work is to investigate a practical approach for computing uniform interpolants when they exist. Note that the worst-case optimal procedure given by Lutz and Wolter (2011) is inherently inefficient as it requires one to explicitly construct the internalisation $C_\mathcal{T}$ of a given TBox $\mathcal{T}$, i.e. a concept $C_\mathcal{T}$ of size double exponential in the size of $\mathcal{T}$ having the property that for any inclusion $C \sqsubseteq D$ it holds that $\mathcal{T} \models C \sqsubseteq D$ iff $\models C \sqcap C_\mathcal{T} \sqsubseteq D$.

Our approach is to introduce a resolution-like calculus for $\mathcal{ALC}$ that derives consequences of a TBox $\mathcal{T}$ such that a concept inclusion $C \sqsubseteq D$ is entailed by $\mathcal{T}$ iff a contradiction can be derived from $\mathcal{T}$ and $C \sqcap \neg D$. Similarly to Herzig and Mengin (2008), we then show that any derivation can be restructured in such a way that inferences on selected concept names always precede inferences on other concept names. Then, if the signature Σ is such that $\mathsf{sig}(\mathcal{T}) \setminus \Sigma$ only contains concept names, we generate a set of Σ-consequences $\mathcal{T}'$ of $\mathcal{T}$ by applying the inference rules in a forward chaining manner such that for an arbitrary Σ-inclusion $C \sqsubseteq D$ a contradiction can be derived from $\mathcal{T}$ and $C \sqcap \neg D$ iff a contradiction can be derived from $\mathcal{T}'$ and $C \sqcap \neg D$. Thus, if the forward-chaining process terminates, $\mathcal{T}'$ is a Σ-uniform-interpolant for $\mathcal{T}$.

$\mathcal{ALC}$-Resolution. $\mathcal{ALC}$-resolution operates on $\mathcal{ALC}$ formulae in a conjunctive normal form that is defined according to the following grammar (which is similar to the normal form introduced by Herzig and Mengin (2008)):

$$\begin{array}{rcl} \text{Literal} & ::= & A \mid \neg A \mid \forall r.\text{Clause} \mid \exists r.\text{CNF} \\ \text{Clause} & ::= & \text{Literal} \mid \text{Clause} \sqcup \text{Clause} \mid \bot \\ \text{CNF} & ::= & \top \mid \text{Clause} \mid \text{Clause} \sqcap \text{CNF} \end{array}$$

To simplify the presentation, we assume that clauses are sets of literals and that CNF expressions are sets of clauses. Then $\bot$ corresponds to the empty clause and $\top$ to the empty set of clauses. In the following, the calligraphic letters $\mathcal{C}, \mathcal{D}, \mathcal{E}$ symbolise clauses and $\mathcal{F}, \mathcal{G}$ represent sets of clauses. Similarly to first-order formulae, every $\mathcal{ALC}$ concept can be transformed into an equivalent set of $\mathcal{ALC}$ clauses. The depth of a clause $\mathcal{C}$, $\mathrm{Depth}(\mathcal{C})$, is defined to be the maximal nesting depth of the quantifiers contained in $\mathcal{C}$.

We additionally assume that every clause is assigned a *type*. Clauses obtained from the clausification of TBox inclusions are of the type *universal*, and clauses resulting from the clausification of inclusions to be tested for entailment by the TBox are of the type *initial*. The type of a derived clause is determined by the types of the clauses from which it is derived and by the derivation rule that is used.

Example 4. *The clausification of $\mathcal{T}$ from Example 2 produces three universal clauses: $\neg A \sqcup B$, $\neg B \sqcup C$, $\neg B \sqcup \exists r.B$.*

We now introduce the two resolution calculi $\mathfrak{T}$ and $\mathfrak{T}^u$. The former calculus assumes the TBox to be empty, whereas the latter takes TBox inclusions into account. Thus, $\mathfrak{T}$ derives the empty clause from the set of initial clauses stemming from the clausification of an inclusion $\top \sqsubseteq C \sqcap \neg D$ iff $\models C \sqsubseteq D$; and $\mathfrak{T}^u$ derives the empty clause from the universal clauses stemming from the clausification of a TBox $\mathcal{T}$ and the initial clauses stemming from the clausification of an inclusion $\top \sqsubseteq C \sqcap \neg D$ iff $\mathcal{T} \models C \sqsubseteq D$.

The calculus $\mathfrak{T}$ is defined with the help of the relation $\Rightarrow_\alpha$ given in Fig. 1. For every $\alpha \in \mathsf{N_C} \cup \{\bot\}$, the relation $\Rightarrow_\alpha$ associates with a set of clauses $\mathcal{N}$ a new clause $\mathcal{C}$ which can be 'derived' from the set $\mathcal{N}$ by 'resolving' on α. $\mathfrak{T}$ now consists of the following two inference rules.

$$\frac{\mathcal{C}}{\mathcal{E}}\ (\text{if } \mathcal{C} \Rightarrow_\alpha \mathcal{E}) \qquad\qquad \frac{\mathcal{C} \quad \mathcal{D}}{\mathcal{E}}\ (\text{if } \mathcal{C}, \mathcal{D} \Rightarrow_\alpha \mathcal{E}),$$

where $\mathcal{C}, \mathcal{D}$, and $\mathcal{E}$ are initial clauses.

The calculus $\mathfrak{T}^u$ operates initial and universal clauses and also consists of two rules:

$$\frac{\mathcal{C}}{\mathcal{E}}\ (\text{if } \mathcal{C} \Rightarrow_\alpha \mathcal{E}) \qquad\qquad \frac{\mathcal{C}' \quad \mathcal{D}}{\mathcal{E}'}\ (\text{if } \mathcal{C}', \mathcal{D} \Rightarrow^u_\alpha \mathcal{E}'),$$

where $\mathcal{C}, \mathcal{C}', \mathcal{D}$ are initial or universal clauses, and $\mathcal{C}', \mathcal{D} \Rightarrow^u_\alpha \mathcal{E}'$ holds iff either $\mathcal{C}', \mathcal{D} \Rightarrow_\alpha \mathcal{E}'$, or $\mathcal{D}$ is a universal clause and there exist role names $r_1, \ldots, r_n \in \mathsf{N_R}$ ($n \geq 1$) such that $\mathcal{C}', \forall r_1. \ldots \forall r_n.\mathcal{D} \Rightarrow_\alpha \mathcal{E}'$. (Intuitively, the calculus $\mathfrak{T}^u$ allows for inferences with universal clauses at arbitrary nesting levels of quantifiers, which the calculus $\mathfrak{T}$ does not.) Then $\mathcal{E}$ is a universal clause if $\mathcal{C}$ is a universal clause, and an initial clause otherwise. Similarly, $\mathcal{E}'$ is a universal clause if both $\mathcal{C}'$ and $\mathcal{D}$ are universal clauses, and an initial clause otherwise.

We assume that every clause $\mathcal{E}$ that results from a $\mathfrak{T}$- or $\mathfrak{T}^u$-inference is implicitly simplified by exhaustively removing all occurrences of literals of the form $\exists r.(\mathcal{F}, \bot)$.

(rule $\bot$)	$\mathcal{C}'_1 \sqcup \forall r.\bot,\ \ \mathcal{C}'_2 \sqcup \exists r.\mathcal{F} \Longrightarrow_\bot \mathcal{C}'_1 \sqcup \mathcal{C}'_2$	
(rule A)	$\mathcal{C}'_1 \sqcup A,\ \ \mathcal{C}'_2 \sqcup \neg A \Longrightarrow_A \mathcal{C}'_1 \sqcup \mathcal{C}'_2$	
(rule $\forall\exists$)	$\mathcal{C}'_1 \sqcup \forall r.\mathcal{C}_1,\ \ \mathcal{C}'_2 \sqcup \exists r.(\mathcal{C}_2,\mathcal{F}) \Longrightarrow_\alpha \mathcal{C}'_1 \sqcup \mathcal{C}'_2 \sqcup \exists r.(\mathcal{C}_2,\mathcal{F},\mathcal{C}_3),$	if $\mathcal{C}_1,\mathcal{C}_2 \Longrightarrow_\alpha \mathcal{C}_3$
(rule $\forall\forall$)	$\mathcal{C}'_1 \sqcup \forall r.\mathcal{C}_1,\ \ \mathcal{C}'_2 \sqcup \forall r.\mathcal{C}_2 \Longrightarrow_\alpha \mathcal{C}'_1 \sqcup \mathcal{C}'_2 \sqcup \forall r.\mathcal{C}_3,$	if $\mathcal{C}_1,\mathcal{C}_2 \Longrightarrow_\alpha \mathcal{C}_3$
(rule $\exists_1$)	$\mathcal{C}' \sqcup \exists r.(\mathcal{C}_1,\mathcal{F}) \Longrightarrow_\alpha \mathcal{C}' \sqcup \exists r.(\mathcal{C}_1,\mathcal{F},\mathcal{C}_2),$	if $\mathcal{C}_1 \Longrightarrow_\alpha \mathcal{C}_2$
(rule $\exists_2$)	$\mathcal{C}' \sqcup \exists r.(\mathcal{C}_1,\mathcal{C}_2,\mathcal{F}) \Longrightarrow_\alpha \mathcal{C}' \sqcup \exists r.(\mathcal{C}_1,\mathcal{C}_2,\mathcal{F},\mathcal{C}_3),$	if $\mathcal{C}_1,\mathcal{C}_2 \Longrightarrow_\alpha \mathcal{C}_3$
(rule $\forall$)	$\mathcal{C}' \sqcup \forall r.\mathcal{C}_1 \Longrightarrow_\alpha \mathcal{C}' \sqcup \forall r.\mathcal{C}_2,$	if $\mathcal{C}_1 \Longrightarrow_\alpha \mathcal{C}_2$

Figure 1: Rules of $\Longrightarrow_\alpha$.

Example 5. *For the universal clauses from Example 4, we have for instance,*

$$\neg A \sqcup B, \neg B \sqcup \exists r.B \ \Rightarrow_B \ \neg A \sqcup \exists r.B \quad \textit{by (rule A).}$$

So, the universal clause $\neg A \sqcup \exists r.B$ is derivable by $\mathfrak{T}^u$ from $\neg A \sqcup B$ and $\neg B \sqcup \exists r.B$. As $\neg B \sqcup C$ is a universal clause and

$$\neg B \sqcup \exists r.B, \forall r.\neg B \sqcup C \Rightarrow_B \neg B \sqcup \exists r.(B,C) \quad \textit{by (rule } \forall\exists\textit{),}$$

the universal clause $\neg B \sqcup \exists r.(B,C)$ is derivable by $\mathfrak{T}^u$ from $\neg B \sqcup \exists r.B$ and $\neg B \sqcup C$. By applying the inference rules to old and newly generated clauses, one can conclude that the universal clauses $\neg A \sqcup \exists r.(B,C)$ and $\neg A \sqcup \exists r.(B, \exists r.B)$ are also derivable by $\mathfrak{T}^u$ from $\mathcal{N} = \{\neg A \sqcup B,\ \neg B \sqcup C,\ \neg B \sqcup \exists r.B\}$.

For $x \in \{\mathfrak{T}, \mathfrak{T}^u\}$, a x-derivation (tree) Δ built from a set of clauses $\mathcal{N}$ is a finite binary tree in which each leaf is labelled with a clause from $\mathcal{N}$ and each non-leaf node n is labelled with a clause $\mathcal{C}$ such that $\mathcal{C}$ results from an x-inference on the parent(s) of n in Δ. We say that Δ is a derivation of a clause $\mathcal{C}$ if the root of Δ is labelled with $\mathcal{C}$. A derivation of the empty clause is called a *refutation*. Every path $n_1, \ldots, n_m$ of nodes in Δ where n_1 is a leaf node and n_m is the root node induces an *inference path* $\alpha_2, \ldots, \alpha_m$, where $\alpha_i \in \mathsf{N_C} \cup \{\bot\}$ $(2 \leq i \leq m)$ denotes the concept name, or $\bot$, which has been resolved upon to obtain the clause that is the label of the node n_i. For a signature $\Upsilon \subseteq \mathsf{N_C}$ and a strict total order $\succ \subseteq \Upsilon \times \Upsilon$, a derivation Δ is a $(x, \Upsilon, \succ)$-derivation if for every inference path $\alpha_1, \ldots, \alpha_n$ of Δ (with $\alpha_i \in \mathsf{N_C} \cup \{\bot\}$ for every $1 \leq i \leq n$) there exists $0 \leq k \leq n$ such that $\{\alpha_1, \ldots, \alpha_k\} \subseteq \Upsilon$, $\alpha_j \succ \alpha_{j+1}$ or $\alpha_j = \alpha_{j+1}$ for every $1 \leq j < k$, and $\alpha_j \notin \Upsilon$ for every $k < j \leq n$.

We prove that for every unsatisfiable set of initial clauses there always exists a $(\mathfrak{T}, \Upsilon, \succ)$-refutation by extending the results and proof methods of Herzig and Mengin (2008).

Theorem 6 ($\mathfrak{T}$-Completeness)**.** *Let $\Upsilon \subseteq \mathsf{N_C}$, let $\succ \subseteq \Upsilon \times \Upsilon$ be a strict total order on Υ and let C and D be $\mathcal{ALC}$ concepts. Then it holds that $\models C \sqsubseteq D$ iff there exists a $(\mathfrak{T}, \Upsilon, \succ)$-derivation of the empty clause from the initial clauses* $\mathrm{Cls}(C \sqcap \neg D)$.

A weaker version of this result, stating that any derivation in $\mathfrak{T}$ can be reordered so that inferences on concept names from Υ always precede inferences on other concept names, or $\bot$, has been previously announced by Herzig and Mengin (2008); however, as we show in the full version of the paper, the proof appears to have some gaps.

To prove completeness for $\mathfrak{T}^u$, we observe the following link between derivations in $\mathfrak{T}$ and $\mathfrak{T}^u$. Let $\mathcal{N}$ be a set of clauses and let

$$\begin{aligned}
\mathrm{Univ}_0(\mathcal{N}) &= \mathcal{N};\\
\mathrm{Univ}_{i+1}(\mathcal{N}) &= \mathrm{Univ}_i(\mathcal{N}) \cup \\
&\qquad \textstyle\bigcup_{r \in \mathsf{N_R} \cap \mathsf{sig}(\mathcal{N})} \{\, \forall r.\mathcal{C} \mid \mathcal{C} \in \mathrm{Univ}_i(\mathcal{N}) \,\}\\
\text{and } \mathrm{Univ}(\mathcal{N}) &= \textstyle\bigcup_{i \geq 0} \mathrm{Univ}_i(\mathcal{N}).
\end{aligned}$$

Theorem 7. *Let $\mathcal{M}$ be a set of initial clauses and let $\mathcal{N}$ be a set of universal clauses. Additionally, let Δ be a $(\mathfrak{T}, \Upsilon, \succ)$-refutation from $\mathcal{M} \cup \mathrm{Univ}(\mathcal{N})$ such that there exists $n \in \mathbb{N}$ with $\mathrm{Depth}(\mathcal{C}) \leq n$ for every $\mathcal{C} \in$ Clauses(Δ). Then there exists a $(\mathfrak{T}^u, \Upsilon, \succ)$-derivation Δ^u of the empty clause from $\mathcal{M} \cup \mathcal{N}$ such that $\mathrm{Depth}(\mathcal{C}) \leq n$ for every $\mathcal{C} \in$ Clauses(Δ^u).*

We then use Theorems 6 and 7 and the fact that every $\mathcal{ALC}$-TBox can be internalised. Notice that the actual TBox internalisation $C_\mathcal{T}$ does not have to be computed as it is only used for the proof of completeness.

Corollary 8 ($\mathfrak{T}^u$-Completeness)**.** *Let $\mathcal{T}$ be an $\mathcal{ALC}$-TBox, let $\Upsilon \subseteq \mathsf{N_C}$, let $\succ \subseteq \Upsilon \times \Upsilon$ be a strict total order on Υ and let C and D be $\mathcal{ALC}$ concepts. Then it holds that $\mathcal{T} \models C \sqsubseteq D$ iff there exists a $(\mathfrak{T}^u, \Upsilon, \succ)$-derivation of the empty clause from the universal clauses* $\mathrm{Cls}(\mathcal{T})$ *and the initial clauses* $\mathrm{Cls}(C \sqcap \neg D)$.

Computing Uniform Interpolants. The procedure UNIFORMINTERPOLANT depicted in Algorithm 1 takes as input an $\mathcal{ALC}$-TBox $\mathcal{T}$, a signature $\Sigma \subseteq \mathsf{sig}(\mathcal{T})$ such that $\Sigma \cap \mathsf{N_R} = \mathsf{sig}(\mathcal{T}) \cap \mathsf{N_R}$ and a strict total order $\succ \subseteq \Upsilon \times \Upsilon$ over $\Upsilon = \mathsf{sig}(\mathcal{T}) \setminus \Sigma$. Following the outline given by Herzig and Mengin (2008), after the clausification of $\mathcal{T}$, the procedure iterates over the concept names contained in Υ in descending order according to the relation $\succ$. In each iteration the clause set $\mathcal{N}$ is expanded with all possible $\mathfrak{T}^u$-inferences on the current concept name $A \in \Upsilon$. Finally, after iterating over all the concept names from $\Upsilon = \mathsf{sig}(\mathcal{T}) \setminus \Sigma$, the operator 'Supp' is applied on the resulting clauses, which replaces all occurrences of Υ concept names in clauses with $\top$ and then simplifies the resulting CNF.

Example 9. *For the clauses obtained in Example 5,* $\mathrm{Supp}(\{B\}, \neg A \sqcup C) = \neg A \sqcup C$, $\mathrm{Supp}(\{B\}, \neg A \sqcup \exists r.B) = \neg A \sqcup \exists r.\top$, $\mathrm{Supp}(\{B\}, \neg A \sqcup \exists r.(B,C)) = \neg A \sqcup \exists r.C$.

Algorithm 1

procedure UNIFORMINTERPOLANT($\mathcal{T}$, Σ, $\succ$)
  $\Upsilon := \mathsf{sig}(\mathcal{T}) \setminus \Sigma$
  $\mathcal{N} := \mathrm{Cls}(\mathcal{T})$
  while $\Upsilon \neq \emptyset$ **do**
    $A := \max_{\succ}(\Upsilon)$
    $\mathcal{N} := \mathrm{Res}^{\infty}_{\mathfrak{T}^u,\{A\}}(\mathcal{N})$
    $\Upsilon := \Upsilon \setminus \{A\}$
  end while
  return $\mathcal{F}_{\Sigma}(\mathcal{T}) = \mathrm{Supp}(\mathsf{sig}(\mathcal{T}) \setminus \Sigma, \mathcal{N})$
end procedure

One can show that if Algorithm 1 terminates, then for all $\mathcal{ALC}$ Σ-concepts C, D such that there exists a $(\mathfrak{T}^u, \Upsilon, \succ)$-refutation Δ^u from the universal clauses $\mathrm{Cls}(\mathcal{T})$ and the initial clauses $\mathrm{Cls}(C \sqcap \neg D)$ it holds that $\mathcal{F}_{\Sigma}(\mathcal{T}) \models C \sqsubseteq D$. Thus, it follows from Corollary 8 that if Algorithm 1 terminates, it computes a Σ-uniform interpolant of $\mathcal{T}$. However, Algorithm 1 does not terminate if a uniform interpolant does not exist. For example, when applied to $\mathcal{T}$ from Example 2, Algorithm 1 can generate, among others, the infinite sequence of universal clauses $\neg A \sqcup \exists r.C$, $\neg A \sqcup \exists r.(C, \exists r.C), \ldots$ and so on. Moreover, as the TBox $\mathcal{T}$ from Example 2 is a subset of $\mathcal{T}'$, and so $\mathrm{Cls}(\mathcal{T}) \subseteq \mathrm{Cls}(\mathcal{T}')$, Algorithm 1 will derive, among others, the same clauses when it is applied on $\mathcal{T}'$. Thus, in some cases Algorithm 1 does not terminate even though a uniform interpolant exists.

To guarantee termination on all inputs, we focus on the notion of depth-bounded uniform interpolation (related to the notion of 'bounded forgetting' (Zhou and Zhang 2011)). Let $\mathcal{T}$ be an $\mathcal{ALC}$-TBox and let $\Sigma \subseteq \mathsf{sig}(\mathcal{T})$ be a signature. We say that an $\mathcal{ALC}$-TBox $\mathcal{T}_{\Sigma}$ is a *depth n-bounded uniform interpolant* of the TBox $\mathcal{T}$ w.r.t. Σ iff $\mathsf{sig}(\mathcal{T}_{\Sigma}) \subseteq \Sigma$, $\mathcal{T} \models \mathcal{T}_{\Sigma}$, and for every $\mathcal{ALC}$ Σ-concept inclusion $C \sqsubseteq D$ with $\mathcal{T} \models C \sqsubseteq D$ and $\max\{\mathrm{Depth}(C), \mathrm{Depth}(D)\} \leq n$ it holds that $\mathcal{T}_{\Sigma} \models C \sqsubseteq D$. Let $\mathcal{F}_{\Sigma,m}(\mathcal{T})$ be the outcome of Algorithm 1 where in Step 6 only clauses up to depth m are generated. The following example shows that it might be necessary to consider intermediate clauses of a depth $m > n$ in order to preserve all the Σ-consequences of depth n entailed by $\mathcal{T}$.

Example 10. *Let $\mathcal{T} = \{A \sqsubseteq \exists r.C,\ C \sqsubseteq \exists s.\top,\ \neg B \sqsubseteq \forall s.\bot\}$, $\Sigma = \{A, B, r, s\}$, $\Upsilon = \{C\}$ and $\succ = \emptyset$. Then every $(\mathfrak{T}^u, \Upsilon, \succ)$-refutation from the universal clauses $\mathrm{Cls}(\mathcal{T})$ and the initial clauses $\{A, \forall r.\neg B\}$ derives the clause $\neg A \sqcup \exists r.(C, \exists s.\top)$.*

We establish, however, that by choosing the maximal depth of derived clauses appropriately, the procedure depicted in Algorithm 1 computes uniform interpolants that preserve consequences up to a specified depth n.

Theorem 11. *Let $\mathcal{T}$ be an $\mathcal{ALC}$-TBox, $\Sigma \subseteq \mathsf{sig}(\mathcal{T})$ a signature such that $\Sigma \cap \mathsf{N_R} = \mathsf{sig}(\mathcal{T}) \cap \mathsf{N_R}$, and let $n \geq 0$. Set $m = n + 2^{|\mathsf{sub}(\mathrm{Cls}(\mathcal{T}))|+1} + \max\{\mathrm{Depth}(\mathcal{C}) \mid \mathcal{C} \in \mathrm{Cls}(\mathcal{T})\}$, where $\mathsf{sub}(\mathrm{Cls}(\mathcal{T}))$ is the set of subconcepts of $\mathrm{Cls}(\mathcal{T})$. Then it holds that $\mathcal{F}_{\Sigma,m}(\mathcal{T})$ is a depth n-bounded uniform interpolant of the TBox $\mathcal{T}$ w.r.t. Σ.*

We can combine this result with the results of (Lutz and Wolter 2011): for any $\mathcal{ALC}$-TBox $\mathcal{T}$ and signature Σ, if a Σ-uniform interpolant of $\mathcal{T}$ exists, then there exists a uniform interpolant of depth bounded by $2^{2^{|\mathcal{T}|+1}} + 1$. Thus, if $\Sigma \cap \mathsf{N_R} = \mathsf{sig}(\mathcal{T}) \cap \mathsf{N_R}$, there exists m, which can be computed based on the bound in Theorem 11 and the results of (Lutz and Wolter 2011), such that $\mathcal{F}_{\Sigma,m}(\mathcal{T})$ is a Σ-uniform interpolant of $\mathcal{T}$.

The bound in Theorem 11 can be significantly improved if the TBox is acyclic. For an acyclic $\mathcal{ALC}$-TBox $\mathcal{T}$ we define $\mathrm{ExpansionDepth}(\mathcal{T}) = \max\{\mathrm{Depth}(A[\mathcal{T}]) \mid A \in \mathsf{sig}(\mathcal{T})\}$, where $A[\mathcal{T}]$ denotes the concept obtained by exhaustively replacing every concept B with C_B if $B \sqsubseteq C_B \in \mathcal{T}$ or $B \equiv C_B \in \mathcal{T}$.

Theorem 12. *Let $\mathcal{T}$ be an acyclic $\mathcal{ALC}$ TBox, $\Sigma \subseteq \mathsf{sig}(\mathcal{T})$ a signature such that $\Sigma \cap \mathsf{N_R} = \mathsf{sig}(\mathcal{T}) \cap \mathsf{N_R}$, and let $n \geq 0$. Set $m = \mathrm{ExpansionDepth}(\mathcal{T}) + n$. Then it holds that $\mathcal{F}_{\Sigma,m}(\mathcal{T})$ is a uniform interpolant limited to consequence depth n of the TBox $\mathcal{T}$ w.r.t. Σ.*

Note that in the description logic $\mathcal{EL}$ (i.e. the fragment of $\mathcal{ALC}$ that does not allow $\bot$, negation, disjunction, or universal quantification) the acyclicity of a TBox guarantees the existence of uniform interpolants (Konev, Walther, and Wolter 2009) for any signature Σ. Interestingly, this is not true in the case of $\mathcal{ALC}$. Moreover, as the following example shows, there exists an acyclic $\mathcal{EL}$-TBox $\mathcal{T}$ and a signature Σ for which no $\mathcal{ALC}$ Σ-uniform interpolant exists.

Example 13. *Consider $\Sigma = \{A, A_0, A_1, A_2, E, r\}$ and $\mathcal{T} = \{A \sqsubseteq \exists r.B,\ A_0 \sqsubseteq \exists r.(A_1 \sqcap B),\ E \equiv A_1 \sqcap B \sqcap \exists r.(A_2 \sqcap B)\}$. Then for every $n \geq 0$, $\mathcal{T}$ entails the inclusion*

$$A_0 \sqcap \prod_{i=1}^{n} \underbrace{\forall r. \ldots \forall r.}_{i}(A \sqcap \neg E \sqcap (A_1 \sqcup A_2)) \sqsubseteq \underbrace{\exists r. \ldots \exists r.}_{n} A_1.$$

This infinite sequence of $\mathcal{ALC}$ consequences of $\mathcal{T}$ cannot be captured by any $\mathcal{ALC}$ Σ-TBox $\mathcal{T}'$, which can be proved formally using Theorem 9 of Lutz and Wolter (2011).

Case Study

We have implemented a prototype of an inference computation architecture using the calculus $\mathfrak{T}^u$ and the inference relation $\Rightarrow_{\alpha}$ in Java. However, it turned out that our initial implementation of Algorithm 1 did not perform well in practice. This was in particular due to the fact that clauses can contain sets $\mathcal{F}$ of other clauses in existential literals $\exists r.\mathcal{F}$, which renders all the possible inferences on clauses from $\mathcal{F}$ 'explicit'. For example, if we resolve the universal clause which just consists of the existential literal $\exists r.(A)$ with the universal clauses $\neg A \sqcup B_1, \ldots, \neg A \sqcup B_n$ on the concept name A, then not only the clauses $\exists r.(A, B_1)$, $\exists r.(A, B_2)$, $\exists r.(A, B_3)$,... could be derived but all clauses of the form $\exists r.(A, \mathcal{G})$, where $\mathcal{G}$ is a subset of $\{B_1, \ldots, B_n\}$.

A common technique to reduce the number of inferences that have to be made is to use forward- and backward deletion of subsumed clauses (Bachmair and Ganzinger 2001). However, it is known (Auffray, Enjalbert, and Hébrard 1990) that the subsumption lemma (stating that if a clause $\mathcal{E}$ results from an inference involving two clauses $\mathcal{C}$ and $\mathcal{D}$, and

Table 1: Uniform Interpolation and Forgetting for BioPortal Ontologies on Small Signatures.

if there exist clauses $\mathcal{C}'$, $\mathcal{D}'$ such that $\mathcal{C}'$ subsumes $\mathcal{C}$ and $\mathcal{D}'$ subsumes $\mathcal{D}$, then either $\mathcal{E}$ is subsumed by one of $\mathcal{C}'$, $\mathcal{D}'$, or a clause $\mathcal{E}'$ can be derived from $\mathcal{C}'$ and $\mathcal{D}'$ such that $\mathcal{E}'$ subsumes $\mathcal{E}$) does not hold even in the modal logic K for the standard *minimal subsumption relation* $\leq_s$ (Auffray, Enjalbert, and Hébrard 1990) and $\Rightarrow_\alpha$. To be able to prove that one can safely discard subsumed clauses, we have modified the inference relation $\Rightarrow_\alpha$ by introducing the following additional rule (rule $\exists_f$)

$$\mathcal{C}_1 \sqcup \forall r.\mathcal{D},\ \ \mathcal{C}_2 \sqcup \exists r.\mathcal{F} \Longrightarrow_{\exists_f} \mathcal{C}_1 \sqcup \mathcal{C}_2 \sqcup \exists r.(\mathcal{F}, \mathcal{D}).$$

We will denote the resulting inference relation by $\Rightarrow_\alpha^f$ with $\alpha \in \mathsf{N_C} \cup \{\bot, \exists_f\}$. One can then prove that a variant of the subsumption lemma holds for the relations $\leq_s$ and $\Rightarrow_\alpha^f$, which allows us to employ forward- and backward deletion of subsumed clauses in our implementation.

In order to further speed up computations, we first extract the locality-based $\top\bot^*$ Σ-module (Cuenca Grau et al. 2008; Sattler, Schneider, and Zakharyaschev 2009) for a given TBox $\mathcal{T}$. The locality-based module entails the same Σ-inclusions as the TBox $\mathcal{T}$ but it is often considerably smaller in size. We also rely on ontologies to have structure: if a concept name occurs in several inclusions, it is likely that it occurs in the same syntactic pattern. We therefore transform clause sets as follows.

1. If the clause set contains some clauses $\mathcal{C}_1 \sqcup \mathcal{D}_\Upsilon, \ldots, \mathcal{C}_m \sqcup \mathcal{D}_\Upsilon$ such that for every $1 \leq i \leq m$ we have $\mathsf{sig}(\mathcal{C}_i) \cap \Upsilon = \emptyset$, we rewrite them into $X \sqcup \mathcal{D}_\Upsilon$, where $X \equiv \mathcal{C}_1 \sqcap \ldots \sqcap \mathcal{C}_m$, perform forgetting on Υ symbols and then replace X with its definition.
2. If the clause set contains a clause $\mathcal{C} \sqcup \exists r.(\mathcal{F}_\Upsilon, \mathcal{G}_1) \sqcup \ldots \sqcup \exists r.(\mathcal{F}_\Upsilon, \mathcal{G}_m)$ where $\mathsf{sig}(\mathcal{G}_i) \cap \Upsilon = \emptyset$ for every $1 \leq i \leq m$, we rewrite it into $\mathcal{C} \sqcup \exists r.(\mathcal{F}_\Upsilon, Y)$, where $Y \equiv \mathcal{G}_1 \sqcup \ldots \sqcup \mathcal{G}_m$, perform forgetting on Υ and then replace Y with its definition.

Experimental setting. All experiments were conducted on PCs equipped with an Intel Core i5-2500K CPU running at 3.30GHz. 15 GiB of RAM were allocated to the Java VM and an execution timeout of 60 CPU minutes was imposed on each problem. Whenever necessary we pre-processed the ontologies we used for our experiments as follows. For a given ontology $\mathcal{T}$, we first rewrote concept disjointness statements and role domain/range restrictions into $\mathcal{ALC}$ inclusions and then removed any remaining axiom which contained non-$\mathcal{ALC}$ concept (or role) constructors to obtain the $\mathcal{ALC}$-fragment of $\mathcal{T}$. We used Algorithm 1 to forget concept names one by one i.e. for $\Upsilon = \{A_1, \ldots, A_n\}$, Algorithm 1 was applied iteratively on $A_1, \ldots, A_n$, and we did *not* impose a bound on the depth of clauses; so the computed clause

Table 2: Computing Uniform Interpolants of DIKB v1.4 and of NCI v08.10e Limited to Expansion Depth 3.

sets contain depth n-bounded uniform interpolants for every $n > 0$. Thus, in all the experiments reported on we computed *true* Σ*-uniform interpolants* (i.e. not a depth-bounded variant). The correctness of our extensions to Algorithm 1 can be shown by model-theoretic arguments.

Experiments with small signatures. We applied our uniform interpolation tool to compute uniform interpolants w.r.t. small concept signatures $\Sigma \subseteq \mathsf{sig}(\mathcal{T})$ with $\mathsf{sig}(\mathcal{T}) \cap \mathsf{N_R} = \Sigma \cap \mathsf{N_R}$ for 21 small to medium size ontologies taken from the BioPortal repository[2]. The number of axioms in the selected ontologies ranges from 192 (for the *Ontology of Medically Related Social Entries*) to 2702 (for the *Subcellular Anatomy Ontology*). To make the experiments more interesting, we also included version 08.10e of the *National Cancer Institute Thesaurus* (NCI). For each considered sample size x and terminology $\mathcal{T}$ we generated 100 signatures Σ by randomly choosing x concept names from $\mathsf{sig}(\mathcal{T})$ and by adding all the role names from $\mathsf{sig}(\mathcal{T})$ to Σ. The results that we obtained are shown in Table 1.

In the left half of Table 1 one can see that the number of successful computations decreased while the size of $\Sigma \cap \mathsf{N_C}$ was increasing, which seems to be due to the fact that the $\top\bot^*$ Σ-modules then contain more symbols that lead to a large number of inferences. Most uniform interpolants that we obtained are relatively small and contain a lot of expressions of the form $\exists r_1 \ldots \exists r_n.\top$. In some cases the process of forgetting certain intermediate concept names generated a few hundred clauses that were simplified or deleted in the remaining computation steps. The success rate, however, varied significantly from one ontology to another. To further investigate this phenomenon, we computed uniform interpolants for a *fragment* of version 08.10e of NCI and for a fragment of version 1.4 of the *Drug Interaction Knowledge Base* (DIKB) that are of expansion depth 3 (that is, we removed all the axioms from both ontologies that led to an expansion depth greater than 3). The resulting DIKB fragment is a small acyclic terminology that contains 120 concept names, 27 roles names, and 127 axioms. The NCI fragment is also an acyclic terminology with 53571 concept names, 78 role names and 62494 axioms (of which 2362 are of the form $A \equiv C$). The results obtained are shown in Table 2. Limiting the expansion depth drastically improved the performance of our prototype implementation with the success rate for signatures containing 5 randomly selected concept names rising from 2% to 85% in the case of DIKB and from 23% to 82% in the case of NCI. For NCI our tool was capable of handling signatures containing up to 150 randomly selected concept names.

As proof of concept for ontology obfuscation, we applied our uniform interpolation tool on (a fragment of) the *Lipid Ontology* (LIPRO) to forget 45 concept names which are intermediate concept names in the ontology's induced concept hierarchy, i.e. those concept names group certain subconcepts together to give structure to the ontology. LIPRO is an acyclic terminology with 593 axioms, 574 concept names and one role name. The maximal size of an axiom is 50. It then took 192 CPU seconds to compute the uniform interpolant, which contains 3415 axioms that have a maximal size of 283. The uniform interpolant that we computed thus approximately contains 6 times more axioms than the origi-

[2] All ontologies used for the experiments reported on in this section can be accessed from the BioPortal repository: http://bioportal.bioontology.org/ontologies

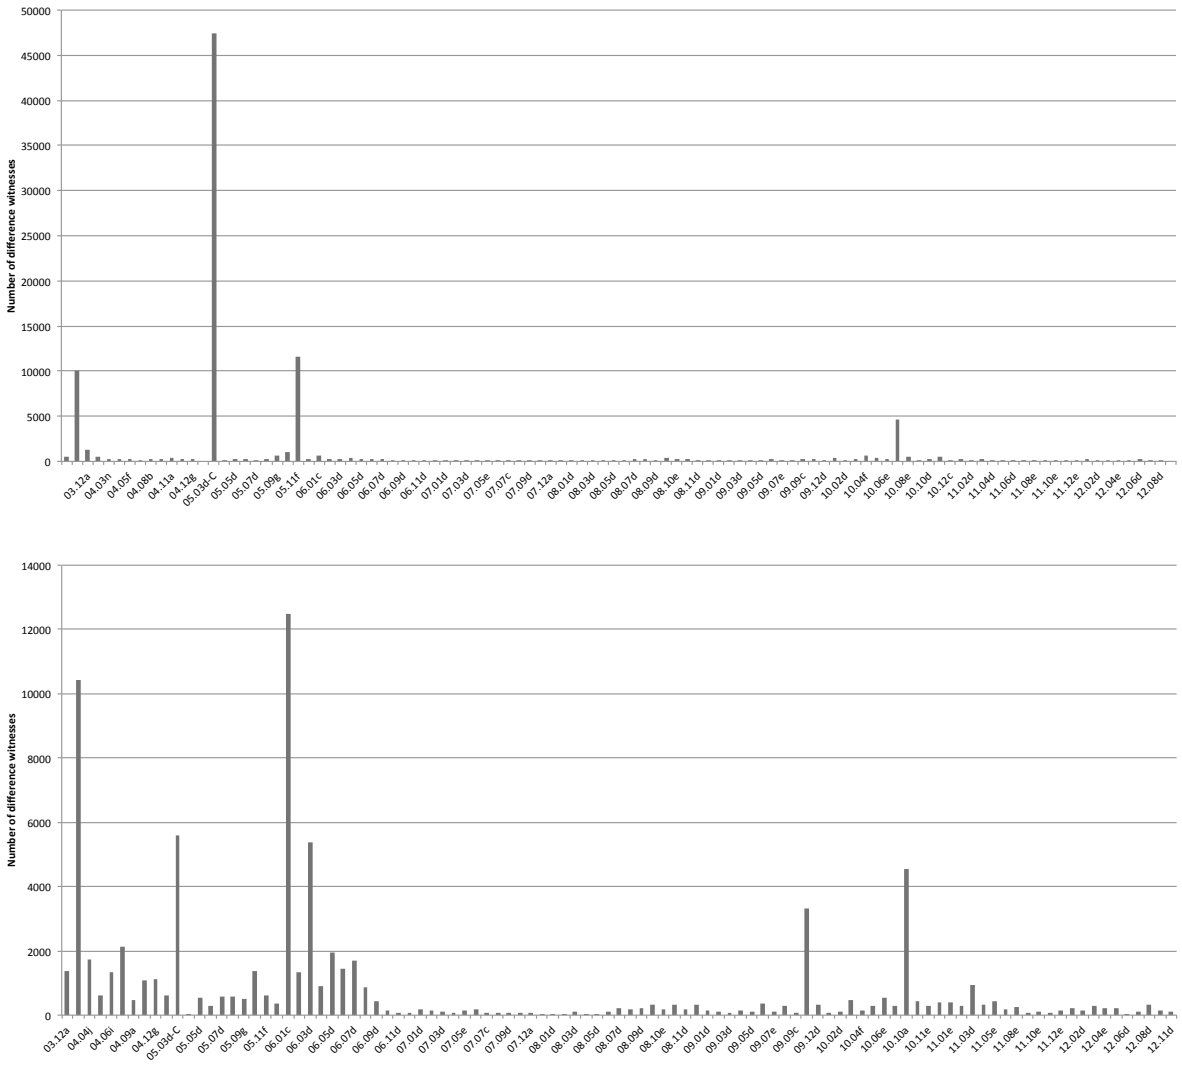

Figure 2: Logical Difference between NCI Versions i and $i+1$ (Top) and Versions $i+1$ and i (Bottom).

nal ontology and the maximal axiom size has increased by a factor of 6 as well. Notice that most of the original structure of the ontology has been destroyed while preserving all the consequences entailed by the retained concept names.

Finally, in the right half of Table 1 we report on our success rate for forgetting a small number of concept names. Notice that our prototype implementation performs significantly better in this scenario. This observation suggests that our tool is suitable for checking whether a change made to an ontology interferes with the meaning of the terms outside the (typically small) fragment under consideration in the context of computing the logical difference between two versions of an ontology.

Computing the Logical Difference. We selected 10 ontologies that have at least 5 submissions and whose expressivity is at least $\mathcal{ALC}$, including 109 versions of the NCI Thesaurus, from the BioPortal repository.

For every pair of consecutive versions $\mathcal{T}_i$ and $\mathcal{T}_{i+1}$, where version $i+1$ represents the more recent version, and every considered signature Σ, we computed both $\mathsf{Diff}_\Sigma(\mathcal{T}_i, \mathcal{T}_{i+1})$ and $\mathsf{Diff}_\Sigma(\mathcal{T}_{i+1}, \mathcal{T}_i)$. We used the reasoner FaCT++ v1.6.2 (Tsarkov and Horrocks 2006) to determine whether any axiom $C \sqsubseteq D \in \mathcal{T}_i^{(\Sigma)}$ is a witness of $\mathsf{Diff}_\Sigma(\mathcal{T}_i, \mathcal{T}_{i+1})$, where $\mathcal{T}_i^{(\Sigma)}$ is the Σ-uniform interpolant of $\mathcal{T}_i$ computed with our tool (similarly for $\mathsf{Diff}_\Sigma(\mathcal{T}_{i+1}, \mathcal{T}_i)$). Note that the signatures Σ we used for the experiments contained (at least) all the roles present in $\mathcal{T}_i$ due to the limitations of our uniform interpolation procedure. However, such a restriction does not limit the applicability of logical difference in the sense that differences involving role names can still be detected. Note further that the results we obtained here are not directly comparable with the logical difference computed for description logics of the $\mathcal{EL}$ family (Konev, Walther, and Wolter 2008; Konev et al. 2012) as illustrated

$\lvert(\mathsf{sig}(\mathcal{T}) \setminus \Sigma) \cap \mathsf{N_C}\rvert$	$\mathsf{Diff}_\Sigma(\mathrm{NCI}_{\text{v08.09d}}, \mathrm{NCI}_{\text{v08.10e}})$ Success Rate (%)	Avrg # Witnesses	$\mathsf{Diff}_\Sigma(\mathrm{NCI}_{\text{v05.03d}}, \mathrm{NCI}_{\text{v05.05d}})$ Success Rate (%)	Avrg # Witnesses	$\mathsf{Diff}_\Sigma(\mathrm{NCI}_{\text{v05.12f}}, \mathrm{NCI}_{\text{v06.01c}})$ Success Rate (%)	Avrg # Witnesses

Table 4: Computing the Logical Difference between Versions of NCI.

by Example 13.

In our first experiment we used $\Sigma = (\mathsf{sig}(\mathcal{T}_i) \cap \mathsf{sig}(\mathcal{T}_{i+1})) \cup \mathsf{N_R}$. This test captures any change to the meaning of the terms common to both versions. The results of computing the logical difference are given in Table 3. Notice that the success rate of computing $\mathsf{Diff}_\Sigma(\mathcal{T}_i, \mathcal{T}_{i+1})$ was slightly higher than the one of the converse direction. This observation can probably be attributed to the fact that these cases correspond to knowledge contained in an older version being removed from a newer one, which does not seem to happen often.

Interestingly, we could observe one of the highest success rates among all our experiments whilst computing logical differences for distinct versions of NCI. This can possibly be explained by the fact that versions of NCI are released frequently and changes to the ontology are hence introduced gradually. Figure 2 depicts the number of witnesses that correspond to the logical difference between consecutive versions of NCI on their common signature. Gonçalves, Parsia, and Sattler (2012) provide a comprehensive analysis of the changes between 14 consecutive versions of NCI using various techniques, ranging from a manual inspection of the log files to approximations of the logical difference. Versions 05.12f, 06.01c, and 06.08d were identified as having the highest number of differences. In our experiments, the highest number of logical difference witnesses were also present in NCI version 06.01c; the computations for versions 05.12f and 06.08d did not finish in time.

Furthermore, to make the experiments more challenging for the reasoner, we focused on comparing version i with version $i + 1$, and vice versa, on the 2 pairs of NCI versions for which the highest number of difference witnesses was identified in the first experiment. We also included version 08.10e as this is the last acyclic $\mathcal{ALC}$ TBox in the corpus. We performed tests on randomly generated large signatures Σ with $\Sigma \cap \mathsf{N_R} = \mathsf{sig}(\mathcal{T}) \cap \mathsf{N_R}$. In that way the computed uniform interpolants remained rather large as well.

For each sample size $x \in \{5, 10, 20, 50, 100\}$ we generated 100 signatures by randomly choosing $|\mathsf{sig}(\mathcal{T}) \cap \mathsf{N_C}| - x$ concept names from $\mathsf{sig}(\mathcal{T})$ and by including all the role names from $\mathsf{sig}(\mathcal{T})$. The results that we obtained are now shown in Table 4.

One can observe that as the size of $\mathsf{sig}(\mathcal{T}) \setminus \Sigma$ increased, i.e. more symbols had to be forgotten from the $\top\bot^*$ Σ-modules, the success rate dropped slightly. Overall, the average number of witnesses and the average maximal size of the witnesses remained comparable throughout the different sample sizes. Also, the axioms generated by the computation of the uniform interpolant did not pose a problem for FaCT++ as computing the logical difference for a given signature never took more than 20 seconds in our experiments.

Conclusion

In this paper we presented an approach based on clausal resolution for computing uniform interpolants of $\mathcal{ALC}$-TBoxes $\mathcal{T}$ w.r.t. signatures $\Sigma \subseteq \mathsf{sig}(\mathcal{T})$ that contain all the role names present in $\mathcal{T}$. We proved that whenever the saturation process under $\mathcal{ALC}$-resolution terminates, the algorithm computes a uniform interpolant. To guarantee termination on all inputs, we introduced a depth-bounded version of our algorithm. We showed that by choosing an appropriate bound on the depth of clauses, one can axiomatise all Σ-inclusions implied by the given TBox up to a specified depth. Combined with a known bound on the size of uniform interpolants, our depth-bounded procedure always computes a uniform interpolant if it exists.

In the second part of this paper we investigated how often our unrestricted resolution-based algorithm terminates with a uniform interpolant by applying our prototype implementation on a number of case studies. Our findings suggest that despite a high computational complexity uniform interpolants can be computed in many practical cases. The com-

putation procedure could further benefit from better redundancy elimination techniques, which, together with extending our approach to forgetting role names, constitutes future work. It would also be interesting to explore proof strategies for our resolution calculi that guarantee termination when uniform interpolants exist.

Certain Answers as Objects and Knowledge

Leonid Libkin
School of Informatics, University of Edinburgh

Abstract

The standard way of answering queries over incomplete databases is to compute *certain answers*, defined as the intersection of query answers on all complete databases that the incomplete database represents. But is this universally accepted definition correct? We argue that this "one-size-fits-all" definition can often lead to counterintuitive or just plain wrong results, and propose an alternative framework for defining certain answers.

The idea of the framework is to move away from the standard, in the database literature, assumption that query results be given in the form of a database object, and to allow instead two alternative representations of answers: as objects defining all other answers, or as knowledge we can deduce with certainty about all such answers. We show that the latter is often easier to achieve than the former, that in general certain answers need not be defined as intersection, and may well contain missing information in them. We also show that with a proper choice of semantics, we can often reduce computing certain answers – as either objects or knowledge – to standard query evaluation. We describe the framework in the most general way, applicable to a variety of data models, and test it on three concrete relational semantics of incompleteness: open, closed, and weak closed world.

1 Introduction

Handling incomplete information is one of the oldest topics in database research. It has been tackled both from the database perspective, resulting in classical notions of the semantics and complexity of query evaluation (Abiteboul, Kanellakis, and Grahne 1991; Imielinski and Lipski 1984), and from the AI perspective, providing an alternative view of the problem, see, e.g., (Reiter 1982; Lenzerini 1991). With the shifting focus in database applications, owing to the ever increasing amounts of data as well as data heterogeneity, the problem of incomplete information is becoming much more pronounced. It appears in many important application areas such as data integration (Lenzerini 2002), data exchange (Arenas et al. 2014), inconsistent databases (Bertossi 2011), probabilistic data (Suciu et al. 2011), and data quality (Fan and Geerts 2012).

The central problem in the database field is of course query answering, and in the presence of incompleteness, one looks for *certain answers*: those that do not depend on the interpretation of unknown data. The concept was first mentioned in (Grant 1977) and formally defined 35 years ago in (Lipski 1979) as follows. Assume that the semantics $[\![D]\!]$ of an incomplete database D is given as the set of all complete databases D' which D can represent. Then the certain answer to Q on D is defined as $\mathsf{cert}_\cap(Q, D) = \bigcap\{Q(D') \mid D' \in [\![D]\!]\}$. Since database queries produce collections (sets, multisets, etc.), it makes sense to talk about their intersection. This definition has been universally applied to all the semantics of incompleteness, and in all the scenarios such as those listed above. The intuition is that this gives us the set of tuples independent of the interpretation of the missing information in D. Such a universal adoption of this basic definition has another consequence: certain answers themselves contain no missing information. In fact many algorithms for computing certain answers have, as the last step, elimination of any objects (say, rows in relational databases) with missing data.

The question that we address here is the following: *Is this standard "one-size-fits-all" definition really the right one to use for all the semantics, and all the applications?* The answer, as we shall argue, is negative: the standard intersection semantics, as well as the assumption that no missing information is present in the answers, leads to many problems, and crucially to producing meaningless query answers.

To argue that this is the case, and to explain some basic ideas behind the alternative approach we present here, note that in the database field, one tends to operate with *objects* (i.e., relations, XML documents, graph databases, etc.); in particular, queries take objects and return objects. Thus, the idea behind certain answers is to find an *object* A representing the *set of objects* $Q([\![D]\!]) = \{Q(D') \mid D' \in [\![D]\!]\}$. Such an object A must contain information common to all the objects in $Q([\![D]\!])$: that is, it must be no more informative than any of the objects in $Q([\![D]\!])$.

Now take a simple example: we have a relation $R = \{(1, 2), (3, \bot)\}$ in a database, where $\bot$ represents a null, or a missing value. The query Q returns R itself. Then $\mathsf{cert}_\cap(Q, D) = \{(1, 2)\}$ under every reasonable semantics of incompleteness. But is it less informative than all of $Q(D')$ for $D' \in [\![D]\!]$? The answer depends on the semantics. Under

the common *open-world* semantics, the answer is yes: in fact $(1, 2)$ is precisely the greatest lower bound of $Q([\![D]\!])$ under the ordering whose meaning is "being less informative". But under the equally common *closed-world* semantics, the answer is no. Even worse, $(1, 2)$ is not less informative than any of the answers $Q(D')$ for $D' \in [\![D]\!]$ which are of the form $\{(1, 2), (3, n)\}$ for different values n. Indeed, under the closed world semantics, the answer $\{(1, 2)\}$ contains *additional* information that no tuple except $(1, 2)$ is present. Thus, returning just $(1, 2)$ in this case makes no sense at all.

The problem with returning the single tuple $(1, 2)$ as the certain answer becomes even more pronounced if we follow the approach, pioneered by (Reiter 1982), that views databases as logical theories and query answering as logical implication. The fact $R(1, 2)$ is certainly implied by the database. But is it the only fact that is implied? Of course not: under the open-world semantics, we can deduce $\exists x\, R(1, 2) \wedge R(3, x)$ with certainty, adding the fact that there is a tuple whose first component is 3. And under the closed world semantics, we know for certain even more, for instance $\exists x \forall y\ (y = 1 \vee y = 2 \vee y = 3 \vee y = x)$, since we cannot expand the database.

Even from this simple example, we learn a few lessons:

- Certain answers can be presented as both objects and logical formulae;
- they depend on both logical languages and semantics used; and
- taking intersection and removing missing values from the answers is not always the right way to compute them.

Note that viewing answers as formulae brings us closer to knowledge bases. The difference though is that while in databases we start with objects and produce objects, and in querying knowledge bases we start with logical theories and produce logical theories, here we may also combine the two, starting with an object, and returning a formula, or a theory, as the result.

The goal of this paper is to develop an alternative framework for handling certain answers to queries. For that, we combine the approaches to viewing databases as objects (Imielinski and Lipski 1984) and as logical theories (Reiter 1982), rather than treat them separately. Specifically, the key elements of our framework are as follows.

- Certain answers can be viewed as either objects or theories, depending on the semantics, and the logical formalism used. The former is in line with the standard database approach, while the latter defines *certain knowledge* about query answers over incomplete databases.
- Both ways are based on extracting certain information from a set of objects. Each way defines certainty as a greatest lower bound: either of a set of objects, or the *theory* of that set of objects, with the ordering meaning "being more informative".
- Proper query answering is based on the notion of *representation systems*: these are a natural relaxation of a rather restrictive concept of what database people call strong representation systems. Representation systems let one define important sets of objects by logical formulae, in the spirit of (Reiter 1982).
- Under the choice of the right semantics for both query inputs and query answers, certain answers – as both objects and knowledge – can be found by straightforward database query evaluation. Thus, with the correct choice of semantics and representation system, we can use *existing* query evaluation techniques for obtaining correct answers in the presence of incomplete information.
- In general, it is easier to find certain answers as knowledge as opposed to certain answers as objects: sometimes the former exists and the latter does not. Thus, representing certain knowledge about query answers is not a mere convenience, it may well be a necessity.

Most of the results in the paper are shown in an abstract setting, for two reasons. First, it makes them applicable to other data models, beyond relational databases (e.g., XML and graph data). Second, it helps us see the essential conditions that need to be imposed on queries and the semantics of incompleteness, without being too "clouded" by details of a particular data model. At the same time we use three common relational semantics – open world, closed world, and weak closed world – to translate general results into concrete examples, to test the approach.

Organization. After presenting basic facts about relational incompleteness in Section 2, we introduce the abstract setting and notions of certainty as objects and knowledge in Section 3. Section 4 defines representation systems and connects knowledge certainty with greatest lower bounds. Section 5 defines certain answers for queries, and Section 6 shows how to compute them. Summary and future work are in Section 7.

2 Background: relational incompleteness

Incomplete databases These have two types of values: *constants* (e.g., $1, 2, \ldots$) and *nulls*. We thus assume countably infinite sets of constants, denoted by Const, and of nulls, denoted by Null. Nulls themselves are denoted by $\bot$, sometimes with sub- or superscripts.

A relational *vocabulary* (often called *schema* in database literature) is a set of relation names with associated arities. An incomplete relational instance D assigns to each k-ary relation symbol R from the vocabulary a k-ary relation R^D over $\mathsf{Const} \cup \mathsf{Null}$, i.e., a finite subset of $(\mathsf{Const} \cup \mathsf{Null})^k$. If the instance D is clear from the context, we may write R instead of R^D. Sets of constants and nulls that occur in D are denoted by $\mathsf{Const}(D)$ and $\mathsf{Null}(D)$. The *active domain* of D is $\mathsf{adom}(D) = \mathsf{Const}(D) \cup \mathsf{Null}(D)$. A *complete* database D has no nulls, i.e., $\mathsf{adom}(D) \subseteq \mathsf{Const}$.

Semantics and valuations A *valuation* of nulls on an incomplete database D is a map $v : \mathsf{Null}(D) \to \mathsf{Const}$ assigning a constant value to each null. It naturally extends to databases, so we can write $v(D)$ as well. The standard semantics of incompleteness in relational databases are defined in terms of valuations, see (Abiteboul, Hull, and Vianu 1995; Imielinski and Lipski 1984). These are the *closed world assumption*, or CWA semantics:

$$[\![D]\!]_{\text{CWA}} = \{v(D) \mid v \text{ is a valuation}\},$$

and the *open-world assumption*, or OWA semantics:

$$[\![D]\!]_{\text{OWA}} = \left\{ D' \;\middle|\; \begin{array}{l} D' \text{ is complete and} \\ v(D) \subseteq D' \text{ for some valuation } v \end{array} \right\}.$$

We shall also consider the *weak* CWA, or WCWA semantics, inspired by (Reiter 1980), given by

$$[\![D]\!]_{\text{WCWA}} = \left\{ v(D) \cup D' \;\middle|\; \begin{array}{l} v \text{ is a valuation and} \\ \text{adom}(D') \subseteq \text{adom}(v(D)) \end{array} \right\}.$$

That is, under CWA, we simply instantiate nulls by constants; under OWA, we can also add arbitrary tuples, and under WCWA, we can only add tuples formed by elements already present. For instance, if $D_0 = \{(\bot, \bot')\}$, then $[\![D]\!]_{\text{CWA}}$ only has instances $\{(c, c')\}$ for $c, c' \in \mathsf{Const}$, while $[\![D]\!]_{\text{WCWA}}$ can have in addition instances that add to (c, c') tuples $(c, c), (c', c')$, and (c', c), and $[\![D]\!]_{\text{OWA}}$ has all instances containing at least one tuple.

Information orderings With an arbitrary semantics $[\![\,]\!]$ of incompleteness, we can associate an *information ordering*

$$D \preceq D' \;\Leftrightarrow\; [\![D']\!] \subseteq [\![D]\!].$$

The meaning is that D' is more informative than D. Indeed, the more possible objects we have in the semantics of an incomplete database, the less we know about it. Note that $\preceq$ is a preorder, i.e., it is reflexive and transitive, but both $D \preceq D'$ and $D' \preceq D$ may be true if $[\![D]\!] = [\![D']\!]$.

We write $\preceq_*$ for the ordering given by $[\![\,]\!]_*$, where $*$ is one of CWA, WCWA, or OWA. These can be described in terms of homomorphisms. Given two relational databases D and D', a homomorphism $h : D \to D'$ is a map from $\text{adom}(D)$ to $\text{adom}(D')$ such that $h(c) = c$ for each constant c, and such that for every relation symbol R and a tuple $\bar{t} \in R^D$, the tuple $h(\bar{t})$ is in $R^{D'}$. The image of the homomorphism is denoted by $h(D)$. A homomorphism is *onto* if $\text{adom}(h(D)) = \text{adom}(D')$, and *strong onto* if $D' = h(D)$.

It is known (Libkin 2011; Gheerbrant, Libkin, and Sirangelo 2013) that $D \preceq_* D'$ iff there exists a

- homomorphism $h : D \to D'$, for $* =$OWA;
- onto homomorphism $h : D \to D'$, for $* =$WCWA;
- strong onto homomorphism $h : D \to D'$, for $* =$CWA.

Classical definition of certain answers Given an incomplete database D, a semantics of incompleteness $[\![\,]\!]$, and a query Q, the standard notion of certain answers under $[\![\,]\!]$ is

$$\mathsf{cert}_\cap(Q, D) = \bigcap \{ Q(R) \mid R \in [\![D]\!] \}.$$

Note that $\mathsf{cert}_\cap(Q, D)$ cannot contain any tuples with nulls.

In some cases, these answers are obtained by almost straightforward query evaluation, namely by evaluating $Q(D)$ and then throwing away the tuples with nulls. We shall denote this by $Q^{\mathsf{C}}(D)$. For instance, if the query Q just returns a relation R, and $R^D = \{(1, 2), (1, \bot)\}$, then both $Q^{\mathsf{C}}(D)$ and $\mathsf{cert}_\cap(Q, D)$ are $\{(1, 2)\}$. In general of course the two need not coincide, as finding certain answers may be computationally very expensive: for instance, undecidable under OWA, or coNP-hard under CWA for first-order queries (Abiteboul, Kanellakis, and Grahne 1991).

Logics Most of database query languages are based on *first-order predicate logic*, or FO, whose formulae are built from relational atoms $R(\bar{x})$, where R is a vocabulary symbol, equational atoms $x = y$, and are closed under Boolean connectives $\wedge, \vee, \neg$ and quantifiers $\exists$ and $\forall$.

The fragment that disallows $\neg$ and $\forall$ (i.e., has $\wedge, \vee, \exists$) is referred to as *existential positive formulae*, denoted by $\exists\mathsf{Pos}$. In terms of their expressiveness, they correspond precisely to *unions of conjunctive queries* (although $\exists\mathsf{Pos}$ formulae can be more compact).

The fragment without negation (i.e., the $\wedge, \vee, \exists, \forall$ fragment) is referred to as *positive formulae*, denoted by Pos.

It is known that $\mathsf{cert}_\cap(Q, D) = Q^{\mathsf{C}}(D)$ for $\exists\mathsf{Pos}$ queries under OWA (Imielinski and Lipski 1984), and for Pos queries under WCWA (Gheerbrant, Libkin, and Sirangelo 2013). There is a fragment for which the equality holds under CWA as well, and it will be given later.

3 Objects and knowledge

The key idea, as explained in the introduction, is to decouple objects and their descriptions in terms of some logical formalisms, i.e., to decouple objects and knowledge about them. We want to do this at the highest level of abstraction, so that the framework would not be limited to just relational databases, but instead would be applicable across multiple data models. For this, we use a very minimalist setting inspired by abstract model theory (Barwise and Feferman 1985) or information systems (Gunter 1992), with some specific features tailored to handle incompleteness, as also used in (Libkin 2011; Gheerbrant, Libkin, and Sirangelo 2013).

We have two basic entities: (database) *objects*, and *formulae* they satisfy. Objects themselves are either incomplete or complete, and each object has its semantics defined as the set of more informative complete objects.

To formalize this, we define a *database pre-domain* as a triple $\mathbb{D}^\circ = \langle \mathcal{D}, \mathcal{C}, [\![\,]\!] \rangle$, where

- $\mathcal{D}$ is a set of database objects (e.g., relational databases over the same schema),
- $\mathcal{C}$ is the set of complete objects (e.g., databases without nulls);
- $[\![\,]\!]$ is a function from $\mathcal{D}$ to subsets of $\mathcal{C}$; the set $[\![x]\!] \subseteq \mathcal{C}$ is the semantics of an incomplete database x.
- We require that for $c \in [\![x]\!]$, two conditions hold: $c \in [\![c]\!]$ and $[\![c]\!] \subseteq [\![x]\!]$.

The last two conditions hold in the standard semantics of incompleteness: they say that a complete object should denote at least itself, and that we have less uncertainty about an object c in the semantics of x than about x itself.

As for relational semantics seen earlier, we have the *information ordering*

$$x \preceq y \;\Leftrightarrow\; [\![y]\!] \subseteq [\![x]\!].$$

Note that $c \in [\![x]\!]$ implies $x \preceq c$, i.e., an incomplete object is less informative than the objects it represents.

A *pre-representation system* is a triple $\mathbb{RS}^\circ = \langle \mathbb{D}^\circ, \mathbb{F}, \models \rangle$, where

- $\mathbb{D}^\circ$ is a pre-domain;

- $\mathbb{F}$ is a set of *formulae*, and
- $\models$ is the satisfaction relation, i.e., a subset of $\mathcal{D} \times \mathbb{F}$ such that $x \preceq y$ and $x \models \varphi$ imply $y \models \varphi$.

The intuition is that formulae in $\mathbb{F}$ express knowledge we possess about objects in $\mathcal{D}$, and if we know something about an object, we also know it about a more informative object.

We shall write $\mathsf{Th}(x)$ for the *theory* of x, i.e., $\{\varphi \mid x \models \varphi\}$ and $\mathsf{Mod}(\varphi)$ for models of φ, i.e., $\{x \mid x \models \varphi\}$. These are extended to sets in the usual way: $\mathsf{Th}(X) = \bigcap_{x \in X} \mathsf{Th}(x)$ and $\mathsf{Mod}(\Phi) = \bigcap_{\varphi \in \Phi} \mathsf{Mod}(\varphi)$.

Note that Mod and Th define a Galois connection between $\mathcal{D}$ and $\mathbb{F}$; in particular $\mathsf{Mod}(\mathsf{Th}(\cdot))$ is a closure operator.

Certain information

Computing certain answers boils down to finding certain information contained in a set of objects; in the case of query answering, in $Q([\![D]\!]) = \{Q(D') \mid D' \in [\![D]\!]\}$. Thus, we need to know how to define certain information contained in a set of objects $X \subseteq \mathcal{D}$. The usual database approach is to represent this information as another object, but of course we argue that it can be viewed as both object and knowledge.

Certain information as object If we want to represent what we know about X with certainty by an object y, this object must be less informative than any object $x \in X$ (as it reflects knowledge contained in all other objects in X as well). If we have two such objects y and y', and $y' \preceq y$, then of course we prefer y as giving us more information.

Thus, the object that we seek must be less informative than all objects in X, and at the same time the most informative among such objects. This is precisely the *greatest lower bound* of X, with respect to $\preceq$ (or $\bigwedge X$, using the standard order-theoretic notation). If it is exists, we denote it by $\Box_{\mathcal{O}} X$.

Certain information as knowledge We want to describe X by a single formula summarizing what we know about it with certainty. If $X = \mathsf{Mod}(\varphi)$, then φ is such a formula, but generally, X need not be of the form $\mathsf{Mod}(\varphi)$.

So we go for the next best thing: we want a formula that is equivalent to the *theory* of X. Of course two sets of formulae are equivalent when they have the same models, so a formula equivalent to the theory of X is a formula φ such that $\mathsf{Mod}(\varphi) = \mathsf{Mod}(\mathsf{Th}(X))$. We denote such a formula by $\Box_{\mathcal{K}} X$.

Thus, certain information contained in X is described as:

- At the object level as $\Box_{\mathcal{O}} X = \bigwedge X$; and
- At the knowledge level as a formula $\Box_{\mathcal{K}} X$ so that $\mathsf{Mod}(\Box_{\mathcal{K}} X) = \mathsf{Mod}(\mathsf{Th}(X))$.

We now make a couple observations about these concepts. First, neither $\Box_{\mathcal{O}} X$ nor $\Box_{\mathcal{K}} X$ need exist in general (in fact it is easy to come up with the examples of preorders without greatest lower bounds).

Second, even if they exist, they are not unique. This is not an issue, however, as they are *equivalent*. Since $\preceq$ is a preorder, the greatest lower bound is, technically speaking, a set of objects, but every two such objects y, y' are equivalent: $y \preceq y'$ and $y' \preceq y$, and thus $[\![y]\!] = [\![y']\!]$. If we have multiple formulae φ for which $\mathsf{Mod}(\varphi) = \mathsf{Mod}(\mathsf{Th}(X))$, then every two such formulae φ, φ' are equivalent: $\mathsf{Mod}(\varphi) = \mathsf{Mod}(\varphi')$. So we shall write $y = \Box_{\mathcal{O}} X$ or $\varphi = \Box_{\mathcal{K}} X$, meaning y or φ is one of the equivalent objects or formulae.

Also note that a rudimentary case of $\Box_{\mathcal{K}} X$ was used in (David, Libkin, and Murlak 2010), which looked at certain answers for XML queries. There, the set $\mathbb{F}$ of formulae was $\mathcal{D}$ itself, and $x \models y$ simply meant $y \preceq x$. Just in that simple case, Theorem 1 below is a consequence of (Libkin 2011).

Example Consider the example from the introduction, of a database D containing $(1, 2)$ and $(3, \bot)$ in a relation R. if $X = [\![D]\!]_{\text{OWA}}$, then $\Box_{\mathcal{O}} X$ is just D itself, as expected. If $\mathbb{F} = \exists\mathsf{Pos}$, then $\Box_{\mathcal{K}} X = \exists z\, R(1, 2) \wedge R(3, z)$. If $\mathbb{F}$ is the set of ground facts and their conjunctions, then $\Box_{\mathcal{K}} X = R(1, 2)$.

If $X = [\![D]\!]_{\text{CWA}}$, then $\bigwedge X$ is still D, but we need a more complex class to describe $\Box_{\mathcal{K}} X$; in fact the two formulae above can easily be shown to violate the definition of $\Box_{\mathcal{K}} X$ in this case. We shall continue with this example in the next section and present a formula $\Box_{\mathcal{K}} X$ under CWA, that comes from a more expressive subclass of FO.

4 Representation systems

So far we imposed no conditions on pre-representation systems. We now define representation systems, which are pre-representation systems with two conditions imposed. These conditions, that hold in the standard semantics of incompleteness, say essentially that the sets of objects and formulae are not too "thin": there are enough complete objects, and there are formulae defining some fairly basic sets of objects.

There are enough objects To motivate this condition, consider a database D with a single tuple $(\bot, \bot)$. In its semantics, we are allowed to replace this tuple by an arbitrary tuple (c, c) with $c \in \mathsf{Const}$. Moreover, the resulting database is isomorphic to the original one: for instance, they agree on logical formulae not mentioning constants. Even if we have a logical formula mentioning constants from a finite set C, we can replace $\bot$ by constants outside this set C: this is what we mean by the existence of enough complete objects. Then D and the result of the replacement will still agree on formulae that only refer to constants in C.

To formalize this, define a *database domain* $\mathbb{D}$ as a tuple $\langle \mathcal{D}, \mathcal{C}, [\![\,]\!], \text{Iso}\rangle$ where $\langle \mathcal{D}, \mathcal{C}, [\![\,]\!]\rangle$ is a pre-domain, and Iso is a family $\{\approx_j\}_{j \in J}$ of equivalence relations on $\mathcal{D}$ so that:

- The set $[\![x]\!]_{\approx_j} = \{c \in [\![x]\!] \mid x \approx_j c\}$ is nonempty for each $x \in \mathcal{D}$ and $j \in J$;
- for every $j, j' \in J$, there is $k \in J$ so that $\approx_k \subseteq \approx_j \cap \approx_{j'}$.

Coming back to the relational intuition, $j \in J$ enumerate finite sets of constants $C_j \subset \mathsf{Const}$, and $D \approx_j D'$ means that there is an isomorphism between D and D' preserving constants in C_j. Then the first condition says that we can replace nulls by constants outside C_j (since $\mathsf{Const} - C_j$ is infinite), and the second one says that $C_k = C_j \cup C_{j'}$ preserves constants in both C_j and $C_{j'}$.

There are enough formulae First, we assume that formulae are closed under conjunction, i.e. for $\varphi, \psi \in \mathbb{F}$ we have $\varphi \wedge \psi \in \mathbb{F}$ with $\mathsf{Mod}(\varphi \wedge \psi) = \mathsf{Mod}(\varphi) \cap \mathsf{Mod}(\psi)$.

The second assumption is that the set $\uparrow x = \{y \mid x \preceq y\}$ of objects more informative than x can be defined by a formula. We shall see shortly that this is true in the classical incompleteness semantics, and that this is equivalent to finite axiomatizability of $\mathsf{Th}(x)$.

Formally the condition states that for each object x, there is a formula δ_x in $\mathbb{F}$, such that $\mathsf{Mod}(\delta_x) = \uparrow x$.

Representation systems A *representation system* is a triple $\mathbb{RS} = \langle \mathbb{D}, \mathbb{F}, \models \rangle$, where:

- $\mathbb{D}$ is a database domain and $\langle \mathbb{D}, \mathbb{F}, \models \rangle$ is a pre-representation system whose formulae are closed under conjunction;
- for each $x \in \mathcal{D}$, there is a formula δ_x with $\mathsf{Mod}(\delta_x) = \uparrow x$;
- for each $\varphi \in \mathbb{F}$, there is $j \in J$ so that $x \models \varphi \Leftrightarrow y \models \varphi$ whenever $x \approx_j y$.

The last condition is essentially the analog of the condition that a formula can only refer to finitely many constants, and thus cannot distinguish objects equivalent with respect to $\approx_j$ for some j.

Examples of domains and representation systems

We now provide examples of representation systems corresponding to relational OWA, WCWA, and CWA semantics. We use the notation $\mathcal{D}(\sigma)$ for the set of all relational databases of vocabulary σ over $\mathsf{Const} \cup \mathsf{Null}$, and $\mathcal{C}(\sigma)$ for the set of all such databases that do not use nulls in Null. The database domains will be of the form $\mathbb{D}_*(\sigma) = \langle \mathcal{D}(\sigma), \mathcal{C}(\sigma), [\![\,]\!]_*, \mathrm{Iso} \rangle$, where $*$ is one of OWA, WCWA, or CWA.

The equivalence relations Iso are as follows. Let J enumerate all the finite subsets of Const. Given such a finite set C, we have $D \approx_C D'$ if there is an isomorphism $f : D \to D'$ such that both f and f^{-1} are identity on C.

In what follows, we describe formulae $\mathbb{F}$ and formulae δ_D for each D. Let $\mathrm{PosDiag}(D)$ be the positive diagram of D in the vocabulary including constants for each $a \in \mathsf{Const}$, where with each null $\bot_i$ in D we associate a variable x_i. For instance, if D contains relation R with tuples $(1,2), (2,\bot_1), (\bot_1,\bot_2)$, then $\mathrm{PosDiag}(D) = R(1,2) \wedge R(2,x_1) \wedge R(x_1,x_2)$.

OWA The OWA representation system is $\mathbb{RS}_{\mathrm{OWA}}(\sigma) = \langle \mathbb{D}_{\mathrm{OWA}}(\sigma), \exists\mathsf{Pos}, \models \rangle$. For each D with $\mathsf{Null}(D) = \{\bot_1, \ldots, \bot_n\}$, we have $\delta_D = \exists x_1, \ldots, x_n\ \mathrm{PosDiag}(D)$.

WCWA The WCWA representation system is $\mathbb{RS}_{\mathrm{WCWA}}(\sigma) = \langle \mathbb{D}_{\mathrm{WCWA}}(\sigma), \mathsf{Pos}, \models \rangle$. For each D with $\mathsf{Const}(D) = \{a_1, \ldots, a_m\}$ and $\mathsf{Null}(D) = \{\bot_1, \ldots, \bot_n\}$, the formula δ_D is

$$\exists x_1 \ldots x_n \big(\mathrm{PosDiag}(D) \wedge \forall y\, (\bigvee_{i=1}^{m} y = a_i \ \vee \ \bigvee_{i=1}^{n} y = x_i)\big)$$

CWA We need to define an extension of the class of positive formulae, introduced by (Compton 1983) and used recently in (Gheerbrant, Libkin, and Sirangelo 2013). The class, denoted by $\mathsf{Pos}^{\forall \mathsf{G}}$, extends Pos with a special type of guarded formulae. It is defined as the closure of positive atoms of the form $R(\bar{x})$ and $x = y$ under $\wedge, \vee, \forall, \exists$ and the following rule: if $\varphi(\bar{x}, \bar{y})$ is a $\mathsf{Pos}^{\forall \mathsf{G}}$ formula in which all variables in $\bar{x}$ are distinct, and R is a relation symbol of the arity $|\bar{x}|$, then $\forall \bar{x}\ (R(\bar{x}) \to \varphi(\bar{x}, \bar{y}))$ is a $\mathsf{Pos}^{\forall \mathsf{G}}$ formula.

With this, the CWA representation system is defined as $\mathbb{RS}_{\mathrm{OWA}}(\sigma) = \langle \mathbb{D}_{\mathrm{CWA}}(\sigma), \mathsf{Pos}^{\forall \mathsf{G}}, \models \rangle$. For each D with $\mathsf{Null}(D) = \{\bot_1, \ldots, \bot_n\}$, the formula δ_D is

$$\exists x_1, \ldots, x_n \Big(\mathrm{PosDiag}(D) \wedge \bigwedge_{R \in \sigma} \forall \bar{y}\, \big(R(\bar{y}) \to \bigvee_{\bar{t} \in R^D} \bar{y} = \bar{t}\big)\Big),$$

where the length of $\bar{y}$ and $\bar{t}$ is the arity of R, and $\bar{y} = \bar{t}$ means $\bigwedge_{i \le \mathrm{arity}(R)} (y_i = t_i)$.

Proposition 1 *Each of $\mathbb{RS}_{\mathrm{OWA}}(\sigma)$, $\mathbb{RS}_{\mathrm{WCWA}}(\sigma)$, and $\mathbb{RS}_{\mathrm{CWA}}(\sigma)$ is a representation system.*

Proof sketch. Conditions on Iso are easily checked: sets $[\![D]\!]_C$ are nonempty, since one can replace nulls with distinct constants from $\mathsf{Const} - C$, and $\approx_{C \cup C'} \subseteq \approx_C \cap \approx_{C'}$. Monotonicity follows from the description of orderings $\preceq_*$ by the existence of homomorphisms (see Section 2) and the fact that $\exists\mathsf{Pos}$ (resp., Pos and $\mathsf{Pos}^{\forall \mathsf{G}}$) formulae are preserved under homomorphisms (resp., onto and strong onto), see (Rossman 2008; Chang and Keisler 1990; Compton 1983). And the properties of δ_D again follow from the properties of the ordering, as one can easily check that $\mathsf{Mod}(\delta_D)$ are the structures into which there is a homomorphism (resp., onto or strong onto homomorphism) from D. □

Properties of representation systems

We now collect some useful properties of representation systems. First, we look at certain information contained in sets $[\![x]\!]$ and prove that, as expected, it is represented at the object level by x, and at the knowledge level by δ_x.

Proposition 2 *In a pre-domain, $\Box_{\mathcal{O}}[\![x]\!] = x$ for every x.*

Proof. Assume that $x \neq \bigwedge [\![x]\!]$. Then there is $y \not\preceq x$ such that $y \preceq c$ for each $c \in [\![x]\!]$. Since $y \not\preceq x$ we have $[\![x]\!] \not\subseteq [\![y]\!]$, i.e., there is $c \in [\![x]\!]$ such that $c \notin [\![y]\!]$. But since $y \preceq c$, we have $[\![c]\!] \subseteq [\![y]\!]$, and since $c \in \mathcal{C}$, this implies $c \in [\![y]\!]$ as $c \in [\![c]\!]$, which gives us the desired contradiction. □

Let $\approx = \bigcup_{j \in J} \approx_j$, and let $[\![x]\!]_{\approx} = \{c \in [\![x]\!] \mid c \approx x\}$. In case of relational databases, $D \approx D'$ if D, D' are isomorphic objects; for instance, $D = \{(\bot, \bot)\}$ and $D' = \{(1,1)\}$ are isomorphic. Note that FO formulae not using constants are preserved by $\approx$. In general though, objects related by $\approx_j$ may not agree on all the formulae of $\mathbb{F}$ (e.g., D and D' do not agree on $\exists x\ (x = 1)$) and hence there are potentially formulae in $\mathsf{Th}([\![x]\!]_{\approx_j})$ which are not satisfied by x. However,

Proposition 3 *In a representation system, $\mathsf{Th}([\![x]\!]) = \mathsf{Th}([\![x]\!]_{\approx}) = \mathsf{Th}(x)$ for every x.*

Proof. It suffices to prove $\mathsf{Th}([\![x]\!]_{\approx}) = \mathsf{Th}(x)$ since $\mathsf{Th}(x) \subseteq \mathsf{Th}([\![x]\!]) \subseteq \mathsf{Th}([\![x]\!]_{\approx})$. Let $c \in [\![x]\!]_{\approx}$; then $x \preceq c$ and thus $\mathsf{Th}(x) \subseteq \mathsf{Th}(c)$, and hence $\mathsf{Th}(x) \subseteq \mathsf{Th}([\![x]\!]_{\approx})$. Conversely, take $\varphi \in \mathsf{Th}([\![x]\!]_{\approx})$. We know that there is $j \in J$ so that whenever $y \approx_j y'$, then y, y' agree on φ. Note that $\varphi \in \mathsf{Th}([\![x]\!]_{\approx_j})$, since $[\![x]\!]_{\approx_j} \subseteq [\![x]\!]_{\approx}$. We know that $[\![x]\!]_{\approx_j} \neq \emptyset$, so pick $c \in [\![x]\!]_{\approx_j}$. Since $\varphi \in \mathsf{Th}([\![x]\!]_{\approx_j})$, we have $c \models \varphi$, and since $c \approx_j x$, we have $x \models \varphi$. Hence $\varphi \in \mathsf{Th}(x)$, as required. □

Now we can show:

Proposition 4 *In a representation system, $\delta_x = \Box_{\mathcal{K}}[\![x]\!]$ for every x.*

Proof. We first show that $\mathsf{Mod}(\mathsf{Th}(x)) = \uparrow x$. Let $y \succeq x$. By monotonicity we have $y \in \mathsf{Mod}(\mathsf{Th}(x))$. Conversely let $y \not\succeq x$; then $\delta_x \in \mathsf{Th}(x) - \mathsf{Th}(y)$ and hence $y \notin \mathsf{Mod}(\mathsf{Th}(x))$. Thus indeed $\mathsf{Mod}(\mathsf{Th}(x)) = \uparrow x$. Since $\uparrow x = \mathsf{Mod}(\delta_x)$ and $\mathsf{Mod}(\mathsf{Th}(x)) = \mathsf{Mod}(\mathsf{Th}([\![x]\!]))$ by Proposition 3, we have $\mathsf{Mod}(\delta_x) = \mathsf{Mod}(\mathsf{Th}([\![x]\!]))$, i.e., $\delta_x = \Box_{\mathcal{K}}[\![x]\!]$. □

Corollary 1 *In a representation system:*

- $\mathsf{Mod}(\delta_x) = \mathsf{Mod}(\mathsf{Th}(x))$, *and*
- $\Box_{\mathcal{O}}[\![x]\!] \models \Box_{\mathcal{K}}[\![x]\!]$

for every x.

We finally give a condition equivalent to the existence of formulae δ_x. A set Φ of formulae is *finitely axiomatizable* if there is a finite set Φ_0 such that $\mathsf{Mod}(\Phi) = \mathsf{Mod}(\Phi_0)$.

Proposition 5 *In a pre-representation system $\mathbb{RS}^{\circ}$ whose formulae are closed under conjunction, the following are equivalent:*

1. *Each $\mathsf{Th}(x)$ is finitely axiomatizable, and $\mathsf{Th}(x) \subseteq \mathsf{Th}(y)$ implies $x \preceq y$ for all x, y;*
2. *for each x, there is a formula δ_x so that $\mathsf{Mod}(\delta_x) = \uparrow x$.*

Proof sketch. If Φ is a finite axiomatization of $\mathsf{Th}(x)$, it is easy to see that δ_x can be taken to be $\bigwedge\{\varphi \mid \varphi \in \Phi\}$. Conversely, one shows that δ_x axiomatizes $\mathsf{Th}(x)$. □

$\Box_{\mathcal{K}}$ as a greatest lower bound

We now show that $\Box_{\mathcal{K}}X$ can be viewed as a greatest lower bound as well. Note that we have a well-known preorder on sets of formulae, namely implication: $\Phi \vdash \Psi$ iff $\mathsf{Mod}(\Phi) \subseteq \mathsf{Mod}(\Psi)$. Thus, for any set of formulae Φ, we can look at its greatest lower bound in this preorder, i.e., a formula φ so that $\varphi \vdash \Phi$, and whenever $\psi \vdash \Phi$, we have $\psi \vdash \varphi$. If such a formula exists, it is denoted by $\bigwedge \Phi$. Note that as with objects, $\vdash$ is a preorder, so technically $\bigwedge \Phi$ is a set of formulae, all of which, however, are equivalent, so we shall write $\varphi = \bigwedge \Phi$ when φ is one of such formulae.

Theorem 1 *In a representation system, $\Box_{\mathcal{K}}X = \bigwedge \mathsf{Th}(X)$ for every set X of objects.*

Proof. Assume that $\alpha = \bigwedge \mathsf{Th}(X)$ exists. We have $\mathsf{Mod}(\alpha) \subseteq \mathsf{Mod}(\varphi)$ for each $\varphi \in \mathsf{Th}(X)$ and thus $\mathsf{Mod}(\alpha) \subseteq \mathsf{Mod}(\mathsf{Th}(X))$. Suppose, for the sake of contradiction, that $\mathsf{Mod}(\alpha) \subsetneq \mathsf{Mod}(\mathsf{Th}(X))$, and take $y \in \mathsf{Mod}(\mathsf{Th}(X)) - \mathsf{Mod}(\alpha)$. Since $y \models \varphi$ for each $\varphi \in \mathsf{Th}(X)$, we have that the same is true for every $z \succeq y$, and hence $\mathsf{Mod}(\delta_y) \subseteq \mathsf{Mod}(\varphi)$ for each $\varphi \in \mathsf{Th}(X)$. Thus $\delta_y \vdash \mathsf{Th}(X)$, and by the definition of α as the greatest lower bound, we have $\delta_y \vdash \alpha$, and thus $\mathsf{Mod}(\delta_y) \subseteq \mathsf{Mod}(\alpha)$.

Now assume $\mathsf{Mod}(\alpha) \subseteq \mathsf{Mod}(\delta_y)$. Then $\mathsf{Mod}(\alpha) = \mathsf{Mod}(\delta_y)$ and $y \in \mathsf{Mod}(\alpha)$, a contradiction. Hence, $\mathsf{Mod}(\alpha) \not\subseteq \mathsf{Mod}(\delta_y)$. But then $\mathsf{Mod}(\delta_y) \not\subseteq \mathsf{Mod}(\alpha)$ since $y \not\models \alpha$, and at the same time $\mathsf{Mod}(\delta_y) \subseteq \mathsf{Mod}(\mathsf{Th}(X))$ since $y \in \mathsf{Mod}(\mathsf{Th}(X))$. Thus sets $\mathsf{Mod}(\delta_y)$ and $\mathsf{Mod}(\alpha)$ are incomparable subsets of $\mathsf{Mod}(\mathsf{Th}(X))$: in particular, $\alpha \vdash \mathsf{Th}(X)$, $\delta_y \vdash \mathsf{Th}(X)$, and yet neither $\alpha \vdash \delta_y$ nor $\delta_y \vdash \alpha$ holds, contradicting the assumption that $\alpha = \bigwedge \mathsf{Th}(X)$. This shows that $\mathsf{Mod}(\mathsf{Th}(X)) - \mathsf{Mod}(\alpha) = \emptyset$ and thus $\mathsf{Mod}(\alpha) = \mathsf{Mod}(\mathsf{Th}(X))$.

Conversely, suppose we have α so that $\mathsf{Mod}(\alpha) = \mathsf{Mod}(\mathsf{Th}(X)) = \bigcap_{\varphi \in \mathsf{Th}(X)} \mathsf{Mod}(\varphi)$. Then $\mathsf{Mod}(\alpha) \subseteq \mathsf{Mod}(\varphi)$ for each $\varphi \in \mathsf{Th}(X)$ and thus $\alpha \vdash \varphi$ for each such φ. If there is any other formula ψ such that $\psi \vdash \varphi$ for each $\varphi \in \mathsf{Th}(X)$, then $\mathsf{Mod}(\psi) \subseteq \bigcap_{\varphi \in \mathsf{Th}(X)} \mathsf{Mod}(\varphi) = \mathsf{Mod}(\alpha)$ and thus $\psi \vdash \alpha$, proving that $\alpha = \bigwedge \mathsf{Th}(X)$. □

5 Defining certain answers to queries

Now we move to answering queries. A query is a mapping Q that takes an object and returns another object. For instance, relational queries take relational databases and return relational databases (most commonly, single relations: queries in FO, or in commercial languages such as SQL, are such).

Thus, for two database domains $\mathbb{D} = \langle \mathcal{D}, \mathcal{C}, [\![\,]\!], \mathrm{Iso} \rangle$ and $\mathbb{D}' = \langle \mathcal{D}', \mathcal{C}', [\![\,]\!]', \mathrm{Iso}' \rangle$, a *query* $Q : \mathbb{D} \to \mathbb{D}'$ is a mapping associating with an object $x \in \mathcal{D}$ its answer, $Q(x) \in \mathcal{D}'$.

We require that if $x \preceq y$ then $Q(x) \preceq' Q(y)$, where $\preceq'$ is the ordering associated with the semantics $[\![\,]\!]'$. Indeed, the semantics of answers must be such that if we know more about the input, then we know more about the output. In particular, using blindly the same semantics for both databases and query results (as is often actually done) does not necessarily make sense.

Certain answers to Q on an object x represent certain information in the set $Q([\![x]\!]) = \{Q(c) \mid c \in [\![x]\!]\}$. We have seen that there are two ways to define it: as object, and as knowledge. For the letter, we need to have a representation system $\mathbb{RS} = \langle \mathbb{D}', \mathbb{F}, \models \rangle$ over the target domain $\mathbb{D}'$. If we have it, we can either extract the most general object representing $Q([\![x]\!])$, or the most general knowledge representing $\mathsf{Th}(Q([\![x]\!]))$. That is, we have two certain answers notions, as objects and as knowledge:

- As objects: $\mathsf{cert}_{\mathcal{O}}(Q, x) = \Box_{\mathcal{O}} Q([\![x]\!])$;
- As knowledge: $\mathsf{cert}_{\mathcal{K}}(Q, x) = \Box_{\mathcal{K}} Q([\![x]\!])$.

Comparing with relational theory Let us now review the standard approach to query answering in relational databases. Ideally, one tries to find a query answer A so that $[\![A]\!]' = Q([\![D]\!])$. This is often impossible, in fact even for very simple queries (Imielinski and Lipski 1984). So the next attempt is to find a formula $\varphi_{Q,D}$ in some logical formalism so that

$$\mathsf{Mod}(\varphi_{Q,D}) = Q([\![D]\!]) \tag{1}$$

When this happens, one refers to such a logical formalism as a *strong representation system* (see (Abiteboul, Hull, and Vianu 1995; Imielinski and Lipski 1984)), which explains why we used the name 'representation system'.

The problem is that the structure of $Q(\llbracket D \rrbracket)$ may be too "irregular" to be described by a nice formalism. For instance, it is known that under CWA, for relational calculus queries formulae $\varphi_{Q,D}$ can be of the following form: $\exists \bar{u}\ (\alpha(\bar{u}) \wedge \bigwedge_{R \in \sigma} \forall \bar{x}\ (R(\bar{x}) \leftrightarrow \bigvee_i (\bar{x} = \bar{v}_i \wedge \beta_i(\bar{x}, \bar{u}))))$, where α and β_i are boolean combinations of equalities, $\bar{v}_i$s combine variables from $\bar{u}$ and constants, and $\bar{u}$ ranges over the underlying domain of constants rather than the active domain, see (Imielinski and Lipski 1984). Syntactically, this is quite heavy, and it works only under the CWA.

If the set $Q(\llbracket D \rrbracket)$ does not happen to be of the form $\mathsf{Mod}(\varphi)$ for some nice formula φ, the approach adopted in the database literature is to consider the object $\bigcap Q(\llbracket D \rrbracket)$ as the answer. This is completely ad hoc, however: as we have seen in the Introduction (and as we shall see in the next section), in general it does not have much in common with certain information contained in $Q(\llbracket D \rrbracket)$.

It seems much better to ask then, in place of (1), for an answer $\varphi_{Q,D}$ that is *equivalent to the theory* of $Q(\llbracket D \rrbracket)$, rather than defining $Q(\llbracket D \rrbracket)$ precisely. That is, we replace (1) with

$$\mathsf{Mod}(\varphi_{Q,D}) \ = \ \mathsf{Mod}(\mathsf{Th}(Q(\llbracket D \rrbracket))) \tag{2}$$

which is, of course, our definition of certain answers expressed as knowledge.

Note that (1) implies (2): this is an immediate consequence of the fact that $\mathsf{Mod}(\cdot)$ and $\mathsf{Th}(\cdot)$ define a Galois connection. Thus, the notion of certain answers as knowledge in a representation system is a weakening of the notion of the strong representation system, but much less ad hoc that replacing $Q(\llbracket D \rrbracket)$ with $\bigcap Q(\llbracket D \rrbracket)$.

Example: when representation system makes a difference We can easily construct examples of relational queries Q and representation systems so that (1) fails while (2) is easily achieved. Suppose we have a schema with two relations R, S (for simplicity, just sets), and the query $R - S$ (in FO, $R(x) \wedge \neg S(x)$), and assume closed-world semantics. Consider D in which $R = \{1, 2\}$ and $S = \{\bot\}$. Then $Q(\llbracket D \rrbracket_{\text{CWA}}) = \{\{1\}, \{2\}, \{1, 2\}\}$. Suppose the representation system is $\langle \mathbb{D}(\sigma), \exists\mathsf{Pos}, \models \rangle$. Then there is no α with $\mathsf{Mod}(\alpha) = Q(\llbracket D \rrbracket_{\text{CWA}})$ but there is one such that $\mathsf{Mod}(\alpha) = \mathsf{Mod}(\mathsf{Th}(Q(\llbracket D \rrbracket_{\text{CWA}})))$; in fact, the obvious answer $\alpha = A(1) \vee A(2)$ does the job.

6 Computing certain answers

We now look at computing certain answers. We show that with the proper semantics of query answering, where more informative inputs lead to more informative answers, finding certain answers is reduced to query evaluation:

(a) for objects, $\mathsf{cert}_{\mathcal{O}}(Q, x) = Q(x)$;

(b) for knowledge, $\mathsf{cert}_{\mathcal{K}}(Q, x) = \delta_{Q(x)}$.

Crucially, (a) is a corollary of (b): without a representation system for query answers, (a) may not be true. We explain how these general results apply to relational OWA, WCWA, and CWA semantics. We also revisit the intersection-based definition of certain answers and show that it only makes sense with restricted representation systems under OWA, and is just plain wrong under CWA. Finally, we show that the knowledge approach to certain answers gives us extra flexibility compared to the object approach.

Recall that queries are required to be monotone: $x \preceq y$ implies $Q(x) \preceq' Q(y)$. We need an additional condition of *genericity*, standard in the database context (see, e.g., (Abiteboul, Hull, and Vianu 1995)). In our abstract framework it is expressed as follows: for every j, there is k so that $x \approx_k y$ implies $Q(x) \approx'_j Q(y)$. Essentially, this condition says that queries applied to isomorphic objects return isomorphic objects. For instance, for FO queries that do not refer to constants, it is usually formulated as $D \approx D' \Rightarrow Q(D) \approx Q(D')$. We use a slightly more refined version that, in the case of logically expressed queries, accounts for constants by using multiple equivalence relations. All queries expressed in FO and other logics over the vocabulary of relation symbols and constants are generic in the standard database domains for relational databases.

Theorem 2 *Let $Q : \mathbb{D} \to \mathbb{D}'$ be a monotone generic query, and let $\mathbb{RS} = \langle \mathbb{D}', \mathbb{F}, \models \rangle$ be a representation system. Then, for every object x,*

- $\mathsf{cert}_{\mathcal{O}}(Q, x) = Q(x)$, *and*
- $\mathsf{cert}_{\mathcal{K}}(Q, x) = \delta_{Q(x)}$.

Proof. We start by showing $\mathsf{cert}_{\mathcal{K}}(Q, x) = \delta_{Q(x)}$. By the definition of $\mathsf{cert}_{\mathcal{K}}(Q, x)$ as $\Box_{\mathcal{K}} Q(\llbracket x \rrbracket)$, it suffices to show that

$$\mathsf{Mod}(\delta_{Q(x)}) \ = \ \mathsf{Mod}(\mathsf{Th}(Q(\llbracket x \rrbracket))) \tag{3}$$

for every x. Since we know that $\mathsf{Mod}(\delta_z) = \mathsf{Mod}(\mathsf{Th}(z))$, for every z, by Corollary 1, we just need to show

$$\mathsf{Th}(Q(\llbracket x \rrbracket)) \ = \ \mathsf{Th}(Q(x)) \tag{4}$$

to conclude (3). Suppose $\varphi \in \mathsf{Th}(Q(x))$. Since $c \succeq x$ for every $c \in \llbracket x \rrbracket$, then $Q(x) \preceq' Q(c)$ and $Q(c)$ satisfies φ as well by the properties of representation systems, proving that $\varphi \in \mathsf{Th}(Q(\llbracket x \rrbracket))$.

Conversely, if $\varphi \in \mathsf{Th}(Q(\llbracket x \rrbracket))$, consider j such that $z \approx'_j z'$ implies that z, z' agree on φ for every z, z' (which exists by the definition of representation systems). By genericity, we have k so that $y \approx_k y'$ implies $Q(y) \approx'_j Q(y')$ for every y, y'. We know that $\llbracket x \rrbracket_{\approx_k}$ is nonempty; this pick an element c in this set. We have $c \in \llbracket x \rrbracket$ and $c \approx_k x$. Hence (a) $Q(c) \in Q(\llbracket x \rrbracket)$ and (b) $Q(c) \approx'_j Q(x)$. Then (a) implies that $Q(c) \models \varphi$, and (b) then implies that $Q(x) \models \varphi$, thus showing that $\varphi \in \mathsf{Th}(Q(x))$ and proving (4) and (3).

Now we prove the result about certain answers at the object level. Since Q is monotone, we have $Q(x) \preceq' z$ for each $z \in Q(\llbracket x \rrbracket)$ (we denote this by $Q(x) \preceq' Q(\llbracket x \rrbracket)$. Suppose we have $y \preceq' Q(\llbracket x \rrbracket)$. Then $\mathsf{Th}(y) \subseteq \mathsf{Th}(Q(\llbracket x \rrbracket))$ and by (4), $\mathsf{Th}(y) \subseteq \mathsf{Th}(Q(x))$. Since $\delta_y \in \mathsf{Th}(y)$, we have $\delta_y \in \mathsf{Th}(Q(x))$, and thus $Q(x) \models \delta_y$ and $y \preceq' Q(x)$. Thus, $Q(x)$ is the greatest lower bound of $Q(\llbracket x \rrbracket)$, i.e., $Q(x) = \mathsf{cert}_{\mathcal{O}}(Q, x)$. □

Remark It is easy to construct examples of monotone queries for which, in the absence of a representation system over query answers, $\mathsf{cert}_{\mathcal{O}}(Q,x) \neq Q(x)$. Thus, it is essential to go via certain answer as knowledge to get its object representation as well.

The following easy observation shows that classes of queries for which certain answers can be computed by directly evaluating the query are closed under composition, giving us a way of producing more complex queries that behave well with respect to certain answer computation.

Proposition 6 *If $Q : \mathbb{D} \to \mathbb{D}'$ and $Q' : \mathbb{D}' \to \mathbb{D}''$ are monotone and generic, then so is $Q' \circ Q : \mathbb{D} \to \mathbb{D}''$.*

Genericity applies to most of the logical formalisms used for querying databases, but not all: formalisms capable of referring to infinitely many constants would not fall into that category. Examples of such formalisms occur, for instance, in data exchange, where one deals with logics that use the predicate $const(\cdot)$ to distinguish constants from nulls, see (Arenas, Barceló, and Reutter 2009; Fagin 2007).

There is another condition we can use in place of genericity, namely a substitution property with respect to two representation systems $\mathbb{RS} = \langle \mathbb{D}, \mathbb{F}, \models \rangle$ and $\mathbb{RS}' = \langle \mathbb{D}', \mathbb{F}', \models' \rangle$. We say that a query Q has the *substitution property* with respect to $\mathbb{RS}$ and $\mathbb{RS}'$ if for each $\varphi \in \mathbb{F}'$, there exists $\varphi_Q \in \mathbb{F}$ so that $x \models \varphi_Q$ iff $Q(x) \models \varphi$. Intuitively, we can think of both φ and Q given as logical formulae, and allow Q to be substituted for predicate symbols used in φ.

Theorem 3 *Let $Q : \mathbb{D} \to \mathbb{D}'$ be a monotone query, and assume we have representation systems $\mathbb{RS}$ and $\mathbb{RS}'$ so that Q has the substitution property with respect to them. Then, for every object x,*

- $\mathsf{cert}_{\mathcal{O}}(Q,x) = Q(x)$*, and*
- $\mathsf{cert}_{\mathcal{K}}(Q,x) = \delta_{Q(x)}$.

Proof. We just need to prove (4) and then the proof of Theorem 2 will apply. The $\mathsf{Th}(Q(x)) \subseteq \mathsf{Th}(Q([\![x]\!]))$ inclusion is proved as before. For the converse, let φ be in $\mathsf{Th}(Q([\![x]\!]))$; take φ_Q that exists by the substitution property. Since $Q(c) \models \varphi$ for each $c \in [\![x]\!]$, we have $c \models \varphi_Q$, and thus $\varphi_Q \in \mathsf{Th}([\![x]\!])$. But we know by Proposition 3 that $\mathsf{Th}([\![x]\!]) = \mathsf{Th}(x)$ and hence $\varphi_Q \in \mathsf{Th}(x)$. But now the substitution property and $x \models \varphi_Q$ imply $Q(x) \models \varphi$, showing $\varphi \in \mathsf{Th}(Q(x))$ and proving the reverse inclusion. □

Certain answers for relational queries

We now look at examples of concrete domains and representation systems for relational databases. The domains are always $\mathbb{D}_*(\sigma)$, containing databases of vocabulary σ, with $*$ being the semantics. If a query Q returns sets of m-ary tuples, the domain $\mathbb{D}'$ will have as objects databases of vocabulary σ_m that contains a single m-ary relation $A(\cdot)$. But what will the semantics be? A natural thing to do is to assume the same semantics for query answers and input data. But will this guarantee conditions that let us apply results of the previous section?

It turns out that for classes of queries given by the same first-order formulae we use in representation systems $\mathbb{RS}_*$, we have all the required conditions.

Proposition 7 *Consider an m-ary relational query $Q : \mathbb{D}_*(\sigma) \to \mathbb{D}_*(\sigma_m)$. Then Q is monotone*

- *for $* = $*OWA*: when Q is an $\exists\mathsf{Pos}$ query;*
- *for $* = $*WCWA*: when Q is an Pos query;*
- *for $* = $*CWA*: when Q is an $\mathsf{Pos}^{\forall\mathsf{G}}$ query.*

Moreover, for $*$ being OWA *or* WCWA*, each such Q has the substitution property with respect to $\mathbb{RS}_*(\sigma)$ and $\mathbb{RS}_*(\sigma_m)$.*

Proof. It is very similar to the proof of Proposition 1, as it follows from the preservation properties of the classes of formulae we use. The second property is by a simple inspection of the syntactic structure of the formulae. □

Corollary 2 *Let Q be an m-ary relational query. Under the* OWA*,* WCWA*, and* CWA *semantics, if Q comes from $\exists\mathsf{Pos}$, Pos, or $\mathsf{Pos}^{\forall\mathsf{G}}$ respectively, then $\mathsf{cert}_{\mathcal{O}}(Q,D) = Q(D)$ and $\mathsf{cert}_{\mathcal{K}}(Q,D) = \delta_{Q(D)}$ for every database D (with δ coming from $\mathbb{RS}_*(\sigma_m)$, when $*$ is* OWA*,* WCWA*, or* CWA*).*

Returning to the first example from the introduction, assume that our query just returns a relation R itself, and $R = \{(1,2),(3,\bot)\}$. Then, at the object level, $\mathsf{cert}_{\mathcal{O}}(Q,R) = R$ for all three semantics. Certain answers as knowledge, or $\mathsf{cert}_{\mathcal{K}}(Q,R)$ are given:

- under OWA, by the $\exists\mathsf{Pos}$ formula $\exists x \big(R(1,2) \wedge R(3,x)\big)$;
- under WCWA, by the Pos formula

$$\exists x \left(R(1,2) \wedge R(3,x) \ \wedge \ \forall y \ \left(\begin{array}{l} y = 1 \vee y = 2 \\ \vee \ \ y = 3 \vee y = x \end{array} \right) \right);$$

- and under CWA, by the $\mathsf{Pos}^{\forall\mathsf{G}}$ formula

$$\exists x \left(\begin{array}{l} R(1,2) \wedge R(3,x) \\ \wedge \ \ \forall y,z \ \left(R(y,z) \rightarrow \ \begin{array}{l} (y = 1 \wedge z = 2) \\ \vee \ \ (y = 3 \wedge z = x) \end{array} \right) \end{array} \right)$$

No intersection for certain answers

Now we return to the "classical" of defining certain answers which involves throwing away tuples with nulls and computing intersection, and give more evidence to the fact that this practice does not really work, outside a fairly restrictive representation system under the OWA. As already mentioned in the preliminaries section, for the classes of queries listed in Proposition 7, the well-known equivalences say that $\mathsf{cert}_{\cap}(Q,D)$ is the same $Q^{\mathsf{C}}(D)$, which is $Q(D)$ from which tuples of nulls have been eliminated. We can also view this as a composition of two mappings: Q^{C} is $\pi^{\mathsf{C}} \circ Q$, where π^{C} simply keeps all tuples that only use constants.

The condition that we need on π^{C}, and on Q^{C}, is monotonicity. However, these are not guaranteed in general.

Proposition 8 *The mapping π^{C} is monotone with respect to the ordering $\preceq_{\text{OWA}}$ but it is* not *monotone with respect to $\preceq_{\text{CWA}}$ and $\preceq_{\text{WCWA}}$.*

In fact there are $\exists\mathsf{Pos}$ queries Q such that Q^{C} is not monotone with respect to $\preceq_{\text{CWA}}$ and $\preceq_{\text{WCWA}}$.

Proof. Since there is the identity homomorphism from any substructure to the structure, we have monotonicity under $\preceq_{\text{OWA}}$. For closed world semantics, simply take $R = \{(1,2),(2,\bot)\}$. Then $\pi^{\mathsf{C}}(R) = R^{\mathsf{C}} = \{(1,2)\}$ and $R \not\preceq_{\text{CWA}} R^{\mathsf{C}}$ nor $R \not\preceq_{\text{WCWA}} R^{\mathsf{C}}$. Thus the $\exists\mathsf{Pos}$ query can be taken to be the query returning relation R. □

The consequences of this under WCWA and CWA are twofold. We may easily have situations such that:

- $Q^{\mathsf{C}}(D) \not\preceq \mathsf{cert}_{\mathcal{O}}(Q, D)$, and
- $\mathsf{cert}_{\mathcal{K}}(Q, D)$ does not logically imply $\delta_{Q^{\mathsf{C}}(D)}$.

In other words, such constant 'certain answer' need not represent certain information in $Q([\![D]\!])$, and thus may contain some false positives. This is also true for certain answers defined as intersection because in the example used in Proposition 8, we have $Q^{\mathsf{C}}(D) = \bigcap\{Q(D') \mid D' \in [\![D]\!]\}$ under both WCWA and CWA semantics.

Thus, the use of the intersection operator is indeed very problematic under WCWA and CWA. In fact this should not come as a surprise at all, even if we deal with query answering at the object level. The $\bigcap$ operator is a greatest lower bound for the $\subseteq$ ordering, and $\subseteq$ results in a more informative instance only under OWA, but not under closed-world assumptions! Thus, choosing $\bigcap$ to define certain answers for all semantics was a completely ad hoc choice.

OWA: when intersection still makes sense We now look at OWA, the only case where the mapping π^{C} is monotone, and where intersection corresponds to the greatest lower bound in an ordering compatible with the semantics.

Given a database domain $\mathbb{D} = \langle \mathcal{D}, \mathcal{C}, [\![\,]\!], \text{Iso}\rangle$, let $\mathbb{D}^{\mathsf{C}}$ be its restriction to complete objects, i.e., $\mathbb{D}^{\mathsf{C}} = \langle \mathcal{C}, \mathcal{C}, [\![\,]\!], \text{Iso}\rangle$. It is easy to check that this is still a database domain.

Let $\mathsf{PBCatom}$ stand for the set of Positive Boolean Combinations of atoms $R(\bar{c})$, with $\bar{c}$ consisting only of elements of Const. Recall that for OWA, we used the representation system $\mathbb{RS}_{\text{OWA}}(\sigma) = \langle \mathbb{D}(\sigma), \exists\mathsf{Pos}, \models\rangle$. Define a new representation system $\mathbb{RS}^{\mathsf{C}}_{\text{OWA}}(\sigma) = \langle \mathbb{D}^{\mathsf{C}}(\sigma), \mathsf{PBCatom}, \models\rangle$.

Proposition 9 *$\mathbb{RS}^{\mathsf{C}}_{\text{OWA}}(\sigma)$ is a representation system, and if Q is an $\exists\mathsf{Pos}$ query, then Q^{C} is monotone and generic with respect to it.*

Proof. Immediate from the fact that $\text{PosDiag}(D)$ for a complete D is a conjunction of atoms of the form $R(\bar{c})$, and that $\exists\mathsf{Pos}$ queries are preserved under homomorphisms. □

Thus, for every database D, and every $\exists\mathsf{Pos}$ query Q, we have $\mathsf{cert}_{\mathcal{O}}(Q^{\mathsf{C}}, D) = Q^{\mathsf{C}}(D)$ and $\mathsf{cert}_{\mathcal{K}}(Q^{\mathsf{C}}, D) = \delta_{Q^{\mathsf{C}}(D)}$ with respect to $\mathbb{RS}^{\mathsf{C}}_{\text{OWA}}(\sigma)$. Hence, under OWA, the traditional way of finding certain answers makes sense if we use a representation system that only 'cares' about complete databases.

Certain knowledge is more flexible

Note that for sets X of the form $Q([\![x]\!])$ for monotone generic queries Q, we have $\Box_{\mathcal{O}}X \models \Box_{\mathcal{K}}X$, as is implied by Theorem 2. In general, however, this need not be the case. The reason is that taking the greatest lower bound of X may lose more information than taking the greatest lower bound of $\mathsf{Th}(X)$, which indicates that working with certain answers as knowledge may be preferable, as they convey more information.

Proposition 10 *There is a representation system and a set of objects X such that $\Box_{\mathcal{O}}X \not\models \Box_{\mathcal{K}}X$.*

Proof. Consider a domain $\mathcal{D}$ with the ordering $x_1 \succeq x_2 \succeq \ldots \succeq x_n \succeq \ldots \succeq x_*$. We assume that all $\approx_j$s are the same, and for each x_i, there is $c_i \succeq x_i$ with $x_i \approx c_i$. The formulas are φ_i for $i \geq 0$. Let $\mathsf{Th}(x_i) = \{\varphi_0\} \cup \{\varphi_j \mid j \geq i\}$ (with $\mathsf{Th}(c_i) = \mathsf{Th}(x_i)$) and $\mathsf{Th}(x_*) = \emptyset$. Let $X = \{x_i \mid i \neq 0\}$. Then $\bigwedge X = x_*$ and $\mathsf{Th}(X) = \{\varphi_0\}$; hence $\Box_{\mathcal{O}}X = x_*$ and $\Box_{\mathcal{K}}X = \varphi_0$ and thus $\Box_{\mathcal{O}}X \not\models \Box_{\mathcal{K}}X$. □

We finish with examples showing that certain answer may not exist as an object while it still exists as knowledge over an appropriate representation system. Take a query $Q = R - S$, and a database D with $R^D = \{1,2\}$ and $S^D = \{3,\bot\}$.

Under CWA, we have $Q([\![D]\!]_{\text{CWA}}) = \{\ \{1,2\}, \{1\}, \{2\}\ \}$. If we take the greatest lower bound of these, then for $\preceq_{\text{CWA}}$ (and $\preceq_{\text{WCWA}}$) it simply does not exist. For the subset ordering, or the $\preceq_{\text{OWA}}$ ordering, the greatest lower bound is $\emptyset$, which is, incidentally, what a commercial DBMS would return if one runs this query in SQL (e.g., as *select r.a from r where r.a not in (select * from s)*). It seems bizarre, to say the least, to use $\preceq_{\text{OWA}}$ while dealing with the CWA semantics. However, the alternative is to return no answers at all!

This is of course yet another illustration that returning certain answers as objects is not always possible, and one needs to return certain answers as knowledge instead. What sort of knowledge will depend, of course, on the representation system. If we use the set of $\exists\mathsf{Pos}$ formulae, then the best way of describing certain answers will be $A(1) \vee A(2)$.

Next, consider the same query under OWA. Then $Q([\![D]\!]_{\text{OWA}}) = \{A \mid 3 \notin A\}$. Again, this is not representable by a single object: taking the greatest lower of $Q([\![D]\!]_{\text{OWA}})$ results again in $\emptyset$, missing some valuable information. If we use representation systems that allow negations of atomic formulae, then $\neg A(3)$ will represent the certain answer properly.

7 Conclusions

We have argued that the standard definition of certain answers in the database literature has a number of deficiencies, and proposed a new approach to handling queries over incomplete databases. Its key features are as follows.

- Certain answers can be defined at two different levels: as (database) objects, or as knowledge we possess about query answers with certainty.
- The proposed framework, that applies to multiple data models, defines both types of certain answers as greatest lower bounds in orderings that capture the level of informativeness. It also leads to a proper definition of representation systems for query answers.
- If the semantics of query answering is chosen properly, then the process of finding certain answers is reduced to

query evaluation, at both object and knowledge level. Furthermore, the knowledge level is crucial for obtaining results at the object level.

- This tells us that with the right choice of semantics, no new tools are needed for computing query answers and one can rely on the standard database query evaluation engine. It also tells us that using the traditional way of finding certain answers only makes sense under OWA, and with restricted representation systems.
- In general, certain answers as knowledge give us more information than certain answers as objects.

Future work. There are several directions to consider. Commercial languages such as SQL use multi-valued logic for reasoning. Evaluation algorithms of similar nature have been explored in the knowledgebase literature (Levesque 1998), sometimes even using database evaluation techniques (Liu and Levesque 2003). While not directly applicable to relational databases, the connection is worth studying, especially for representing certain answers as knowledge.

Another direction has to do with the detailed study of the efficiency of computing certain answers, and, if intractability is encountered, finding either tractable restrictions, or approximation schemes, perhaps in the spirit of (Reiter 1986).

Yet another direction is to apply the framework to non-relational models, particularly semi-structured and XML, for which incompleteness has been studied extensively (Abiteboul, Segoufin, and Vianu 2006; Barceló et al. 2010; Calvanese, De Giacomo, and Lenzerini 1998; David, Libkin, and Murlak 2010), and beyond, to graph data, where only preliminary results have been established so far (Barceló, Libkin, and Reutter 2014).

A Formalization of Programs in First-Order Logic with a Discrete Linear Order*

Fangzhen Lin (flin@cs.ust.hk)

Clear Water Bay, Kowloon, Hong Kong

Abstract

We consider the problem of representing and reasoning about computer programs, and propose a translator from a core procedural iterative programming language to first-order logic with quantification over the domain of natural numbers that includes the usual successor function and the "less than" linear order, essentially a first-order logic with a discrete linear order. Unlike Hoare's logic, our approach does not rely on loop invariants. Unlike typical temporal logic specification of a program, our translation does not require a transition system model of the program, and is compositional on the structures of the program. Some non-trivial examples are given to show the effectiveness of our translation for proving properties of programs.

Introduction

In computer science, how to represent and reason about computer programs effectively has been a major concern since the beginning. For imperative, non-concurrent programs that we are considering here, notable approaches include Dijkstra's calculus of weakest preconditions (Dijkstra 1976; Dijkstra and Scholten 1990), Hoare's logic (Hoare 1969), dynamic logic (Harel 1979), and separation logic (Reynolds 2002). For the most part, these logics provide rules for proving assertions about programs. In particular, for proving assertions about iterative loops, these logics rely on what have been known as Hoare's loop invariants. In this paper, we propose a way to translate a program to a first-order theory with quantification over natural numbers. The properties that we need about natural numbers are that they have a smallest element (zero), are linearly ordered, and each of them has a successor (plus one). Thus we are essentially using first-order logic with a predefined discrete linear order. This logic is closely related to linear temporal logic, which is a main formalism for specifying concurrent programs (Pnueli 1981).

Given a program, we translate it to a first-order theory that captures the relationship between the input and output values of the program variables, independent of what one may want to prove about the program. For instance, trivially, the following assignment

```
X = X+Y
```

can be captured by the following two axioms:

$$X' = X + Y,$$
$$Y' = Y,$$

where X and Y denote the initial values of the corresponding program variables and X' and Y' their values after the statement is performed. Obviously, the question is how the same can be done for loops. This is where quantification over natural numbers come in. Consider the following while loop

```
while X < M do { X = X+1 }
```

It can be captured by the following set of axioms:

$$M' = M,$$
$$X \geq M \rightarrow X' = X,$$
$$X < M \rightarrow X' = X(N),$$
$$X(0) = X,$$
$$\forall n. X(n+1) = X(n) + 1,$$
$$X(N) \geq M,$$
$$\forall n. n < N \rightarrow X(n) < M,$$

where N is a natural number constant denoting the total number of iterations that the loop runs to termination, and $X(n)$ the value of X after the nth iteration. Thus the third axiom says that if the program enters the loop, then the output value of the program variable X, denoted by X', is $X(N)$, the value of X when the loop exits.

The purpose of this paper is to describe how this set of axioms can be systematically generated, and show by some examples how reasoning can be done with this set of axioms. Without going into details, one can already see that unlike Hoare's logic, our axiomatization does not make use of loop invariants. One can also see that unlike typical temporal logic specification of a program, we do not need a transition system model of the program, and do not need to keep track of program execution traces. We will discuss related work in more detail later.

Preliminaries

We use a typed first-order language. We assume a type for natural numbers (non-negative integers). Depending on the programs, other types such as integers may be used. For natural numbers, we use constant 0, linear ordering relation $<$ (and $\leq$), successor function $n+1$, and predecessor function $n-1$. We follow the convention in logic to use lower case letters, possibly with subscripts, for logical variables. In particular, we use m and n for natural number variables, and x, y, and z for generic variables. The variables in a program will be treated as functions in logic, and written as either upper case letters or strings of letters.

We use the following shorthands. The conditional expression:

$$e_1 = \text{ if } \varphi \text{ then } e_2 \text{ else } e_3$$

is a shorthand for the conjunction of the following two sentences:

$$\forall \vec{x}.\varphi \rightarrow e_1 = e_2,$$
$$\forall \vec{x}.\neg\varphi \rightarrow e_1 = e_3,$$

where $\vec{x}$ are all the free variables in φ and e_i, $i = 1, 2, 3$. Typically, all free variables in φ occur in e_1.

Our most important shorthand is the following expression which says that e is the smallest natural number that satisfies $\varphi(n)$:

$$smallest(e, n, \varphi)$$

is a shorthand for the following formula:

$$\varphi(n/e) \wedge \forall m.m < e \rightarrow \neg\varphi(n/m),$$

where n is a natural number variable in φ, m a new natural number variable not in e or φ, $\varphi(n/e)$ the result of replacing n in φ by e, similarly for $\varphi(n/m)$. For example, $smallest(M, k, k < N \wedge found(k))$ says that M is the smallest natural number such that $M < N \wedge found(M)$:

$$M < N \wedge found(M) \wedge \forall n.n < M \rightarrow \neg(n < N \wedge found(n)).$$

Finally, we use the convention that free variables in a displayed sentence are implicitly universally quantified from outside. For instance,

$$n < M \rightarrow \neg(n < N \wedge found(n))$$

stands for $\forall n.n < M \rightarrow \neg(n < N \wedge found(n))$. Notice however, that in the macro $smallest(M, k, k < N \wedge found(k))$, k is not a free variable.

The following two useful properties about the smallest macro are easy to prove.

Proposition 1 *If $\exists n\varphi(n)$, then $\exists m.smallest(m, n, \varphi(n))$.*

Proposition 2 *If $smallest(N, n, \varphi(n)) \wedge N > 0$, then $\varphi(N) \wedge \neg\varphi(N-1)$. Furthermore, if $\varphi(n)$ has the following property*

$$\exists n[(\forall m.m > n \rightarrow \varphi(m)) \wedge (\forall m.m \leq n \rightarrow \neg\varphi(m))] \quad (1)$$

then

$$smallest(N, n, \varphi(n)) \equiv \varphi(N) \wedge \neg\varphi(N-1).$$

Proof: If $smallest(N, n, \varphi(n))$, then $\varphi(N)$ and $\forall m.m < N \rightarrow \neg\varphi(m)$. Since $N > 0$, thus $\neg\varphi(N-1)$. Now suppose that $\varphi(N) \wedge \varphi(N-1)$. By (1), for some natural number M,

$$[(\forall m.m > M \rightarrow \varphi(m)) \wedge (\forall m.m \leq M \rightarrow \neg\varphi(m))].$$

This means that $M = N-1$, and $smallest(N, n, \varphi(n))$. ■

A simple class of programs

Consider the following simple class of programs:

```
E ::= array(E,...,E) |
      operator(E,...,E)
B ::= E = E |
      boolean-op(B,...,B)
P ::= array(E,...,E) = E |
      if B then P else P |
      P; P |
      while B do P
```

Here arrays are program variables, and operators are functions. The difference between the two is that the former can occur in the left hand side of an assignment and their values be changed while the latter cannot. Notice that instead of, for example in the case of two dimensional array, the notation of "array[i][j]" commonly used in programming languages to refer to an array element, we use the notation "array(i,j)" more commonly used in mathematics and logic.

As one can see, programs here are constructed using assignments, sequences, if-then-else, and while loops. Other constructs such as if-then and for-loop can be defined using these constructs. For instance, "if B then P" can be defined as "if B then P else X=X".

Given a program P and a set $\vec{X}$ of program variables including all variables used in P, we define inductively the set of axioms for P and $\vec{X}$, written $A(P, \vec{X})$, as follows:

- If P is

  `V(E1,...,Ek) = E`

  then $A(P, \vec{X})$ consists of following axioms that say that only the value of `V(E1,...,Ek)` is possibly changed:

  $$V'(\vec{x}) = \text{ if } (x_1 = E_1 \wedge \cdots \wedge x_k = E_k) \text{ then } E \text{ else } V(\vec{x}),$$
  $$X'(\vec{y}) = X(\vec{y}), \ X \in \vec{X} \text{ and } X \text{ different from } V$$

  where $\vec{x} = (x_1, ..., x_k)$, and k is the arity of the program variable (array) V. Recall that by our convention, these variables are universally quantified.

- If P is

  `if B then P1 else P2`

  then $A(P, \vec{X})$ is constructed from $A(P_1, \vec{X})$ and $A(P_2, \vec{X})$ as follows:

  $$B \rightarrow \varphi, \text{ for each } \varphi \in A(P_1, \vec{X}),$$
  $$\neg B \rightarrow \varphi, \text{ for each } \varphi \in A(P_2, \vec{X}).$$

- If P is

  `P1; P2`

  Then $A(P, \vec{X})$ is constructed from $A(P_1, \vec{X})$ and $A(P_2, \vec{X})$ by connecting the outputs of P_1 with the inputs of P_2 as follows:

  $$\varphi(\vec{X}'/\vec{Y}), \text{ for each } \varphi \in A(P_1, \vec{X}),$$
  $$\varphi(\vec{X}/\vec{Y}), \text{ for each } \varphi \in A(P_2, \vec{X}),$$

where $\vec{Y} = (Y_1, ..., Y_k)$ is a tuple of new program variables (array names) such that each Y_i is of the same arity as X_i in $\vec{X}$, $\varphi(\vec{X}'/\vec{Y})$ is the result of replacing in φ each occurrence of X_i' by Y_i, and similarly for $\varphi(\vec{X}/\vec{Y})$. By renaming if necessary, we assume here that $A(P_1, \vec{X})$ and $A(P_2, \vec{X})$ have no common program variables except those in $\vec{X}$.

- If P is

  `while B do P1`

  Then $A(P, \vec{X})$ is constructed by adding an index parameter n to all functions and predicates in $A(P_1, \vec{X})$ to record their values after the body P_1 has been executed n times. Formally, it consists of the following axioms:

$$\varphi[n], \text{ for each } \varphi \in A(P_1, \vec{X}),$$
$$X_i(\vec{x}) = X_i(\vec{x}, 0), \text{ for each } X_i \in \vec{X}$$
$$smallest(N, n, \neg B[n]),$$
$$X_i'(\vec{x}) = X_i(\vec{x}, N), \text{ for each } X_i \in \vec{X}$$

  where n is a new natural number variable not already in φ, and N a new constant not already used in $A(P_1, \vec{X})$, and for each formula or term α, $\alpha[n]$ denotes the value of α after the body P_1 has been executed n times, and is obtained from α by performing the following recursive substitutions:

  - for each X_i in $\vec{X}$, replace all occurrences of $X_i'(e_1, ..., e_k)$ by $X_i(e_1[n], ..., e_k[n], n+1)$, and
  - for each program variable X in α, replace all occurrences of $X(e_1, ..., e_k)$ by $X(e_1[n], ..., e_k[n], n)$. Notice that this replacement is for every program variable X, including those temporary program variables not in $\vec{X}$, but introduced during the construction of $A(P_1, \vec{X})$.

While we have used $A(P, \vec{X})$ to denote "the" set of axioms for P and $\vec{X}$, the construction above does not yield a unique set of axioms as the new program variables (functions in our first-order language) introduced when constructing axioms for program sequences are not unique. However, $A(P, \vec{X})$ is unique upto the renaming of these new program variables. In particular, any two different sets of these axioms are logically equivalent when considering only program variables from $\vec{X}$, i.e. when the new program variables are "forgotten". More precisely, given two theories Σ_1 and Σ_2, we say that they are equivalent when considering a subset Ω of their vocabularies if any model M_1 of Σ_1 can be modified into a model M_2 of Σ_2 such that M_1 and M_2 agree on Ω, and conversely any model of Σ_2 can be similarly modified into a model of Σ_1.

It is easy to see the following "local" property of our construction, similar to the "frame rule" in separation logic.

Proposition 3 *Let $\vec{Y}$ be a tuple of program variables that are not in P and not used in $A(P, \vec{X})$. Then considering only $\vec{X} \cup \vec{Y}$, $A(P, \vec{X} \cup \vec{Y})$ is equivalent to the union of $A(P, \vec{X})$ and the set of following "frame axioms":*

$$Y'(\vec{y}) = Y(\vec{y}), \textit{ for each } Y \in \vec{Y}$$

The construction rule for a sequence $P; Q$ can also be modified so that new program variables only need to be introduced for those that occur in both P and Q.

Proposition 4 *Let $\vec{X}$ be a tuple of program variables including those used in either P or Q, and $\vec{V} = (V_1, ..., V_k)$ the tuple of program variables used in both P and Q (thus a subset of $\vec{X}$). When considering only $\vec{X}$, $A(P; Q, \vec{X})$ is equivalent to the set of following axioms:*

$$\varphi(\vec{V}'/\vec{Y}), \textit{ for each } \varphi \in A(P, \vec{X}),$$
$$\varphi(\vec{V}/\vec{Y}), \textit{ for each } \varphi \in A(Q, \vec{X}),$$

where $\vec{Y} = (Y_1, ..., Y_k)$ is a tuple of new program variables such that each Y_i is of the same arity as V_i in $\vec{V}$. Again we assume that, by renaming if necessary, $A(P, \vec{X})$ and $A(Q, \vec{X})$ have no common program variables other than those in $\vec{X}$.

The following important property about our axiomatization says that we do not need to wait until we have the full set of axioms to do simplification. During the construction of the axioms for a program, we can simplify first the axioms for its subprograms. This greatly simplifies the above recursive procedure for constructing axioms of a program.

Proposition 5 *Let $\vec{X}$ be a tuple of program variables, including all those that occur in program P. For any subprogram P', if T is equivalent to $A(P', \vec{X})$ when considering only $\vec{X}$, then if we use T instead of $A(P', \vec{X})$ in computing $A(P, \vec{X})$, the resulting theory is equivalent to $A(P, \vec{X})$ when considering only $\vec{X}$ as well.*

Notice that in the above proposition, when we use T instead of $A(P', \vec{X})$ in computing $A(P, \vec{X})$, we assume that we will also rename program variables when necessary to avoid name conflicts. For example, if P is $P_1; P_2$, and a theory equivalent to $A(P_1, X)$ is

$$X' = Y \wedge Y = X + 1. \tag{2}$$

If $A(P_2, X)$ also mentions the temporary variable Y, then we need to rename either the Y in (2) or the Y in $A(P_2, X)$ when constructing $A(P, X)$.

Before we consider more interesting examples, we illustrate our construction of $A(P, \vec{X})$ using two simple programs.

A simple sequence

Consider the following program P and two program variables X_1 and X_2 (notice that X_1 is used in P, but X_2 is not):

```
X1 = 1; X1 = X1+1
```

$A(X1 = 1, (X_1, X_2))$ is the set of the following two sentences

$$X_1' = 1,$$
$$X_2' = X_2$$

and $A(X1 = X1 + 1, (X_1, X_2))$ the set of following two sentences:

$$X_1' = X_1 + 1,$$
$$X_2' = X_2$$

Thus $A(P, (X_1, X_2))$ is

$$Y_1 = 1,$$
$$Y_2 = X_2,$$
$$X_1' = Y_1 + 1,$$
$$X_2' = Y_2$$

Eliminating the helper names (temporary program variables) Y_1 and Y_2, we get $X_1' = 2$ and $X_2' = X_2$.

A simple loop

Consider the following program P with a simple loop.

```
while I < N do
  if X < A(I) then X = A(I);
  I = I+1
```

Notice that the program variables are X, A, I, and N. Among them, A is unary (a list), and the rest are 0-ary (constants).

Let P_1 be the body of the loop. $A(P_1, (X, A, I, N))$ is the set of following sentences (Y_1, Y_2, Y_3, Y_4 are helper names):

$$Y_1 = \text{ if } X < A(I) \text{ then } A(I) \text{ else } X,$$
$$Y_2(x) = \text{ if } X < A(I) \text{ then } A(x) \text{ else } A(x),$$
$$Y_3 = \text{ if } X < A(I) \text{ then } I \text{ else } I,$$
$$Y_4 = \text{ if } X < A(I) \text{ then } N \text{ else } N,$$
$$X' = Y_1,$$
$$A'(x) = Y_2(x),$$
$$I' = Y_3 + 1,$$
$$N' = Y_4.$$

Instead of using this set to compute $A(P, (X, A, I, N))$, by Proposition 5, we can simplify it first by eliminating the helper names Y_1, Y_2, Y_3, Y_4, and get the following equivalent set of axioms:

$$X' = \text{ if } X < A(I) \text{ then } A(I) \text{ else } X,$$
$$A'(x) = A(x),$$
$$I' = I + 1,$$
$$N' = N.$$

Thus $A(P, (X, A, I, N))$ is

$$X(0) = X,$$
$$A(x, 0) = A(x),$$
$$I(0) = I,$$
$$N(0) = N,$$
$$X(n+1) = \text{ if } X(n) < A(I(n), n) \text{ then } A(I(n), n) \text{ else } X(n),$$
$$A(x, n+1) = A(x, n),$$
$$I(n+1) = I(n) + 1,$$
$$N(n+1) = N(n),$$
$$smallest(M, n, \neg I(n) < N(n)),$$
$$X' = X(M),$$
$$A'(x) = A(x, M),$$
$$I' = I(M),$$
$$N' = N(M).$$

Clearly $A(x)$ and N do not change: $A(x, n) = A(x)$ and $N(n) = N$. So we get the following sentences by expanding the $smallest$ macro:

$$X(0) = X,$$
$$I(0) = I,$$
$$X(n+1) = \text{ if } X(n) < A(I(n)) \text{ then } A(I(n)) \text{ else } X(n),$$
$$I(n+1) = I(n) + 1,$$
$$I(M) \geq N,$$
$$n < M \rightarrow I(n) < N,$$
$$X' = X(M),$$
$$A'(x) = A(x),$$
$$I' = I(M),$$
$$N' = N.$$

Now suppose that initially $I = 0$. Solving the recurrence:

$$I(0) = 0,$$
$$I(n+1) = I(n) + 1$$

we have $I(n) = n$. It is also easy to see that $M = N$, so we can eliminate $I(n)$ and M and get the following axioms:

$$X(0) = X,$$
$$X(n+1) = \text{ if } X(n) < A(n) \text{ then } A(n) \text{ else } X(n),$$
$$X' = X(N),$$
$$A'(x) = A(x),$$
$$I' = N,$$
$$N' = N.$$

An example assertion to prove about the program is the following

$$0 \leq n < N \rightarrow X' \geq A(n), \tag{3}$$

which is equivalent to

$$0 \leq n < N \rightarrow X(N) \geq A(n),$$

which is easily proved by induction on N using the recurrence about $X(n+1)$.

Partial and total correctness

A program is partially correct w.r.t. a specification if the program satisfies the specification when it terminates. It is totally correct if it is partially correct and terminates.

In our framework, a program P with variables $\vec{X}$ is represented by a set of sentences, $A(P, \vec{X})$. Whatever properties that one wants to show about P are proved using this set

of sentences. A partial correctness corresponds to proving a sentence about $\vec{X}$ and $\vec{X}'$ from $A(P, \vec{X})$. An example is the assertion (3) above for the simple loop. On the other hand, termination of a program is proved by showing that the new natural number constants introduced by the loops and used in the $smallest$ macro expressions are well-defined. For instance, for the above simple loop, the smallest macro is $smallest(M, n, \neg I(n) < N(n))$. The fact that there is indeed a natural number M that satisfies this macro expression follows from Proposition 1 and the fact that $I(N) \geq N$ holds.

If a loop does not terminate, then its smallest macro will cause a contradiction. For instance, consider the following loop:

```
while I < M do
  if I>0 then I = I+1.
```

If initially $I = 0$ and $M > 0$, then it will loop forever. Our axioms for the loop are:

$$
\begin{aligned}
&I' = I(N) \wedge M' = M,\\
&I(0) = I,\\
&I(n+1) = \text{ if } I(n) > 0 \text{ then } I(n) + 1 \text{ else } I(n),\\
&n < N \rightarrow I(n) < M,\\
&I(N) \geq M.
\end{aligned}
$$

If we add $I = 0 \wedge 0 < M$ to these axioms, we will conclude $\forall n.I(n) < M$, which contradicts the last axiom $I(N) \geq M$.

Related work

Our formalization of the simple loop above also illustrates the difference between our approach and Hoare's logic, arguably the dominant approach for reasoning about non-parallel imperative computer programs. To begin with, an assertion like (3) would be represented by a triple like

$$\{I = 0\}P\{\forall m(0 \leq m < N \rightarrow X \geq A(m))\}$$

in Hoare's logic. To prove this assertion, one would need to find a suitable "loop invariant", a formula that if true initially will continue to be true after each iteration. In general, there are infinite number of such loop invariants. The key is to find one that, in conjunction with the negation of the loop condition, can entail the postcondition in the assertion. For this simple loop, the following is such a loop invariant:

$$\forall m(I_0 \leq m < I \rightarrow X \geq A(m)).$$

Finding suitable loop invariants is at the heart of Hoare's logic, and it is not surprising that there has been much work on discovering loop invariants (e.g. (Wegbreit 1974; Bjørner, Browne, and Manna 1997; Ernst et al. 2001; 2007; Nguyen et al. 2012)).

In comparison, our proof of (3) uses ordinary mathematical induction and recurrences on $I(n)$ and $X(n)$.

Another difference between our approach and Hoare's logic is that Hoare's logic is a set of general rules about program assertions, while we provide a translation from programs to first-order theories with quantification over natural numbers. Once the translation is done, assertions about it are proved with respect to the translated first-order theory, without reference to the original program. This is similar to Pnueli's temporal logic approach to program semantics (Pnueli 1981). According to a common classification used in formal method community (cf. (Kozen and Tiuryn 1990; Emerson 1990)): approaches like Hoare's logic and dynamic logic are *exogenous* in that they have programs explicitly in the language, while temporal logic approach to program semantics is typically *endogenous* in that a fixed program is often assumed and a program execution counter part of the specification language. Our approach is certainly not exogenous. It is a little endogenous as we use natural numbers to keep track of loop iterations, but not as endogenous as typical temporal logic specifications which requires program counters to be part of states. In particular, our mapping from programs to theories is compositional, build up from the structure of the program. Barringer *et al.* (1984) proposed a compositional approach using temporal logic, but only in the style of Hoare's logic, using Hoare triples. However, a caveat is that so far temporal logic approach to program semantics has been mainly for concurrent programs, while what we have proposed is for non-parallel programs. Given the close relationship between temporal logics and first-order logic with a linear order, if there are no nested loops, then our translation can be reformulated in a temporal logic. It is hard to see how this can be done when there are nested loops, as this will lead to nested time lines, modeled here by predicates with multiple natural number arguments. Of course, one can always construct a transition graph of a program, and model it in a temporal logic. But then the structure of the original program is lost.

We are certainly not the first to use first-order logic with a linear order to model dynamic systems. For instance, it has been used to model Turing machines in the proof of Trakhtenbrot's theorem in finite model theory (see, e.g. (Libkin 2004)).

A closely related work is Charguéraud's characteristic formulas for functional programs (Charguéraud 2010; 2011). However, these formulas are higher-order formulas that reformulate Hoare's rules by quantifying over preconditions and postconditions.

Our use of natural numbers as "indices" to model iterations is similar to Wallace's use of natural numbers to model rule applications in his semantics for logic programs (Wallace 1993).

While we use natural numbers to formalize loops, Levesque *et al.* (1997) used second-order logic to capture Golog programs with loops in the situation calculus. Recently, Lin (2014) showed that under the foundational axioms of the situation calculus, Golog programs can be defined in first-order logic as well. However, the crucial difference between the work here and the work in the situation calculus on Golog is that our axioms try to capture the changes of states in terms of values of program variables, while the semantics of Golog programs is more about defining legal sequences of executions. To illustrate the difference here, consider a program consists of assignments that make no change (nil actions). For this program, it would still be non-

trivial to define sequences of legal executions, although it does not matter which sequences are legal as none of them change the values of program variables. Another difference is that we consider only assignments and deterministic programs, while Golog programs allow any actions that can be axiomatized by successor state axioms, and can have nondeterministic choices.

However, perhaps the best way to show the correctness of our axiomatization is to connect it with Golog in the situation calculus. Given a program P, and a tuple $\vec{X}$ of program variables that include all those used in P, we can consider each X in $\vec{X}$ as a functional fluent in the situation calculus, and write successor state axioms for these fluents, assuming that the assignments used in P are the only actions. We can then show that M is a model of $A(P, \vec{X})$ iff there is a situation calculus model W such that for each $X \in \vec{X}$, $X^M = X^W(S_0)$, and $(X')^M = X^W(S_1)$, where S_1 is such that $W \models Do(P, S_0, S_1)$ (a program P here can be considered as a Golog complex action in a straightforward way). We omit the detail here as this should present no conceptual difficulties.

Cohen's integer division algorithm

For a more complex example, consider the following program P which implements the well-known Cohen's integer division algorithm (Cohen 1990) (our program below is adapted from (Nguyen et al. 2012)). It has two loops, one nested inside another.

```
// X and Y are two input integers
  Q=0; // quotient
  R=X; // remainder
  while (R >= Y) do {
    A=1;
    B=Y;
    while (R >= 2*B) do {
      A = 2*A;
      B = 2*B;
    }
    R = R-B;
    Q = Q+A
  }
//  return Q = X/Y;
```

The program variables are A, B, Q, R, X, Y, where X and Y are inputs, and Q is the output. Let $\vec{X} = (A, B, Q, R, X, Y)$. There are two loops. Let's name the inner loop $Inner$, and outer loop $Outer$. When computing $A(P, \vec{X})$, we again consider only equivalence under $\vec{X}$ and use Proposition 5 to simplify the process.

It is easy to see that $A(P, \vec{X})$ is equivalent to the union of $A(Outer, \vec{X})$ and $\{Q = 0 \wedge R = X\}$. To compute $A(Outer, \vec{X})$, we compute first $A(Inner, \vec{X})$, which is equivalent to the set of following sentences:

$$
\begin{aligned}
&A(n+1) = 2A(n),\\
&B(n+1) = 2B(n),\\
&Q(n+1) = Q(n),\\
&R(n+1) = R(n),\\
&X(n+1) = X(n),\\
&Y(n+1) = Y(n),\\
&A(0) = A,\\
&B(0) = B,\\
&Q(0) = Q,\\
&R(0) = R,\\
&X(0) = X,\\
&Y(0) = Y,\\
&smallest(N, n, R(n) < 2B(n)),\\
&A' = A(N),\\
&B' = B(N),\\
&Q' = Q(N),\\
&R' = R(N),\\
&X' = X(N),\\
&Y' = Y(N).
\end{aligned}
$$

Solving the recurrences, we have

$$
\begin{aligned}
&A(n) = 2^n A,\\
&B(n) = 2^n B,\\
&Q(n) = Q,\\
&R(n) = R,\\
&X(n) = X,\\
&Y(n) = Y\\
&smallest(N, n, R < 2^{n+1}B),\\
&A' = 2^N A,\\
&B' = 2^N B,\\
&Q' = Q,\\
&R' = R,\\
&X' = X,\\
&Y' = Y.
\end{aligned}
$$

We can now eliminate terms like $A(n)$ and $B(n)$, expand the smallest macro expression, and obtain $A(Inner, \vec{X})$ as the set of following sentences:

$$
\begin{aligned}
&R < 2^{N+1}B,\\
&m < N \rightarrow R \geq 2^{m+1}B,\\
&A' = 2^N A,\\
&B' = 2^N B,\\
&Q' = Q,\\
&R' = R,\\
&X' = X,\\
&Y' = Y.
\end{aligned}
$$

Thus the set of sentences for the body of the loop $Outer$ is equivalent to the set of the following sentences:

$$
\begin{aligned}
&R < 2^{N+1}Y,\\
&m < N \rightarrow R \geq 2^{m+1}Y,
\end{aligned}
$$

$$A' = 2^N,$$
$$B' = 2^N Y,$$
$$Q' = Q + A',$$
$$R' = R - B',$$
$$X' = X,$$
$$Y' = Y.$$

Thus $A(Outer, \vec{X}) \cup \{Q = 0, R = X\}$ is equivalent to

$$R(n) < 2^{N(n)+1} Y(n),$$
$$m < N(n) \rightarrow R(n) \geq 2^{m+1} Y(n),$$
$$A(n+1) = 2^{N(n)},$$
$$B(n+1) = 2^{N(n)} Y(n),$$
$$Q(n+1) = Q(n) + 2^{N(n)},$$
$$R(n+1) = R(n) - 2^{N(n)} Y(n),$$
$$X(n+1) = X(n),$$
$$Y(n+1) = Y(n),$$
$$A(0) = A,$$
$$B(0) = B,$$
$$Q(0) = 0,$$
$$R(0) = X,$$
$$X(0) = X,$$
$$Y(0) = Y,$$
$$smallest(M, n, R(n) < Y(n)),$$
$$A' = A(M),$$
$$B' = B(M),$$
$$Q' = Q(M),$$
$$R' = R(M),$$
$$X' = X(M),$$
$$Y' = Y(M).$$

Now get rid of $X(n)$ and $Y(n)$ as they do not change: $X(n) = X$ and $Y(n) = Y$, get rid of A and B as they are irrelevant now, and expand the smallest macro expression, we obtain $A(P, \vec{X})$ as the set of following sentences:

$$R(n) < 2^{N(n)+1} Y,$$
$$m < N(n) \rightarrow R(n) \geq 2^{m+1} Y,$$
$$Q(n+1) = Q(n) + 2^{N(n)},$$
$$R(n+1) = R(n) - 2^{N(n)} Y,$$
$$Q(0) = 0,$$
$$R(0) = X,$$
$$R(M) < Y,$$
$$m < M \rightarrow R(m) \geq Y,$$
$$Q' = Q(M),$$
$$R' = R(M).$$

From these axioms, we can show the correctness of Cohen's algorithm by proving the following two properties:

$$0 \leq R' < Y,$$
$$X = Q'Y + R'.$$

For the first property, $R' < Y$ trivially follows from the condition of the $Outer$ loop. For $R' \geq 0$, we have $R' = R(M) = R(M-1) - 2^{N(M-1)} Y$. By the axiom

$$m < N(n) \rightarrow R(n) \geq 2^{m+1} Y,$$

let $n = M-1$ and $m = N(M-1)-1$, we have $R(M-1) \geq 2^{(N(M-1)-1)+1} Y = 2^{N(M-1)} Y$. Thus $R' \geq 0$. For the second property, we have

$$\begin{aligned} & Q'Y + R' \\ &= Q(M)Y + R(M) \\ &= (Q(M-1) + 2^{N(M-1)})Y + R(M-1) - 2^{N(M-1)} Y \\ &= Q(M-1)Y + R(M-1) \\ &= \cdots = Q(0)Y + R(0) = X. \end{aligned}$$

Again this is partial correctness. To prove the termination, we need to show that the new terms introduced by the smallest macro expressions are all well-defined. For this program, it means that M (the outer loop counter) is bounded, and for every n, $N(n)$ (the inner loop counter for each outer loop iteration) is bounded. By Proposition 1, these can be proved by showing the following two properties:

$$\exists m.R(m) < Y,$$
$$\forall n \exists m.R(n) < 2^{m+1} Y.$$

Again we remark that we relied on mathematical induction in our proof and made no use of loop invariants. Notice also that our proof actually shows that for integer division, any program of the following form is correct:

```
// X and Y are two input integers
  Q=0; // quotient
  R=X; // remainder
  while (R >= Y) do {
    A=1;
    B=Y;
    while (R >= k*B) do {
      A = k*A;
      B = k*B;
    }
    R = R-B;
    Q = Q+A
  }
//  return Q = X/Y;
```

where $k > 1$ can be any constant.

Functions

One may ask how general our proposed approach is. Can it be done for programs with more complex structures like pointers, functions, classes, concurrency? We believe so. We have extended it to pointers and functions. Classes should present no problem as they are basically user defined types. While we have not done it for concurrency, we believe it can be done as well given that we were able to provide a first-order axiomatization of ConGolog (Lin 2014). In this section, we describe how the same approach can be used to axiomatize programs with user defined functions.

In practice, a program consists of a set of functions. To illustrate how we can handle functions, including recursive functions, consider the following class of programs:

```
E ::= array(E,...,E) |
      operator(E,...,E) |
      function(E,...,E) |
B ::= E = E |
      boolean-op(B,...,B)
Body ::= array(E,...,E) = E |
         if B then P else P |
         P; P |
         while B do P |
         return E
F ::= function(variable,...,variable)
      { Body }
P ::= F | P; P
```

Thus a program is a collection of functions. Presumably, one of them is the "main" function, the one that will be executed first when the program is run. In some programming languages, these functions can communicate by sharing some global variables. To simplify things a bit, we assume here that there are no global variables, and that all program variables in the body of a function must occur in the parameter list of the function.

If P is $F_1; \cdots; F_k$, then the set of axioms for P is the union of the sets of axioms for F_i, $1 \leq i \leq k$, with renaming of program variables in them if needed to avoid conflict of names.

Given a function definition $f(\vec{X})\{Body\}$, the set of sentences for it, written $A(f)$, is

$$\forall \vec{x} \varphi(\vec{X}/\vec{x})(Result'/f(\vec{x})), \varphi \in A(Body, \vec{X} \cup \{Result\}),$$

where

- $\varphi(\vec{X}/\vec{x})(Result'/f(\vec{x}))$ is the result of replacing in φ each X_i in $\vec{X}$ by x_i, X_i' by a new function name $g(\vec{x})$, and $Result'$ by $f(\vec{x})$. We assume that $Result$ is a reserved word used to denote the value of the function. Notice that once we replace each X_i by a variable x_i, X_i', the value of X_i when the function exits, is no longer relevant. Here we just replace it by a dummy new function g.
- $A(Body, \vec{X} \cup \{Result\})$ is defined as before, except that when $Body$ is `return E`, the axioms are

$$Result' = E,$$
$$X_i'(\vec{x}) = X_i(\vec{x}),\ X_i \text{ is a program variable.}$$

Notice that according to our axiomatization here, while the body of a function may execute the return statement multiple times, only the last time matters. For example, given

```
foo() { return 1; return 2 }
```

only the second return statement is meaningful, and the function is captured by the axiom $foo() = 2$. One could argue that it does not make sense for more than one instances of the return statement to be executed, and it is the programmer's responsibility to make sure that this does not happen. Alternatively, one can assume that as soon as a return statement is executed, the function exits. This can be modeled by introducing a special flag $Exit$, and replace each return statement by

```
if -Exit then {return E; Exit = true}
```

For a more meaningful example, consider the following two mutually defined functions $isEven$ and $isOdd$:

```
isEven(N) {
  if N=0 then return true
         else return -isOdd(N-1) }
isOdd(N) {
  if N=0 then return false
         else return -isEven(N-1) }
```

Suppose that we denote the body of $isEven(N)$ by $Body1$, and that of $isOdd(N)$ by $Body2$. Then $A(Body1, (N, Result))$ consists of the following axioms:

$$N' = N,$$
$$Result' = \text{ if } N = 0 \text{ then } true \text{ else -}isOdd(N-1)$$

and similarly for $A(Body2, (N, Result))$:

$$N' = N,$$
$$Result' = \text{ if } N = 0 \text{ then } false \text{ else -}isEven(N-1)$$

Thus $A(isOdd) \cup A(isEven)$ is

$$f(x) = x,$$
$$isEven(x) = \text{ if } x = 0 \text{ then } true \text{ else -}isOdd(x-1),$$
$$g(x) = x,$$
$$isOdd(x) = \text{ if } x = 0 \text{ then } false \text{ else -}isEven(x-1),$$

where f and g are two new functions used to denote the values of x when the functions $isEven(x)$ and $isOdd(x)$, respectively, return. They are irrelevant, so the two corresponding axioms can be deleted. By induction on n, it is easy to prove that the following hold for all $n \geq 0$:

$$isEven(2n) = true,$$
$$isOdd(2n) = false,$$
$$isEven(2n+1) = false,$$
$$isOdd(2n+1) = true.$$

Now consider the following program with a type definition:

```
List ::= [] | a::List

length(X:List) {
 if X=[] then return 0
   else return length(tail(X))+1}
tail(X:List) {
 if X=[] then return []
   else if X=a::X1 then return X1}
append(X:List, Y:List) {
 if X=[] then return Y
   else if X=a::X1
        then return a::append(X1,Y)}
```

To model the data type `List`, we introduce a corresponding $List$ sort in our first-order language, and write $(x : List)$

to mean that x is of sort $List$. In first-order terms, the definition of $List$ yields the following axioms:

$$(\forall x\!:\!List).x = [] \vee \exists a(\exists y\!:\!List)x = a :: y,$$
$$\forall a, b(\forall x, y\!:\!List).a :: x = b :: y \rightarrow (a = b \wedge x = y),$$
$$\forall a(\forall x\!:\!List)[] \neq a :: x,$$

and the three functions yield the following axioms:

$$\begin{aligned}
&(\forall x\!:\!List).length(x) = \text{ if } x = [] \text{ then } 0\\
&\qquad \text{else } length(tail(x)) + 1,\\
&(\forall x\!:\!List).tail(x) = \text{ if } x = [] \text{ then } []\\
&\qquad \text{else if } \exists a(\exists y\!:\!List)x = a :: y \text{ then } y,\\
&(\forall x, y\!:\!List).append(x, y) = \text{ if } x = [] \text{ then } y\\
&\qquad \text{else if } \exists a(\exists x_1\!:\!List)x = a :: x_1\\
&\qquad\qquad \text{then } a :: append(x1, y).
\end{aligned}$$

With these axioms, one can prove, for example $length(a :: b :: []) = 2$. However, they are not sufficient for proving general properties like the following simple one:

$$(\forall x, y\!:\!List)length(append(x, y)) = length(x)+length(y).$$

To prove properties like this, we need induction on lists. This can be done by using a second-order axiom on sort $List$, similar to the one on natural numbers. However, since we already have natural numbers, this is not necessary. We can introduce lists of n elements, and define a list to be a list of n elements, for some n. This way, we can use mathematical induction on natural numbers to prove inductive properties about lists. We show how this is done here. We introduce a binary predicate $List(x, n)$, meaning that x is a list with exactly n elements:

$$(\forall x\!:\!List)\exists n.List(x, n),$$
$$List(x, 0) \equiv x = [],$$
$$List(x, n + 1) \equiv (\exists a)(\exists y\!:\!List).x = a :: y \wedge List(y, n)$$

We first show that if x is a list, then there is a unique n such that $List(x, n)$ holds:

$$List(x, n) \wedge List(x, m) \rightarrow m = n. \qquad (4)$$

Suppose x is a list, and $List(x, m)$ and $List(x, n)$ are true. We do simultaneous induction on n and m. If $n = 0$, then $x = []$. If $m \neq 0$, then for some k, $m = k + 1$ and $x = [] = a :: y$ for some a and list y, a contradiction with one of our axioms about lists. Thus $m = 0$ as well. Similarly, if $m = 0$, then $n = 0$ as well. Suppose $n = k_1 + 1$ and $m = k_2 + 1$, and suppose inductively that for any $i, j < max\{m, n\}$, we have that

$$List(y, i) \wedge List(y, j) \rightarrow i = j$$

for any list y. We then have $x = y_1 :: z_1$ for some list z_1 such that $List(z_1, k_1)$ holds, and $x = y_2 :: z_2$ for some list z_2 such that $List(z_2, k_2)$ holds. From $y_1 :: z_1 = y_2 :: z_2$, we have $z_1 = z_2$, thus by the inductively assumption, $k_1 = k_2$. So $m = n$. This concludes the inductive step, thus the proof of (4).

Using (4), we can then prove the induction schema on lists: for any formula $\varphi(x)$,

$\varphi([]) \wedge \forall a(\forall x\!:\!List)(\varphi(x) \rightarrow \varphi(a :: x)) \rightarrow (\forall x\!:\!List)\varphi(x)$.

Suppose the premise is true and for some list x, $\neg\varphi(x)$. Suppose x is a shortest such list: if $List(x, n)$ then for any list y, if $List(y, m) \wedge m < n$, then $\varphi(y)$ holds. Notice that the existence of such an x follows from (4). Suppose $List(x, n)$. If $n = 0$, then $x = []$, which satisfies φ, a contradiction. Suppose $n = m + 1$, then there are some a and y such that $x = a :: y \wedge List(y, m)$. By our assumption about x, $\varphi(y)$ holds. By the premise, $\varphi(a :: y)$ holds as well, a contradiction.

The same idea can be used to axiomatize in first-order logic other inductively defined data structures such as trees.

For recursive functions, a challenge is to distinguish between cycles and undefined values. Consider the following example.

```
foo(X) { if X=0 then return foo(X)
         else if x=1 then return 1}
```

With our axiomatization, the set of axioms for $foo(x)$ is equivalent to a single fact $foo(1) = 1$. It leaves completely open the possible values for $foo(x)$ when $x \neq 1$. One could argue whether this is a right formalization. But operationally, there is a difference between function calls $foo(0)$ and $foo(2)$: calling $foo(0)$ will cause a cycle, but calling foo(2) will terminate without any value being returned. The former causes stack overflow and the latter abnormal exit.

In the following, we provide an axiomatization of functions that can differentiate these two cases address. The key idea is to keep a counter of the number of times a recursive function has been called.

Let $f_1, f_2, ..., f_k$ be functions that are mutually defined recursively: $f_i(X_1, ..., X_m)\{B_i\}$. Extend these functions with one more argument:

$$f_i(X_1, ..., X_m, M)\ \{\text{if } M = 0 \text{ then } B_{i0} \text{ else } B_{i1}\}$$

where

- B_{i0} is the result of replacing each function call $f_j(T_1, ..., T_m)$ in B_i by $Cycle$, and
- B_{i1} is the result of replacing each function call $f_j(T_1, ..., T_m)$ in B_i by $f_j(T_1, ..., T_m, M - 1)$.
- M is a natural number, and $Cycle$ is a new constant.

The set $A(f_i)$ of axioms for f_i is then

$$f_i(\vec{x}) = y \equiv \exists n \forall m \geq n.f_i(\vec{x}, m) = y.$$

Consider again function $foo()$ defined above. We have

```
foo(X,M) { if M=0 then
  {if X=0 then return Cycle else
    if X=1 then return 1} else
  {if X=0 then return foo(X,M-1) else
    if X=1 then return 1}
```

and the following axioms for $foo(X)$ and $foo(X, M)$:

$$\begin{aligned}
&foo(x) = y \equiv \exists m \forall n \geq m.foo(x, n) = y,\\
&foo(0, 0) = Cycle,\\
&foo(1, 0) = 1,\\
&foo(0, n + 1) = foo(0, n),\\
&foo(1, n + 1) = 1
\end{aligned}$$

Thus $\forall n.foo(0,n) = Cycle$ and $\forall n.foo(1,n) = 1$. So $foo(0) = Cycle$ and $foo(1) = 1$. The axioms again leave open the possible values for $foo(x)$ when x is not equal to 0 or 1.

Concluding remarks

My goal is to have a translator from a full programming language like C or Java to first-order logic. In this paper, I show how this is possible for a core procedural programming language with loops and functions. Instead of loop invariants used in Hoare's logic, the approach relies on mathematical induction and recurrences. I show that even for programs with nested while loops such as Cohen's integer division, typical properties about them can be proved effectively using their corresponding first-order theories.

The complexity of the translated first-order theory from a program depends on the domain that the program is about. If all program variables are propositional, then the resulting first-order theory is decidable for proving both partial and total correctness of the program with respect to any given propositional specification. If the program is about natural numbers and involves addition and multiplication, then we may need full arithmetic to reason about it. If the program is about predicting the trajectory of a planet, then a theory of physics is needed in order to prove anything interesting about it. How to integrate logical reasoning with a domain theory has long been a challenge in AI as well as in computer science. I hope that with this work, more KR researchers will take up this challenge and start to contribute to program verification. As a step in this direction, we plan to develop a reasoner for programs about mathematics by integrating a logic solver with Mathematica[1], which has a programmable set of powerful tools for solving problems in mathematics. For instance, it can easily solve the recurrences that we have seen in this paper.

Simultaneous Learning and Prediction

Loizos Michael

Abstract

Agents in real-world environments may have only *partial* access to available information, often in an arbitrary, or hard to model, manner. By reasoning with knowledge at their disposal, agents may hope to recover some missing information. By acquiring the knowledge through a process of learning, the agents may further hope to guarantee that the recovered information is indeed correct. Assuming only a black-box access to a learning process and a prediction process that are able to cope with missing information in some principled manner, we examine how the two processes should interact so that they improve their overall joint performance. We identify natural scenarios under which the interleaving of the processes is provably beneficial over their independent use.

Introduction

Consider a medical database, with one row for each patient, and one column for each attribute of interest to some medical doctor. Due to numerous reasons, not every patient-attribute pair is associated with a definite value. Can the missing values be reliably and efficiently predicted / recovered, given the rest of the available information, and without assuming any particular structure in the way information is missing?

It is typical for research in Knowledge Representation and Reasoning (KRR) to assume that an agent (e.g., the medical doctor in our example scenario) has access to some knowledge base of rules that collectively capture certain regularities in the environment of interest. By applying such rules on the available information, the agent draws inferences on those aspects of its available inputs that are not explicitly observed, effectively recovering some of the missing information. Research, then, seeks to identify how to most appropriately represent and reason with rules for this recovery task.

A knowledge base need not comprise only infallible rules, in that rules need not be fully qualified at an individual or local level. Instead, rules could be qualified via the reasoning process, so that they are blocked from drawing an inference they support if and when another piece of evidence supports a contradictory inference, and the latter takes precedence. First, rules could be *endogenously qualified*, if they are explicitly known to be overridden by certain other rules in the knowledge base (e.g., the rule that "high fever during winter suggests a flu infection" could be overridden by another rule that "high fever near a swamp suggests a malaria infection"). Second, rules could be *exogenously qualified*, if they yield in the presence of explicit, but external to the knowledge base, information that contradicts them (e.g., the rule that "pain or pressure in the chest or arms suggests a heart attack" could yield to an explicit observation of a negative test result.

Accounting for the qualifications, the underlying assumption remains that after applying a (sound) reasoning process on the knowledge base and the available information, the drawn inferences should be accepted as correctly recovering the missing information. And they should be, if the knowledge that is available for the agent to reason with is, indeed, appropriate for the environment on which it is being used.

It has often been argued that the appropriateness of knowledge can be guaranteed if (and in many settings, only if) it is acquired through a process of induction over the agent's experiences from its environment (Valiant 2013). Indeed, by a simple, in retrospect, statistical argument (Valiant 1984), rules that have been found to be correct on past experiences are also *Probably* (i.e., except with a small probability with which the agent did not have typical experiences from its environment) *Approximately Correct* (i.e., they will predict correctly on almost all of the agent's future experiences).

To learn knowledge with the aim to recover some missing information in its future partially observable experiences, an agent has access only to such equally partially observable experiences from which it can learn. It has been shown that the PAC learning semantics (Valiant 1984) can be extended to deal with arbitrarily missing information, and that certain PAC learning algorithms can be easily modified to cope with such experiences (Michael 2010), even under the seemingly arduous requirements that we later impose on the guarantees provided by these algorithms. In the interest of generality, we shall not deal in the sequel with the exact details of how such algorithms work. Instead, we shall, henceforth, assume a black-box access to any algorithm for learning from partially observable experiences, and call it the *base algorithm*.

Applying a base algorithm on the database, a medical doctor may seek to learn a predictor P_i for each of the database attributes x_i, and apply these predictors on each row of the database to complete some of the missing information. Due to partial information and imperfect training, the predictors

Copyright © 2014, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

may sometimes abstain or predict incorrectly when applied, giving rise to a database that is generally more complete, but less sound. The question we seek to answer in this work is this: *Is there a natural and general technique to improve the completeness and soundness of the above naive approach?*

It is important to clarify upfront that the notions of soundness and completeness that are used in this work are akin, but not identical, to those used in KRR research. In the latter, one typically has a semantics that determines, for each input and knowledge base, the inferences that are valid / correct (e.g., by specifying the models of the given input and knowledge base). Then, one may conceivably consider a number of different reasoning processes, and evaluate each one in terms of soundness and completeness thus: a reasoning process is sound if the inferences it produces *agree* with the inferences specified by the semantics, and it is complete if it produces *all* the inferences that are specified by the semantics.

Since knowledge bases in KRR research are typically assumed to truly capture the structure of the environment of interest, a definition of soundness and completeness against a knowledge base is appropriate. When learning is involved, however, the knowledge base is only *approximately* correct. The goal of the combined learning and reasoning processes is, then, to produce inferences not as specified against the agent's own knowledge base, but rather as specified against some "ideal" knowledge base; or in other words, to produce inferences specified by the underlying truth of things.

In effect, this work considers different policies (i.e., ways to apply learned rules) for drawing inferences, and evaluates them in terms of their soundness and completeness. More precisely, we take the stance that soundness should not be compromised (beyond the approximate correctness that cannot be avoided due to learning), and seek to find policies that draw inferences in a manner that improves completeness.

In seeking such policies we ask: When is it meaningful to *learn* the predictors (for each attribute) independently of each other? When is it meaningful to *apply* them independently of each other? Can something be gained by interleaving their learning and their application? We offer formal answers to these questions, and discuss how our results apply when knowledge is acquired through learning in other typical settings, such as supervised classification / regression.

Preliminaries and Notation

Fix a set $\mathcal{A}$ of attributes x_i, with $i \in \{1, \dots n\}$. Denote by $dom[i]$ the domain of attribute x_i, and by $dom[\mathcal{A}]$ the cross product $dom[1] \times \cdots \times dom[n]$ of all attribute domains. A ***complete assignment*** of values to the attributes $\mathcal{A}$ is denoted by $\texttt{asg} \in dom[\mathcal{A}]$, and the value of attribute x_i in $\texttt{asg}$ is denoted by $\texttt{asg}[i]$. To account for partial observability, denote by $dom^*[i]$ the extended domain $dom[i] \cup \{*\}$, and by $dom^*[\mathcal{A}]$ the cross product $dom^*[1] \times \cdots \times dom^*[n]$ of all extended attribute domains; $*$ stands for "don't know". An ***(observed) assignment*** of values to the attributes $\mathcal{A}$ is denoted by $\texttt{obs} \in dom^*[\mathcal{A}]$, and the value of attribute x_i in $\texttt{obs}$ is denoted by $\texttt{obs}[i]$. Our example medical database can, then, be represented simply as a list $\mathcal{S}^*$ of assignments.

Given $\mathcal{S}^*$, we seek a new list $\mathcal{S}'$ of assignments in which some of the $*$ values are replaced with the "actual" (as determined by nature) values, from the domain of the corresponding attributes. That is, given the partial inputs and whatever relevant domain knowledge we have at our disposal, we seek to reason and infer (some of) the information that is not explicitly given in the inputs. For instance, while the height-at-birth attribute of some patient might be missing in medical database $\mathcal{S}^*$, the patient does have some value associated with that attribute, and the goal is to accurately recover it.

Although the recovery process does not have access to the underlying reality, our analysis of the recovery process will make use of it. We shall, henceforth, consider $\mathcal{S}$ to be a list of complete assignments, and assume that $\mathcal{S}^*$ is always such that the j-th observed assignment $\texttt{obs} \in \mathcal{S}^*$ is obtained by applying an unknown fixed process $\texttt{mask}$ on the j-th complete assignment $\texttt{asg} \in \mathcal{S}$. In the general case, the ***masking process*** $\texttt{mask}$ is a (possibly stochastic) mapping from $dom[\mathcal{A}]$ to $dom^*[\mathcal{A}]$. This general treatment captures cases where masking may (arbitrarily) hide or even distort parts of the underlying reality. For this work we shall restrict our attention to masking processes that only hide (without distorting) assignments, by insisting that whenever $\texttt{obs}$ is obtained from $\texttt{mask}(\texttt{asg})$, either $\texttt{obs}[i] = *$ (i.e., information is hidden) or $\texttt{obs}[i] = \texttt{asg}[i]$ (i.e., information is preserved). Such an observed assignment $\texttt{obs}$ shall be said to ***mask*** the complete assignment $\texttt{asg}$, and each attribute $x_i \in \mathcal{A}$ whose value $\texttt{obs}[i]$ is $*$ shall be said to be ***masked*** in $\texttt{obs}$.

A ***base algorithm*** is one that given access to a list $\mathcal{S}^*$ and an attribute $x_i \in \mathcal{A}$, returns a predictor P_i. A ***predictor*** P_i for x_i is a mapping from $dom[\mathcal{A} \setminus \{x_i\}]$ to $dom[i]$ that is computable in time polynomial in n (i.e., in its input size). A given assignment $\texttt{obs} \in dom^*[\mathcal{A}]$ may not necessarily offer enough information to *uniquely* determine the value of the mapping. In such a case, and only then, P_i abstains from making a prediction. Thus, the predictor P_i is naturally lifted to a mapping from $dom^*[\mathcal{A} \setminus \{x_i\}]$ to $dom^*[i]$ to account for abstaining from predictions when sufficient information is not available to determine a definite value. To reduce notation, we shall write $P_i(\texttt{obs})$ to denote the prediction of P_i on assignment $\texttt{obs} \in dom^*[\mathcal{A}]$, with the implicit understanding that only the values of attributes $\mathcal{A} \setminus \{x_i\}$ are read from $\texttt{obs}$. When P_i abstains due to insufficient information in $\texttt{obs}$ to determine a prediction, then $P_i(\texttt{obs}) = *$.

We shall restrict our attention to ***classical*** (or monotonic) predictors, which we take to mean that when they make a definite prediction on some assignment, they do not change that prediction in the presence of more information.[1] Other than that, we shall treat the base algorithm and the returned predictors as black boxes. It is exactly therein that lies the general applicability of our framework and formal results.

Dealing with Multiple Predictors

Consider a medical database $\mathcal{S}^*$ with multiple rows, and 7 columns corresponding to real-valued patient characteristics (e.g., cholesterol level). Let the complete assignment $\texttt{asg} =$

[1] Although reasoning with non-monotonic rules has a very long and rich history in KRR research (Reiter 1980), the learning of non-monotonic rules has received considerably less attention in Learning Theory research (Schuurmans and Greiner 1994) and the practical deployment of Machine Learning techniques (Mitchell 1997).

$\langle -1, 0, 5, 0, 4, -7, 9\rangle \in \mathcal{S}$ determine the actual values that these characteristics take for patient John Doe, and let the observed assignment $\texttt{obs} = \langle -1, 0, *, 0, 4, *, 9\rangle \in \mathcal{S}^*$ correspond to John Doe's (partial) medical record as found in the medical database $\mathcal{S}^*$. Suppose that a doctor reads in a medical journal that the values of certain patient characteristics can be predicted from the values of the other patient characteristics through a set $\mathbb{P}$ of the following[2] predictors:
(i) P_1 predicts according to rule "$x_3 := |\sqrt{x_5}| + |\sqrt{x_7}|$";
(ii) P_2 predicts according to rule "$x_4 := x_2 \cdot x_6$";
(iii) P_3 predicts according to rule "$x_6 := x_3 - x_5/2$".

The doctor wishes to recover reliably as much of the information missing in $\mathcal{S}^*$, and in John Doe's medical record in particular. To this end, the doctor chooses to apply the predictors in $\mathbb{P}$ *in parallel*, in the following sense: each of the predictors is applied on obs independently of the others, the prediction of each predictor is computed, and only then the predictions are used to complete the information that is missing in John Doe's medical record. By following this process, the doctor computes the predictions of P_1, P_2, P_3 to be, respectively, 5, 0, $*$. Note that predictor P_3 abstains since its prediction cannot be determined without the value of x_3. Incorporating these predictions in obs yields $\texttt{obs}' = \langle -1, 0, 5, 0, 4, *, 9\rangle$, which is sound when compared against the underlying truth asg, and more complete than obs.

Applying predictors in parallel is not the only option. For instance, the doctor could choose to apply the predictors *sequentially*, in the following sense: apply one of the predictors on obs, compute its prediction, modify obs to incorporate that prediction, and repeat the process with another predictor. Unlike the parallel process, the second predictor will now be applied not on obs, but on the new version of John Doe's medical record that has incorporated the prediction of the first predictor. By following this process, the doctor applies P_1 on $\texttt{obs} = \langle -1, 0, *, 0, 4, *, 9\rangle$, and its prediction 5 for x_3 turns obs into $\texttt{obs}' = \langle -1, 0, 5, 0, 4, *, 9\rangle$. Subsequently, the doctor considers P_2, but seing that the value of x_4 is already known in $\texttt{obs}'$, the doctor chooses to let $\texttt{obs}'' = \texttt{obs}'$, effectively ignoring the prediction of P_2. Finally, the doctor applies P_3 on $\texttt{obs}''$, and its prediction 3 for x_6 turns $\texttt{obs}''$ into $\texttt{obs}''' = \langle -1, 0, 5, 0, 4, 3, 9\rangle$.

Evidently, the two ways of applying the very same set of predictors yield different results. Indeed, in the second case, predictor P_3 has access to a value for attribute x_3 at the time of its application, and is able to make a definite prediction. The resulting medical record $\texttt{obs}'''$ is now fully complete, but unsound when compared against the underlying truth asg, since the value of x_6 is predicted, but incorrectly.

A set of predictors may be applied in other more involved ways as well; e.g., first apply $\{P_1, P_3\}$ in parallel, and subsequently apply $\{P_2\}$. It is even possible for the value of some attribute to be predicted on multiple occasions by predictors that are applied, however, at different points in the process. Henceforth, we shall assume that an ordering of predictors is implicitly prescribed by each given $\mathbb{P}$. We shall call $\mathbb{P}$ a ***policy***, and think of it as a sequence of non-empty sets of predictors, so that the predictors in each set are applied in parallel (with each predictor in the set predicting the value of a different attribute), before those in the subsequent set are applied, and so on. We shall write $\mathbb{P}(\texttt{obs})$ to mean the final assignment obtained when predictors in $\mathbb{P}$ are applied on obs in the prescribed ordering. We shall write $\mathbb{P}(\mathcal{S}^*)$ to mean the list with elements in $\{\mathbb{P}(\texttt{obs}) \mid \texttt{obs} \in \mathcal{S}^*\}$.

Note that a prediction $\mathbb{P}(\texttt{obs}) \in dom^*[\mathcal{A}]$ of a policy $\mathbb{P}$ on obs determines values in $dom^*[\mathcal{A}]$ for all attributes $\mathcal{A}$, since every attribute on which a predictor in $\mathbb{P}$ abstains will have its value persist from what is given in $\texttt{obs} \in \mathcal{S}^*$. A policy $\mathbb{P}$ is ***complete on*** $\texttt{obs} \in \mathcal{S}^*$ if $\mathbb{P}(\texttt{obs}) \in dom[\mathcal{A}]$. A policy $\mathbb{P}$ is ***sound on*** $\texttt{obs} \in \mathcal{S}^*$ ***against*** $\texttt{asg} \in \mathcal{S}$ if $\mathbb{P}(\texttt{obs})$ masks asg; soundness concisely states that the resulting value for each $x_i \in \mathcal{A}$ is either $*$, or correct according to the nature-assigned value of x_i in asg. By extension: A policy $\mathbb{P}$ is ***complete on*** a given fraction / sublist of $\mathcal{S}^*$ if it is complete on each obs in that fraction / sublist of $\mathcal{S}^*$. A policy $\mathbb{P}$ is ***sound on*** a given fraction / sublist of $\mathcal{S}^*$ ***against*** $\mathcal{S}$ if it is sound on each obs in that fraction / sublist of $\mathcal{S}^*$ against the asg in $\mathcal{S}$ that corresponds to obs.

We shall employ the notions of soundness and completeness mutatis mutandis on individual predictors as well, by thinking of them as policies that include a single predictor.

Before continuing with the technical analysis of different policies in subsequent sections, certain remarks are in order.

The first remark relates to soundness and completeness and how these notions relate to their typical use in KRR. In addition to the points we have already made in the first section, we note also the quantitative nature of the notions. We will not refer to a policy as being simply sound or complete, but we will quantify the fraction / percentage of the given inputs on which soundness and completeness are achieved.

The second remark relates to how rules are applied. Some form of sequentiality when applying rules seems to resemble proof procedures in KRR research more closely than the parallel application of rules. After all, one could argue, the latter approach seems to unnecessarily waste the opportunity to get more complete inferences by having rules interact. On the other hand, the parallel application of rules seems to be closer to what a lot of Machine Learning research has traditionally done when dealing with multiple predictors; certain exceptions of this trend are discussed in the last section.

In the sequel we shall identify the reason behind the above discrepancy, which comes down to the fact that applying *learned* (and hence approximately correct) rules naively in some sequential fashion, can reduce soundness. On the other hand, we shall show that an appropriate application of rules in some non-parallel fashion provably improves their combined soundness and completeness. The main question, then, becomes that of finding how to apply rules so that to exploit this improvement, without sacrificing their soundness.

The third remark relates to the qualification of rules. When each rule in a policy is applied, its prediction is used to update information on an attribute only if information on the attribute's value is missing. If an attribute's value is observed, then the prediction will yield to this explicit observation, and be exogenously qualified. It can be easily observed

[2]Predictors utilizing other representations for the rules according to which they make predictions are also possible. In particular, utilizing boolean attributes and a logic-based representation gives rise to rules closer to what a lot of KRR research employs.

that the same treatment accounts for the endogenous qualification of rules as well. If rules that are applied first do not abstain and do make a prediction, then those predictions will complete missing information, which will subsequently prevent the predictions of rules that are applied later from being recorded; in effect, the former rules override the latter rules.

Our investigation herein seeks to learn these rules, and the ordering in which they are applied. Since ordering captures rule qualification, the knowledge bases that we end up learning are ultimately non-classical (i.e., non-monotonic), even though each individual rule is restricted to being classical.

Benefits of Chaining Predictors

Consider a policy $\mathbb{P}$ that prescribes a sequence of d sets of predictors. We shall call d the ***depth of*** $\mathbb{P}$, and the sets the ***layers of*** $\mathbb{P}$, indexed by their order in the sequence. A policy $\mathbb{P}$ is ***flat*** if its depth d is 1, and is ***chained*** if $d \geq 2$; i.e., when at least one predictor in $\mathbb{P}$ is applied *after* some other predictor in $\mathbb{P}$. An ***empty*** policy $\mathbb{P}$ has depth $d = 0$. A policy $\mathbb{P}_1$ is a ***reordering of*** a policy $\mathbb{P}_2$ if the multi-set of the union of the layers of $\mathbb{P}_1$ matches that of $\mathbb{P}_2$; i.e., the policies share the predictors that are being used, but may differ on their depths and on how predictors are assigned to the policy layers.

We proceed to consider whether having chained policies is ever a good idea. In other words, we seek to understand if a form of sequential application of rules, as done in proof procedures in KRR, is useful when it comes to *learned* rules?

The distinction between *learned* and *programmed* rules is critical and should be emphasized. It is trivial to demonstrate the benefits (in terms of completeness) of chaining in knowledge bases with programmed rules: given the rules "if you have fever then you are sick" and "if you are sick then visit a doctor", the inference "visit a doctor" cannot be drawn from the observation "you have fever" without using both rules, since no single rule can bridge the gap between the available observation and the sought inference. However, when rules are learned, there is nothing preventing the learning process from inducing a single rule that bridges this gap (e.g., "if you have fever then visit a doctor"). In theory, then, the learning process itself could render the need for chaining superfluous.

We have revealed in the preceding section that, despite the concern above, chaining remains provably beneficial for knowledge bases with *learned* rules. To establish this claim, one must consider not only the completeness that a knowledge base can achieve (as in the case of programmed rules), but also the soundness. Indeed, the ability of a learning process to *construct* rules (in contrast to being given *prescribed* rules by a process of programming) may trivially lead to perfect completeness by constructing a constant rule for each attribute. It is only by including soundness in the evaluation of a knowledge base that we can demonstrate the benefits of chaining. This evaluation metric of combined soundness and completeness is captured by the following definition.

Definition 1 (Chaining Collapsibility). ***Chaining collapses on $\mathcal{S}^*$ against $\mathcal{S}$*** *if: for every policy $\mathbb{P}$ that is unsound on an ε fraction of $\mathcal{S}^*$ against $\mathcal{S}$, and incomplete on an ω fraction of $\mathcal{S}^*$, there exists a flat policy $\mathbb{P}'$ of predictors that is unsound on an ε' fraction of $\mathcal{S}^*$ against $\mathcal{S}$, and incomplete on an ω' fraction of $\mathcal{S}^*$ such that $\varepsilon' + \omega' \leq \varepsilon + \omega$.*

The sum of the soundness and completeness of a policy $\mathbb{P}$ on $\mathcal{S}^*$ against $\mathcal{S}$ will play an important role in our analysis, and shall be called the ***performance*** of $\mathbb{P}$ ***on $\mathcal{S}^*$ against $\mathcal{S}$***. Chaining is provably beneficial if a situation can be demonstrated where the performance of a particular policy $\mathbb{P}$ cannot be matched by *any* flat policy (not necessarily a reordering of $\mathbb{P}$). We shall demonstrate such a situation next.

Fix an assignment $\texttt{obs} \in \mathcal{S}^*$, a predictor P_t for attribute $x_t \in \mathcal{A}$, and an attribute $x_i \in \mathcal{A}$ that is masked in $\texttt{obs}$. Consider changing the $*$ value of x_i in $\texttt{obs}$ to a value in $dom[i]$. If at least one such value change causes the prediction of P_t to change, then x_i is ***relevant for*** P_t ***w.r.t.*** $\texttt{obs}$. If at least two such value changes cause the prediction of P_t to change in two different ways, then x_i is ***critical for*** P_t ***w.r.t.*** $\texttt{obs}$.

By way of illustration, consider a predictor P_3 that predicts according to the rule "$x_3 := x_1 \cdot x_2$". Given the assignment $\texttt{obs} = \langle *, 2, -1 \rangle$, the prediction of P_3 is $*$. Changing the value of x_1 in $\texttt{obs}$ to any real number causes the prediction of P_3 to change from $*$ to the double of that number. Thus, attribute x_1 is critical (and relevant) for P_3 w.r.t. $\texttt{obs}$.

Lemma 1 (Uniqueness of Critical Attributes). *Consider a predictor P_t for attribute $x_t \in \mathcal{A}$, and an assignment $\texttt{obs}$. Then: If attribute $x_i \in \mathcal{A}$ is critical for P_t w.r.t. $\texttt{obs}$, then no other attribute $x_j \in \mathcal{A}$ is relevant for P_t w.r.t. $\texttt{obs}$.*

Proof. Consider the assignment $\texttt{obs}_{u,v}$ obtained from $\texttt{obs}$ after replacing $\texttt{obs}[i]$, $\texttt{obs}[j]$ respectively with u, v. If x_i is critical for P_t w.r.t. $\texttt{obs}$, then $P_t(\texttt{obs}_{c,*})$, $P_t(\texttt{obs}_{d,*})$, $*$ are distinct for some $c, d \in dom[i]$, $c \neq d$. Assume, by way of contradiction, that x_j is relevant for P_t w.r.t. $\texttt{obs}$. Then $P_t(\texttt{obs}_{*,a}) \neq *$ for some $a \in dom[j]$. Since P_t is classical, $P_t(\texttt{obs}_{c,a}) = P_t(\texttt{obs}_{*,a}) = P_t(\texttt{obs}_{d,a}) = P_t(\texttt{obs}_{d,*}) \neq P_t(\texttt{obs}_{c,*}) = P_t(\texttt{obs}_{c,a})$; a contradiction, as needed. □

Hence, no classical predictor can have its predictions be unilaterally affected / determined by the values of more than one attribute. Although this limitation does not necessarily burden non-classical predictors, Lemma 1 bears a significant weight due to the widespread use of classical predictors in Machine Learning research. To prove that chaining does not collapse, it suffices to demonstrate any particular policy $\mathbb{P}$ that chains its predictors in a manner that effectively simulates non-classical predictors. We present such a policy next.

Consider a list $\mathcal{S}$ of complete assignments, where unbeknownst to a base algorithm, attributes x_1 and x_2 are always assigned values equal to each other, and x_3 is assigned their product. In all assignments in $\mathcal{S}^*$ available to the base algorithm, both x_3 and exactly one of x_1, x_2 are masked. Given *our* knowledge (of $\mathcal{S}$) that x_1 and x_2 share common values, we may expect the base algorithm to return a predictor P_0 for x_3 that always makes correct predictions. Using this predictor P_0, along with a predictor P_1 that predicts according to the rule "$x_1 := x_2$", and a predictor P_2 that predicts according to the rule "$x_2 := x_1$", we would be able to construct a flat policy that would be perfectly sound and complete. Alas, this scenario is not possible, as a consequence of Lemma 1.

Theorem 2 (The Benefits of Chaining). *There exist lists $\mathcal{S}^*$ and $\mathcal{S}$ such that chaining does not collapse on $\mathcal{S}^*$ against $\mathcal{S}$.*

Proof. Consider lists $\mathcal{S}^*$ and $\mathcal{S}$ as in the paragraph above.

Let policy $\mathbb{P}$ have predictors P_1 and P_2 from above in its first layer, and a predictor P_3 according to the rule "$x_3 := x_1 \cdot x_2$" in its second layer. $\mathbb{P}$ has optimal performance.

Now further specify list $\mathcal{S}^*$ and list $\mathcal{S}$ so that: At least two complete assignments $\mathtt{asg}_1, \mathtt{asg}_2 \in S$ are such that $\mathtt{asg}_1[1] \neq \mathtt{asg}_2[1]$; i.e., two different values in the domain $dom[1]$ of x_1 appear in complete assignments in $\mathcal{S}$. The assignments $\mathtt{obs}_1, \mathtt{obs}_2 \in \mathcal{S}^*$ that correspond to $\mathtt{asg}_1, \mathtt{asg}_2 \in S$ mask attribute x_2. At least one assignment $\mathtt{obs}_3 \in \mathcal{S}^*$ masks attribute x_1, and for each attribute $x_i \in \mathcal{A} \setminus \{x_1, x_2, x_3\}$, it is the case that $\mathtt{obs}_3[i] = \mathtt{obs}_1[i]$; i.e., the "context" defined by the other attributes is the same, although the values of the attributes of interest may differ.

Assume that some flat policy $\mathbb{P}'$ has optimal performance. Then, $\mathbb{P}'$ includes a predictor P_3 for x_3 that always makes a correct definite prediction. Since its predictions on $\mathtt{obs}_1$ and $\mathtt{obs}_2$ differ, then x_1 is critical for P_3 w.r.t. the assignment $\mathtt{obs}_*$ that is obtained from either $\mathtt{obs}_1$ or $\mathtt{obs}_2$ by replacing the value of x_1 with $*$. Necessarily, the prediction of P_3 when applied on $\mathtt{obs}_*$ is $*$. Assignment $\mathtt{obs}_*$ can be obtained also from $\mathtt{obs}_3$ by replacing the value of x_2 with $*$. Since predictor P_3 makes a definite prediction when applied on $\mathtt{obs}_3$, then x_2 is relevant for P_3 w.r.t. the assignment $\mathtt{obs}_*$. A contradiction by Lemma 1, as needed. □

Collectively, the predictors in policy $\mathbb{P}$ given in the proof of Theorem 2 implement a non-classical rule: "$x_3 := (x_1)^2$ if x_2 *is not known*, or $(x_2)^2$ if x_1 *is not known*". The rule's non-classical nature is evidenced by observing that if more information becomes known, the rule may retract a definite prediction it had previously made. As a matter of fact, it can be shown that any "epistemic" rule that makes predictions based not only on what holds, but also on what is *known*, can be simulated by appropriately choosing and chaining classical predictors as part of a certain policy (Michael 2008).

Can the Benefits be Realized?

Chaining predictors in some *appropriate* manner can provably enhance the combined soundness and completeness that is achieved. Are there concrete efficient algorithms that identify such a chaining? We consider two approaches below.

First Learn, Then Chain

In the first approach proceed as follows: First, call the base algorithm on list $\mathcal{S}^*$ to get one predictor P_i for each attribute $x_i \in \mathcal{A}$. Then, order the predictors to obtain a policy $\mathbb{P}$.

Such an approach captures what is implicitly assumed in certain research in KRR: that some process effectively produces the rules in the knowledge base, after which the rules can be applied in any order to draw inferences while safely ignoring the process through which the rules were produced.

Is the approach of first learning and then chaining (FLTC) the predictors ever useful? To answer this question, we need to examine more precisely the guarantees that the base algorithm is assumed to offer on the predictors it returns.

Scenario 1: Guarantees on $\mathcal{S}$

For our first scenario, assume that each P_i is guaranteed to be unsound on only an ε_i fraction of $\mathcal{S}$ against $\mathcal{S}$. Note that the predictive guarantees are w.r.t. the *complete assignments* $\mathcal{S}$, which capture the underlying reality associated with $\mathcal{S}^*$. Thus, soundness is assumed even when the predictors are applied on complete assignments in $\mathcal{S}$ (where, in particular, abstentions are disallowed); a more stringent requirement than the general case where soundness is assumed on $\mathcal{S}^*$ against $\mathcal{S}$. The problem of how such guarantees can be effectively obtained is orthogonal, and is discussed later in this work. Let $\varepsilon \triangleq \sum_{i=1}^{n} \varepsilon_i < 1$. We study the performance of $\mathbb{P}$ on $\mathcal{S}^*$.

Theorem 3 (Soundness in FLTC Setting). *Consider the predictors as described above. Any policy $\mathbb{P}$ that uses these predictors is unsound on at most an ε fraction of $\mathcal{S}^*$ against $\mathcal{S}$.*

Proof. By a union bound, since predictors are classical. □

Theorem 4 (Completeness in FLTC Setting). *Consider the predictors as described above. Let policy $\mathbb{P}$ have n layers, with each predictor appearing in every layer. Let policy $\mathbb{P}'$ be a reordering of $\mathbb{P}$. Then: If $\mathbb{P}$ and $\mathbb{P}'$ are, respectively, incomplete on an ω and ω' fraction of $\mathcal{S}^*$, then $\omega \leq \omega'$.*

Proof. The policy $\mathbb{P} + \mathbb{P}'$ that concatenates the layers of $\mathbb{P}'$ after all the layers of $\mathbb{P}$, is not less complete than $\mathbb{P}'$. It suffices to establish that $\mathbb{P}$ is not less complete than $\mathbb{P} + \mathbb{P}'$. Consider an assignment $\mathtt{obs} \in \mathcal{S}^*$. If $\mathbb{P}(\mathtt{obs}) \in dom[\mathcal{A}]$, then the claim follows. Otherwise, and since $\mathbb{P}$ has n layers, there must exist some layer in $\mathbb{P}$ that does not complete the value of any new attributes (that were not already completed by earlier layers). Since that layer is a superset of each subsequent layer in $\mathbb{P}+\mathbb{P}'$, any subsequent layer will also fail to complete the value of any new attributes. Thus, $\mathbb{P}$ and $\mathbb{P}+\mathbb{P}'$ will abstain on the same attributes. The claim follows. □

Theorems 3–4 offer a first efficient algorithm for chaining predictors, with bounded unsoundness, and optimal, in a defined sense, completeness. However, the assumed guarantees on the predictors might not always be possible to have.

Before moving on, we note that this scenario accounts for what is assumed in some KRR work: each rule truly captures the structure of the environment of interest (i.e., unsound on an $\varepsilon_i = 0$ fraction of $\mathcal{S}$), and so chaining rules in *any* order is justified without cost on the overall soundness (i.e., $\varepsilon = 0$). Further, applying each predictor (in a given knowledge base) as often as possible is optimal in terms of completeness.

Scenario 2: Guarantees on $\mathcal{S}^*$

For our second scenario, assume that each P_i is guaranteed to be unsound on only an ε_i fraction of $\mathcal{S}^*$ against $\mathcal{S}$. The predictive guarantees are w.r.t. the *observed assignments* $\mathcal{S}^*$. Let $\varepsilon \triangleq \sum_{i=1}^{n} \varepsilon_i < 1$. We study the performance of $\mathbb{P}$ on $\mathcal{S}^*$.

Although Theorem 4 holds unchanged, a naive ordering approach compromises Theorem 3 and the soundness of $\mathbb{P}$.

Theorem 5 (Unsoundness in FLTC Setting). *Consider the predictors as described above. Assume that at least one predictor is not constant on all complete assignments. Then: There exists a policy $\mathbb{P}$ (in fact, there exist exponentially in n*

many such policies) that orders these predictors that is unsound on all of $\mathcal{S}^*$ against $\mathcal{S}$, even though some reordering of $\mathbb{P}$ is unsound on at most an ε fraction of $\mathcal{S}^*$ against $\mathcal{S}$.

Proof. Let P_t be a non-constant predictor for $x_t \in \mathcal{A}$. Order $dom[\mathcal{A}]$ as a Gray Code (Knuth 2011). Choose two complete assignments $\mathtt{asg}_1, \mathtt{asg}_2 \in dom[\mathcal{A}]$ that are consecutive in the Gray Code and such that $P_t(\mathtt{asg}_1) \neq P_t(\mathtt{asg}_2)$, and let x_j be the attribute on which the assignments differ. Since P_t does not base its predictions on x_t, then $x_j \neq x_t$, and $\mathtt{asg}_1[t] = \mathtt{asg}_2[t]$. Without loss of generality, let $\mathtt{asg}_1$ be one among the two chosen complete assignments such that $P_t(\mathtt{asg}_1) \neq \mathtt{asg}_1[t]$. Construct the observed assignment $\mathtt{obs}_1$ from $\mathtt{asg}_1$ by replacing $\mathtt{asg}_1[j]$ and $\mathtt{asg}_1[t]$ with $*$.

Let $\mathcal{S}$ include only $\mathtt{asg}_1$, and let $\mathcal{S}^*$ include only $\mathtt{obs}_1$. Then, $P_t(\mathtt{obs}_1) = *$. Choose a predictor P_j for $x_j \in \mathcal{A}$ such that $P_j(\mathtt{obs}_1) = \mathtt{asg}_1[j]$. Choose a predictor P_i for each $x_i \in \mathcal{A} \setminus \{x_t, x_j\}$ such that $P_i(\mathtt{obs}_1) \in \{\mathtt{asg}_1[i], *\}$. It is consistent for all these predictors to have been returned by the base algorithm as assumed in the current scenario. A flat policy of the predictors is sound on all of $\mathcal{S}^*$ against $\mathcal{S}$.

Consider a policy $\mathbb{P}$ out of the exponentially in n many ones that order P_j before P_t. Since $P_j(\mathtt{obs}_1) = \mathtt{asg}_1[j]$, then policy $\mathbb{P}$ will apply P_t on an assignment obtained from $\mathtt{obs}_1$ by replacing $\mathtt{obs}_1[j]$ with $\mathtt{asg}_1[j]$. On this assignment, P_t will predict a value in the domain $dom[t]$ of x_t that differs from $\mathtt{asg}_1[t]$. Therefore, $\mathbb{P}(\mathtt{obs}_1)$ will not mask $\mathtt{asg}_1$, and hence $\mathbb{P}$ is unsound on all of $\mathcal{S}^*$ against $\mathcal{S}$. The flat policy given earlier, which is a reordering of $\mathbb{P}$, is trivially unsound on at most an ε fraction of $\mathcal{S}^*$ against $\mathcal{S}$. □

The severe loss of soundness in the second scenario is not due to the cumulative effect of the unsoundness of individual predictors; that happens in the first scenario. Rather, it is due to chaining *forcing* predictors to make predictions when they would have otherwise abstained. More specifically: The guarantees of each predictor P_i are w.r.t. $\mathcal{S}^*$. Yet, P_i is applied to predict on assignments that are not in $\mathcal{S}^*$, but assignments that have incorporated the predictions of predictors in earlier layers in $\mathbb{P}$. These more complete assignments are the ones that cause P_i to enhance its completeness by abstaining less, at the cost, however, of sacrificing its soundness.

SLAP-ing with Predictors

The naive FLTC approach essentially trades off soundness for completeness. To boost completeness without sacrificing soundness, the predictors need to be applied on assignments w.r.t. which they (will be made to) have guarantees.

The second approach, then, recognizes that learning and prediction cannot proceed independently, and that one needs to simultaneously learn and predict (SLAP) with predictors.

Algorithm 1, henceforth denoted by $\mathcal{L}_{\text{SLAP}}$, achieves the need to SLAP by interleaving learning and prediction to iteratively build a chained policy $\mathbb{P}$. It is given a list $\mathcal{S}^*$ of size m, a non-negative integer d indicating the desired depth of $\mathbb{P}$, and a positive value ε indicating the desired upper bound on the unsoundness of $\mathbb{P}$ on $\mathcal{S}^*$ against an *unspecified* list $\mathcal{S}$.

One should not be surprised with the requirement that algorithm $\mathcal{L}_{\text{SLAP}}$ achieves soundness guarantees on $\mathcal{S}^*$ against an unspecified, and unavailable, list $\mathcal{S}$. Meeting this seemingly inordinate requirement is critically facilitated by the oracle access that algorithm $\mathcal{L}_{\text{SLAP}}$ has to a base algorithm $\mathcal{L}_{\text{base}}$. As in the second scenario of the preceding section, we shall assume that $\mathcal{L}_{\text{base}}$ is able to provide guarantees for individual predictors on $\mathcal{S}^*$ against $\mathcal{S}$. Furthermore, we shall assume that the base algorithm $\mathcal{L}_{\text{base}}$ can be made to reduce the unsoundness of its returned predictors to any specified positive value ε_k, assuming $\mathcal{L}_{\text{base}}$ is given access to list $\mathcal{S}^*$ and is allowed time polynomial in $1/\varepsilon_k$.[3] So, as long as we do not ask for "unreasonably" small (as a function of n and m) values for ε_k, the calls to base algorithm $\mathcal{L}_{\text{base}}$ will not burden the overall computational efficiency of algorithm $\mathcal{L}_{\text{SLAP}}$.

Algorithm 1 Simultaneous Learning and Prediction

input: depth d, n attributes $\mathcal{A}$, soundness error ε, list $\mathcal{S}^*$ of m assignments, base algorithm $\mathcal{L}_{\text{base}}$ as given in text.
Set $\mathcal{S}^*_0$ to equal $\mathcal{S}^*$.
for every $k = 1, 2, \ldots, d$ **do**
  for every attribute $x_i \in \mathcal{A}$ **do**
    Call the base algorithm $\mathcal{L}_{\text{base}}$ on input x_i, $\mathcal{A}$, ε_k, δ_k, and $\mathcal{S}^*_{k-1}$, and let P_i be the predictor that it returns.
  end for
  Let $\mathbb{P}_k$ be a flat policy of the predictors $\{P_i \mid x_i \in \mathcal{A}\}$.
  Let $\mathcal{S}^*_k$ be the list of assignments given by $\mathbb{P}_k(\mathcal{S}^*_{k-1})$.
end for
Set $\mathbb{P}$ so that its j-th layer includes the predictors in $\mathbb{P}_j$.
output: Return the policy $\mathbb{P}$, and terminate.

Given oracle access to base algorithm $\mathcal{L}_{\text{base}}$ with the characteristics described above, algorithm $\mathcal{L}_{\text{SLAP}}$ calls $\mathcal{L}_{\text{base}}$ on $\mathcal{S}^*$ to obtain a predictor for each attribute, and applies these predictors in parallel to update the assignments in $\mathcal{S}^*$. It repeats the process, by calling algorithm $\mathcal{L}_{\text{base}}$ on the new assignments to obtain a new predictor for each attribute, and applying the new predictors in parallel to further update the assignments, and so on for d iterations. Algorithm $\mathcal{L}_{\text{SLAP}}$ keeps track of all predictors $\mathbb{P}_j$ obtained and applied in each iteration, and constructs the policy $\mathbb{P}$ by assigning in its j-th layer the predictors that were used during the j-th iteration.

We have purposefully left unspecified what values would be considered "reasonable" for ε_k, both in the discussion above, and in Algorithm 1. We will examine two scenarios.

For our first scenario, we assume that accessing all assignments in $\mathcal{S}^*$ is conceptually meaningful and computationally plausible; e.g., when seeking to recover missing information in all records of a database. Since time linear in n and m is already needed just for reading all of $\mathcal{S}^*$, it seems reasonable to allow ε_k to be an inverse linear function of n and m.

Observe, then, that setting $\varepsilon_k = 1/2m$ would ensure that each predictor returned by $\mathcal{L}_{\text{base}}$ during the k-th iteration of $\mathcal{L}_{\text{SLAP}}$ would be perfectly sound on $\mathcal{S}^*_{k-1}$, and so would policy $\mathbb{P}_k$. As a result, list $\mathcal{S}^*_k$ would be noiseless, and by induction the returned policy $\mathbb{P}$ would be perfectly sound on $\mathcal{S}^*$.

[3] We have already remarked on the black-box view of base algorithms taken herein, and the emphasis, instead, on their appropriate use. Nonetheless, we remind the reader that such base algorithms can be constructed under typical assumptions (Michael 2010).

For our second scenario, we assume that assignments in $\mathcal{S}^*$ can only be sampled or otherwise only partly accessed; e.g., when seeking to learn predictors from a sample of data with the aim to apply them on future data. Time linear in n is still needed just for reading a single assignment in $\mathcal{S}^*$, but no dependence of the running time on m can be generally assumed.[4] Thus, we shall not allow ε_k to depend on m.

Exactly due to the restricted access assumed on $\mathcal{S}^*$, $\mathcal{L}_{\text{base}}$ may occasionally fail to produce a predictor with the sought unsoundness ε_k. Analogous to our treatment for ε_k, we shall assume that the base algorithm $\mathcal{L}_{\text{base}}$ can be made to reduce the failure probability to any specified positive value δ_k, assuming $\mathcal{L}_{\text{base}}$ is allowed time polynomial in $1/\delta_k$. For reasons same as for ε_k, we shall not allow δ_k to depend on m.

Given a base algorithm $\mathcal{L}_{\text{base}}$ as discussed above, we can establish that SLAP preserves soundness despite chaining.

Theorem 6 (Soundness in SLAP Setting). *For any inputs and value δ, there exist values ε_k and δ_k such that the policy $\mathbb{P}$ returned by algorithm $\mathcal{L}_{SLAP}$ is, except with probability δ, unsound on at most an ε fraction of $\mathcal{S}^*$ against $\mathcal{S}$. For fixed d, algorithm $\mathcal{L}_{SLAP}$ runs in time polynomial in n, $1/\varepsilon$, $1/\delta$.*

Proof. Let $q(n, 1/\varepsilon_k, 1/\delta_k)$ be a polynomial that determines the running time of the base algorithm $\mathcal{L}_{\text{base}}$ on input $\mathcal{A}$, ε_k, δ_k. It is easy to show that algorithm $\mathcal{L}_{\text{SLAP}}$ runs in time

$$O\left(d \cdot poly(n) \cdot \sum_{k=1}^{d} q(n, 1/\varepsilon_k, 1/\delta_k)\right).$$

Set $\delta_k := \delta/2d$. Then, there is a polynomial $p(n, 1/\delta, d)$ and a constant c such that setting $\varepsilon_k := (\varepsilon/p(n, 1/\delta, d))^{c^{d-k}}$ establishes that the running time of algorithm $\mathcal{L}_{\text{SLAP}}$ is polynomial in n, $1/\varepsilon$, $1/\delta$ for fixed d. Furthermore, the choices of δ_k and ε_k guarantee that, except with probability δ, each call of $\mathcal{L}_{\text{base}}$ will return a sufficiently sound predictor such that whenever it is applied in the context of algorithm $\mathcal{L}_{\text{SLAP}}$, its predictions will be sound (i.e., the improbable event of making unsound predictions will never occur). Overall then, except with probability δ, the above effectively reproduces the noiseless intermediate predictions of the first scenario. □

Theorem 6 is to the SLAP setting what Theorem 3 is to the FLTC setting. Analogously to Theorem 4 for the FLTC setting, one can show that the completeness of algorithm $\mathcal{L}_{\text{SLAP}}$ is optimal for certain natural settings. The settings in question are those where attributes (i.e., notions whose definitions one may wish to learn) are defined in terms of one another in a hierarchical fashion, so that there are no directed cycles in the definitions. We formalize such settings below.

A list $\mathcal{S}$ of complete assignments is ***d-stratified*** if for a partitioning $\mathcal{A}_1, \ldots, \mathcal{A}_d$ of $\mathcal{A}$, and for every $x_i \in \mathcal{A}_j$, there is a predictor P_i sound on all of $\mathcal{S}$ against $\mathcal{S}$ and complete on all of $\mathcal{S}$, that does not base its predictions on $A_j \cup \ldots \cup \mathcal{A}_d$.

We shall assume that we have access to base algorithms, which we shall call ***focused***, that return predictors that do not base their predictions on attributes that are clearly irrelevant due to the stratification of $\mathcal{A}$. Such base algorithms can be constructed either by having direct access to the partitioning if it is known, or by exploiting domain-specific knowledge, attribute-efficient learning, or other relevant techniques.

By way of illustration, let $d = 4$, $x_5 \in \mathcal{A}_2$ and $x_3 \in \mathcal{A}_4$, and $\texttt{obs} = \langle 8, -3, *, 7, *, -2\rangle$. Any predictor P_5 for x_5 returned by a focused base algorithm makes a definite prediction, since none of the attributes $\mathcal{A} \setminus (A_2 \cup \mathcal{A}_3 \cup \mathcal{A}_4)$ is masked. On the other hand, a definite prediction by a predictor P_3 for x_3 might not be possible since the value of x_3 may depend on the value of x_5, which is masked in obs. If we consider, however, a policy $\mathbb{P}$ that chains P_3 after P_5, the prediction of the latter predictor necessarily completes x_5's value before the prediction of the former predictor on x_3, *ensuring* that a definite prediction is made by P_3 for x_3.

We show that algorithm $\mathcal{L}_{\text{SLAP}}$ guarantees predictors with optimal completeness in such stratified settings.

Theorem 7 (Completeness in SLAP Setting). *Consider any integer value d, a d-stratified list $\mathcal{S}$ of complete assignments, and an associated list $\mathcal{S}^*$. Assume that algorithm $\mathcal{L}_{SLAP}$ has oracle access to a focused base algorithm $\mathcal{L}_{base}$ and returns a policy $\mathbb{P}$ of depth d. Then: $\mathbb{P}$ is complete on all of $\mathcal{S}^*$.*

Proof. The claim follows by straightforward induction. □

Theorems 6–7 offer a second algorithm for chaining predictors, with bounded unsoundness, and optimal completeness when in stratified settings. The algorithm is efficient for constant-depth policies. Unlike the first algorithm of Theorems 3–4, the second algorithm is more realistic in assuming a base algorithm with guarantees w.r.t. $\mathcal{S}^*$, instead of $\mathcal{S}$.

Although it remains open whether the efficiency guarantees of Theorem 6 can be extended to hold for super-constant values of d, several natural modifications to algorithm $\mathcal{L}_{\text{SLAP}}$ fail to resolve this question: *(i)* Employing base algorithms that produce predictors by expending sub-linear resources in the inverse error parameter $1/\varepsilon_k$ are excluded (Ehrenfeucht et al. 1989). *(ii)* Base algorithms that *identify* their inaccurate predictions (Rivest and Sloan 1994) employ a strategy that does not scale up to expressive predictors, and fails to work when instead of complete assignments one has access to arbitrary assignments. *(iii)* Training all predictors on a common set of assignments (Valiant 2000) corresponds, effectively, to the FLTC scenario and not to the SLAP scenario considered herein. *(iv)* Appealing to noise-resilient base algorithms also fails,[5] as the unsound predictions of the predictors in earlier layers of $\mathbb{P}$ can be shown (Michael 2008) to correspond to malicious noise for the predictors in later layers of $\mathbb{P}$. Such malicious noise is known to be especially intolerable by base algorithms (Kearns and Li 1993).

Overall, then, evidence suggests that interleaving learning and prediction is a solid approach when seeking to improve

[4] Under this second scenario, algorithm $\mathcal{L}_{\text{SLAP}}$ can no longer be assumed to explicitly compute the list $\mathcal{S}^*_k := \mathbb{P}_k(\mathcal{S}^*_{k-1})$ during the last step of the k-th iteration. This can be easily dealt with, by lazily computing parts of $\mathcal{S}^*_k$ if and when needed for subsequent steps.

[5] We are not suggesting that noise-resilient (or otherwise robust) base algorithms be avoided altogether, only that doing so does not improve asymptotically the achieved chaining depth. One can investigate how the noise-resilience of base algorithms relates to that of $\mathcal{L}_{\text{SLAP}}$ (as done for soundness and completeness). We have not considered noise in this work to avoid obscuring the main points.

completeness without sacrificing soundness. Even in scenarios where d-stratification is not a priori guaranteed, calling $\mathcal{L}_{\text{SLAP}}$ with increasing values for d allows the effective trade-off of time for possibly better, but never worse, performance.

Explicit Completeness

We have established in certain settings *explicit* bounds on the unsoundness of our considered policies, but only a type of optimal, not always specific, degree of completeness. Why not expect algorithms to return policies with *explicit* bounds on their degree of completeness? The answer is two-fold:

First, completeness depends externally on the masking process used to produce list $\mathcal{S}^*$ from list $\mathcal{S}$. In the interest of generality — and this happens to be the case in certain natural settings — no assumptions on how this masking process operates have been (or can be) made. The more information is missing in list $\mathcal{S}^*$ the more a policy is forced to abstain, as long as one insists, as we have done herein, that soundness should not be severely compromised to boost completeness.

Second, even if one can construct efficiently a policy that achieves either perfect soundness or perfect completeness, and even if sufficient information is available in list $\mathcal{S}^*$ for some policy to make perfectly sound and perfectly complete predictions, it is still not possible, in general, to achieve efficiency, soundness, and completeness together. We establish next a barrier to efficiently constructing a policy that simultaneously has soundness that is slightly better than a policy that predicts with constant predictors, and has completeness that is slightly better than a policy that makes no predictions.

Definition 2 (Properties of Policy-Learning Algorithms). *In what follows, **parameters** are: an integer $n > 1$, a list $\mathcal{S}$ of complete assignments over a set $\mathcal{A}$ of n attributes, and a list $\mathcal{S}^*$ of assignments. A policy-learning algorithm $\mathcal{L}$:*

*(i) is **computationally efficient** if there is a polynomial $r(\cdot,\cdot)$ such that for every choice of the parameters, $\mathcal{L}$ takes $\mathcal{A}$ and $\mathcal{S}^*$ as input, and returns a policy $\mathbb{P}$ in time $r(n, |\mathcal{S}^*|)$;*

*(ii) achieves **non-trivial soundness** if there is a polynomial $s(\cdot)$ such that for every choice of the parameters, $\mathcal{L}$ takes $\mathcal{A}$ and $\mathcal{S}^*$ as input, and returns a policy $\mathbb{P}$ that is sound on an $1/2 + 1/s(n)$ fraction of $\mathcal{S}^*$ against $\mathcal{S}$;*

*(iii) achieves **non-trivial completeness** if there is a polynomial $c(\cdot)$ such that for every choice of the parameters, $\mathcal{L}$ takes $\mathcal{A}$ and $\mathcal{S}^*$ as input, and returns a policy $\mathbb{P}$ that is complete on an $1/c(n)$ fraction of $\mathcal{S}^*$.*

Given these desirable properties for a policy-learning algorithm, the following observations are immediate: The trivial algorithm that returns the empty policy is computationally efficient and perfectly sound. The trivial algorithm that returns a policy comprising one constant predictor for each attribute is computationally efficient and perfectly complete.

Achieving perfect soundness and perfect completeness is easily shown to be impossible if information is hidden adversarially. Assume, therefore, that we are in a non-adversarial setting, where this third combination of two desirable properties is achievable. It it still the case that achieving all three properties simultaneously is impossible, even if only non-trivial soundness and non-trivial completeness is required.

Theorem 8 (Barriers to Explicit Completeness). *Under typical cryptographic assumptions (Kearns and Vazirani 1994), no algorithm that returns policies is computationally efficient and achieves non-trivial soundness and non-trivial completeness. This is so even if there is a perfectly sound and perfectly complete policy, and such policy can be approximated by a (possibly inefficient) PAC learning algorithm.*

Proof. Assume that the claim does not hold for an algorithm $\mathcal{L}$, and consider the polynomials $r(\cdot,\cdot)$, $s(\cdot)$, $c(\cdot)$ from Definition 2. Consider any concept class known not to be weakly PAC-learnable under standard cryptographic assumptions (Kearns and Vazirani 1994). For any function in the class, and every distribution $\mathcal{D}$ over examples, construct a list $\mathcal{S}$ of $m \cdot c(n) \cdot (s(n)+1)$ complete assignments by sampling examples from $\mathcal{D}$ and assigning to x_1 their label according to f. Construct the list $\mathcal{S}^*$ by masking attribute x_1 in each assignment except with probability $1/(c(n) \cdot (s(n)+1))$.

The policy that includes only predictor f for x_1 is sound on all of $\mathcal{S}^*$ against $\mathcal{S}$, and complete on all of $\mathcal{S}^*$. In addition, choosing m to be sufficiently large (but still polynomial in n and the PAC error parameters $1/\varepsilon$ and $1/\delta$), PAC learning can be achieved by finding any function in the concept class that is consistent with assignments in $\mathcal{S}^*$ that are complete.

Running algorithm $\mathcal{L}$ on $\mathcal{S}^*$ for time $r(n, |\mathcal{S}^*|)$ will return a policy $\mathbb{P}$ that is non-trivially complete on $\mathcal{S}^*$, and, therefore, complete on $|\mathcal{S}^*|/c(n)$ assignments, which is more than those already complete in $\mathcal{S}^*$. Then, $\mathbb{P}$ includes a predictor g for x_1 that makes predictions on every assignment in $\mathcal{S}^*$. Policy $\mathbb{P}$ is also non-trivially sound on $\mathcal{S}^*$ against $\mathcal{S}$, and, therefore, sound on at least $(1/2 + 1/s(n)) \cdot |\mathcal{S}^*|$ assignments against $\mathcal{S}$. Ignoring the assignments that are complete in $\mathcal{S}^*$ (and on which the prediction of g is qualified), g predicts correctly with probability $((1/2 + 1/s(n)) \cdot |\mathcal{S}^*| - m)/(|\mathcal{S}^*| - m) \geq 1/2 + 1/2s(n)$. Since $|\mathcal{S}^*|$ is polynomial, so is $r(n, |\mathcal{S}^*|)$, and therefore the concept class is weakly PAC-learnable; a contradiction, and the claim follows. □

Applications and Implications

We have chosen to motivate and present our framework in the context of a single list $\mathcal{S}^*$ of observed assignments that one seeks to complete further. The choice mostly serves to not clatter our central claims: *(i)* chaining predictors is provably beneficial, and *(ii)* the benefits can be realized by (and only by — at least for certain natural strategies) an iterative learning and prediction process. The same ideas and formal results presented herein can be applied to other settings that have been traditionally studied in Machine Learning.

The first point worth making is that the framework applies equally well to the traditional setting of *distinct* training and testing sets. There, $\mathcal{S}^*$ plays the role of the testing set, while another list $\mathcal{T}$ of assignments plays the role of the training set accessed by the base learning algorithm to provide the sought guarantees on each predictor P_i. The only modification needed to the framework is that of giving access to $\mathcal{T}$ instead of $\mathcal{S}^*$ to the learning algorithms. In the first scenario of the FLTC setting, $\mathcal{T}$ is a list of complete assignments drawn from the same distribution as those in $\mathcal{S}$. In the second scenario of the FLTC setting and in the SLAP setting, $\mathcal{T}$ is a list of assignments drawn from the same distribution as those in $\mathcal{S}^*$. Existing models of learning from complete (Valiant

1984; Michael 2011a) or observed (Michael 2010) assignments, show that these choices of $\mathcal{T}$ suffice to efficiently and reliably obtain the guarantees on P_i assumed herein.

A second important point is that the central claims of this work apply also to the traditional supervised classification / regression setting, where certain, possibly continuous and / or unobserved, features are used to inform a prediction on a *single* target attribute $x_t \in \mathcal{A}$, which is observed during training but not during testing. First, note that the proofs of our results, other than those in the SLAP section, go through even if we insist that some target attribute x_t is never observed in the testing set $\mathcal{S}^*$, and always observed in the training set $\mathcal{T}$ that one uses to produce each predictor P_i.

For the results in the SLAP section, we argue as follows: Assume that some target attribute x_t is always observed both in the testing set $\mathcal{S}^*$ and in the training set $\mathcal{T}$. Theorem 6 holds for this choice of $\mathcal{S}^*$. Now, mask x_t in all assignments in $\mathcal{S}^*$ to obtain $\overline{\mathcal{S}^*}$. The change from $\mathcal{S}^*$ to $\overline{\mathcal{S}^*}$ affects only the completeness of $\mathbb{P}$, and hence Theorem 6 still holds. To avoid affecting completeness also, and to ensure that Theorem 7 holds, choose a partitioning with $x_t \in \mathcal{A}_d$, so that no predictor can base its prediction on the value of x_t, and so that the completeness guarantees on $\mathcal{S}^*$ and on $\overline{\mathcal{S}^*}$ coincide.

So, chaining predictors is beneficial for supervised learning, and SLAP helps realize these benefits. Seeking to develop classification / regression algorithms that are robust to missing information is bound to either produce non-classical predictors or result in worse performance than SLAP.

A final point relates to using predictors to complete missing values, but never to override observed values. This view aligns with KRR work that treats observations as indefeasible, and as exogenously qualifying rules (Kakas, Michael, and Miller 2011; Michael 2013b). Although we have chosen to adopt this treatment, we note that predictors that override observed values would also be useful, especially in settings where a prediction might possibly correct an observed noisy value. This choice is inconsequential for our results herein.

Conclusions and Related Work

This work has initiated a formal investigation of interleaving learning and prediction with multiple predictors, examining the guarantees one may get under minimum assumptions.

Among works that interleave learning and prediction, Inductive Logic Programming (Muggleton 1991) typically differs from this work in: *(i)* placing less emphasis on computational efficiency; *(ii)* seeking to fit available data instead of providing statistical guarantees during prediction; *(iii)* producing predictors that never abstain (under the Closed World Assumption) instead of bounding their incompleteness.

Some form of interleaved learning and prediction is found in Transformation-Based Learning (Brill 1993), although little emphasis seems to have been placed on its formal analysis. TBL predictors aim to correct initial heuristic predictions rather than make predictions only when it is justified.

Rivest and Sloan (1994) learn predictors in a layered manner, with subsequent predictors being trained on the predictions of earlier ones. This resembles the SLAP setting, but their approach does not extend to assignments with missing information. Also, unlike us, they achieve super-constant depth of chaining, at the expense, however, of considering severely restricted classes of predictors. Attempting to integrate their and our approach is certainly worth looking into.

Valiant (2000) considers the parallel learning of predictors before their chaining, as in the first scenario under the FLTC setting. As in our approach, it is the availability of base algorithms with guarantees on complete assignments that allows the decoupling of learning and prediction. Both of our works place emphasis on efficiency and predictive guarantees. The relational learning and the two types of missing information that he employs can be carried over to our framework.

Read et al. (2009) investigate a version of multi-label classification with predictions for a label being available when training predictors for other labels. To account for their suboptimal random ordering of the predictors, they produce ensembles of such orderings. Instead of a distinguished fixed set of labels, we allow predictions on all attributes that may happen to be masked. Instead of an ensemble of orderings, we produce a single universal ordering. Finally, our emphasis is on the formal analysis and understanding of when SLAP is provably useful. To that end, the principled treatment of missing information and abstentions is essential.

Chaining learned predictors differs from learning circuits, neural networks, or other expressive functions, where the values of internal nodes are never observed during the training (or testing) phase. Furthermore, missing information (on internal nodes) is only implicitly completed during prediction, whereas we do so explicitly, and also allow abstentions.

In the spirit of implicit reasoning, Juba (2013) considers a setting of partially observed assignments closely following the one of our work (Michael 2010), and chains learned rules without, however, explicitly representing them. It remains an intriguing question to understand the comparative advantages of the implicit and explicit representations of learned rules, in terms of the performance (soundness and completeness) achieved when they are chained to draw inferences.

On the empirical front, the benefits of chaining have been demonstrated on the massive-scale extraction of commonsense knowledge from raw text (Michael and Valiant 2008) and on other language-related tasks (Doppa et al. 2011). The results obtained in this work can be seen to offer a formal basis for these experimental results, while the latter exemplify the applicability of our framework in real-world settings.

Some arguments and empirical evidence in other contexts also point to the benefits of chaining rules (Dietterich 2000; Valiant 2006), for reasons ultimately related to limitations of the base algorithms: hypothesis class expressivity, statistical and computational constraints, data availability. This work *formally* ties the benefits of chaining to a limitation of rules (cf. Lemma 1), and seeks ways to realize them. Certain ideas from our work have been argued (Michael 2009) to be important in the Recognizing Textual Entailment task (Dagan, Glickman, and Magnini 2005). The design of base algorithms has been considered (Michael 2010), with applications (Michael 2013a), and open problems (Michael 2011b).

The goal of enhancing completeness resembles the goal of "boosting" from Machine Learning, where one seeks to improve a weakly sound predictor. A typical boosting approach (Schapire 1990) proceeds by learning a sequence of predic-

tors, each trained on those assignments on which the preceding predictor was unsound. At this abstract level, the parallels with our work are immediate: SLAP attempts to improve a weakly complete predictor set by learning a sequence of such predictor sets, each trained on those assignments on which the preceding predictor set was incomplete. Of course there are critical differences as well, not the least of which being that an unsound prediction cannot be identified during testing, whereas an incomplete one can. Understanding the parallels and differences in more technical detail may allow boosting techniques to be adapted and adopted for the problem of improving the completeness of predictors.

Regarding discussions pointing out that Machine Learning research has focused on the construction of flat (in our defined sense) predictors (Dietterich 2003), this work offers a glimpse of what one may expect when moving to a chained (and more structured) use of predictors. The work presented herein offers a concrete basis upon which a large scale investigation of this intriguing phenomenon may be carried out.

Tackling Winograd Schemas by Formalizing Relevance Theory in Knowledge Graphs

Abstract

We study disambiguating of pronoun references in Winograd Schemas, which are part of the Winograd Schema Challenge, a proposed replacement for the Turing test. In particular we consider sentences where the pronoun can be resolved to both antecedents without semantic violations in world knowledge, that means for both readings of the sentence there is a possible consistent world. Nevertheless humans will strongly prefer one answer, which can be explained by pragmatic effects described in Relevance Theory. We state formal optimization criteria based on principles of Relevance Theory in a simplification of Roger Schank's graph framework for natural language understanding. We perform experiments using Answer Set Programming and report the usefulness of our criteria for disambiguation and their sensitivity to parameter variations.

Introduction

The Winograd Schema Challenge (Levesque, Davis, and Morgenstern 2012) is an anaphora resolution task which was proposed as a challenging but more reasonable alternative for the Turing Test. The challenge has received interest in the Artificial Intelligence community and beyond (Marcus 2013) as a chance to push forward natural language *understanding* capabilities of computers.

Winograd Schemas (WSs) are pairs of sentences that are referential ambiguous, i.e., they can be semantically interpreted in at least two distinct ways. Only one of these interpretations is correct and humans easily identify the correct one.

$$\begin{array}{l}\text{There is [a gap]}_g \text{ in [the wall]}_w.\\ \text{You can see the garden through it}_{w,g?}.\end{array} \quad (1)$$

$$\begin{array}{l}\text{There is [a gap]}_g \text{ in [the wall]}_w.\\ \text{You can see the garden behind it}_{w,g?}.\end{array} \quad (2)$$

(1) and (2) show such a pair of sentences, where we denote phrases with square brackets and coreference using subscripts. Here the pronoun 'it' is ambiguous between noun phrases 'a gap' and 'the wall'. In (1) the solution is 'it_w' — we can see the garden through the gap, in (2) the solution is 'it_g' — we can see the garden behind the wall. Note that only a single word differs between (1) and (2). This WS can be disambiguated by reasoning over world knowledge such as 'walls are solid objects', 'solid objects are nontransparent', and 'one cannot see through nontransparent objects'. An interesting challenge of WSs is that they seem to *require deep reasoning* beyond the surface of the text, in particular beyond the current state of the art of (mostly statistical) natural language processing technology.

Some schemas can be disambiguated using linguistic theories of text structure, for example the following.

$$\begin{array}{l}\text{[Pete]}_p \text{ envies [Martin]}_m\\ \text{because he}_{p,m?} \text{ is very successful.}\end{array} \quad (3)$$

$$\begin{array}{l}\text{[Pete]}_p \text{ envies [Martin]}_m\\ \text{although he}_{p,m?} \text{ is very successful.}\end{array} \quad (4)$$

In (3) the word 'because' indicates that '$\text{he}_{p,m?}$ is very successful' is a plausible reason for 'Pete envies Martin'. As a result we can rule out the coreference 'he_p' because Martin's success is a more plausible cause for Pete's envy than Pete's success, hence the solution is 'he_m'.

Such reasoning is already challenging, however it is not always sufficient: there are WSs where both possible coreferences correspond to a world where the sentence makes sense — text structure and world knowledge are not sufficient for tackling Winograd Schemas.

One example for such a schema is the following.

$$\begin{array}{l}\text{[Sam's drawing]}_s \text{ was hung just above [Tina's } \emptyset]_t \text{ and}\\ \text{it}_{s,t?} \text{ did look much better with another one below it.}\end{array} \quad (5)$$

$$\begin{array}{l}\text{[Sam's drawing]}_s \text{ was hung just above [Tina's } \emptyset]_t \text{ and}\\ \text{it}_{s,t?} \text{ did look much better with another one above it.}\end{array} \quad (6)$$

(The '$\emptyset$' indicates an omission (ellipsis) of 'drawing'.)

In these sentences we can imagine a world where the drawing 'below it' or 'above it' is a third drawing, neither Sam's nor Tina's: then the pronoun can be either 'it_s' or 'it_t'.

Humans intuitively chose 'it_s' for (5) and 'it_t' for (6), intuitively because these readings of the sentences are much *more relevant* and *less far-fetched* than their alternatives.

In this work we focus on the disambiguation of such Winograd Schemas, schemas where we have to go beyond semantics and text structure because they are not sufficient for disambiguation.

We will approach this problem using Relevance Theory (Wilson and Sperber 2006), which measures relevance in

terms of *positive cognitive effect* – intuitively defined as the amount of inferences that are possible – minus the *processing effort* of achieving that effect. Relevance Theory is based on informal notions of human reasoning, hence integrating this theory into formal reasoning is not straightforward.

We propose a method for disambiguating WSs based on a formalization of criteria of Relevance Theory and present the following contributions.

- We formally describe a *knowledge graph* data structure which is a simplification of Roger Schank's psychological model of natural language understanding (Schank 1972).
- We formally describe a *reasoning process* that combines an input knowledge graph with background knowledge graphs, including constraints on certain intuitively necessary graph properties.
- Based on notions from Relevance Theory we propose a *relevance fitness function* on knowledge graphs.
- We report on *experiments* for *evaluating parameters* of that fitness function using Answer Set Programming.

Preliminaries

Winograd Schemas (WSs) were described by Winograd (1972), they are twin sentences with an ambiguous pronoun (see Hirst (1981) for a survey) and a *special word* such that exchanging this word with its *alternate word* changes the reference to another entity in the sentence. For example in the pair (1)/(2), the pronoun 'it' is ambigous between antecedent noun phrases 'a gap' and 'the wall', the special word is 'through' with its alternate word 'behind', the correct coreference is 'it_g' for (1) and 'it_w' for (2).

Levesque, Davis, and Morgenstern (2012) proposed the Winograd Schema Challenge as an alternative for the Turing Test, arguing that disambiguating WS requires true understanding of text on the one hand, and is more practical and more reasonable than the Turing Test on the other hand because (i) it does not require deception by the computer, (ii) does not require conversation, (iii) permits objective and automatic scoring, and (iv) requires deep reasoning over the input and the utilization of world knowledge.

They describe two important conditions on WSs used in such a challenge: (1) it shall not be possible to disambiguate the coreference by *selectional restrictions*, i.e., both antecedents must be of the same gender and number, moreover *straightforward statistical methods* shall not allow a clear disambiguation.[1] Moreover, (2) untrained human subjects shall identify the *correct* answer *without effort*.

The aim of the first condition is to require true text understanding to achieve success in the challenge, the second condition aims at a strong methodology with repeatable tests.

The original proposal of the challenge contains sentence pairs with a question, where the answer of the question asks for the referent of the pronoun. We will omit that question and instead check if the pronoun was resolved correctly.

Pragmatics is the linguistic field that analyses the effects of *context* on utterances. Note that'utterance' in linguistics denotes written, spoken, and signed natural language, similarly 'speaker' resp., 'hearer' denotes producers resp., consumers of natural language in all modalities. Moreover 'context' denotes linguistic, historical, cultural, and situative context.

From the perspective of WSs, pragmatics can provide useful insights about how the first part of a WS (the context) influences anaphora resolution in the second part (where the pronoun is located).

Relevance Theory (RT) is a popular theory within pragmatics, developed by Wilson and Sperber (2006). Their *Communicative Principle of Relevance* states that every utterance raises the expectation of its own optimal relevance, i.e., a hearer may interpret an utterance under the assumption that it is most relevant among all possible alternative utterances.

RT aims to 'explain in cognitively realistic terms what these expectations of relevance amount to, and how they might contribute to an empirically plausible account of comprehension.' This aim led to cognitive results that we will carry over to terms of knowledge representation, automated reasoning, and computation.

We will focus on three definitions of RT: relevance, processing effort, and positive cognitive effect.

Relevance of an utterance depends on two factors: other things being equal, (a) the greater the *processing effort* spent on interpreting an utterance, the lower its relevance, and (b) the greater the *positive cognitive effects* achieved by interpreting an utterance, the greater its relevance.

Processing effort is defined as the effort spent on perception, memory, and inference. Different contexts have different levels of accessibility (salience) for certain concepts such that processing effort for the same utterance can differ greatly between contexts.

Positive Cognitive Effect is 'a worthwhile difference to the individual's representation of the world'. Concretely it is defined wrt. the knowledge that can be concluded by a hearer using some mechanism of inference in human cognition.

According to RT, the most important cognitive effect is *contextual implication*: knowledge inferred from context C and utterance U that is not inferrable from C or U alone. Further positive cognitive effects are strengthening, revision, or abandonment of available *assumptions*.

Roger Schank's Knowledge Representation (1972) aims to provide a theory of human natural language understanding based on a graph formalism of concepts and dependencies that represent utterances and whole discourses.

A concept is either a nominal (e.g., 'book' or 'John'), an action (e.g., most verbs), or a modifier (e.g., adjectives). Dependencies can be of several types and directions, for example 'John $\leftrightarrow$ sleep' means that John sleeps. They can be annotated with temporal information, e.g., 'I $\leftrightarrow^p$ hit $\leftarrow^o$ John' means that John was hit by me (o indicates the object role and p the past).

Reasoning is described as looking up graph snippets from a library when encountering related input, a 'conceptual processor' that connects graph snippets according to conceptual rules, a 'syntactic processor' that ensures no syntactic constraints are violated. Later work by Schank (1980) makes several of these ideas more concrete (in particular memory

[1] As an example, if the antecedents are 'women' and 'pills' and the special words are 'pregnant' and 'carcinogenic', then the schema is too obvious to resolve, it is 'not Google-proof'.

organization) but is still far away from a formal account of how that reasoning is performed.

Related Work

Rahman and Ng (2012) proposed a machine-learning approach for tackling Winograd Schemas. They take into regard features such as narrative chains, FrameNet information, semantic compatibility, and polarity biases, and report a correctness result of 73% compared to 55% obtained via the state-of-the-art Stanford resolver (Lee et al. 2011). Some of their features are related to biases in language cognition.

Such biases are described by Kehler et al. (2008) who describe that pronoun interpretation is influenced by which coherence relations are likely to appear and which expectations about following entities are likely to occur. This is explained in more detail by Hartshorne (2013): e.g., a pronoun in a 'result' clause will most likely refer to the previous clauses' affected entity, while a pronoun in an 'explantory' clause most likely refers to entities that are causes.

As WSs are twin sentences, these biases should not make disambiguation easier. However, note that this is not true, if the word that evokes the bias is the special word itself (i.e., 'because' and 'although' should not be special words).

Relevance Formalizations. Gärdenfors (1978) discusses a logical account of relevance that formalizes whether some piece of logical evidence can influence the truth value of a sentence. Delgrande and Pelletier (1998) go a step further and define relevance as a property of sentences in relation to conditionals in conditional logic (which allows nonmonotonic inferences). They state that relevance in a logical formalism must be defined on the meta-level instead of within that formalism. We similarly apply our relevance fitness function on a meta-level to evaluate the reasoning process and its potential outcomes.

Understanding natural language requires taking assumptions and truly engaging in a process of *interpreting* a given linguistic input. This makes natural language so efficient but allows for complex misunderstandings. Relevance Theory, and the notion of relevance we pursue in this work, aims to pinpoint the *correct assumptions* a hearer has to make about a linguistic input such that the hearer obtains the interpretation intended by the speaker. (E.g., a flight attendant can use 'seat 3a' to refer to a passenger or to the purchase of a passenger at that seat.) Hence our notion of relevance is related to Gärdenfors, Delgrande and Pelletier's approaches but it is about human interpretation rather than about logical truth.

Hobbs et al. (1993) interpret natural language by abducing as few as possible assumptions to explain as much as possible observed input. The approach we introduce in the following can be considered to be abduction, but we evaluate relevance not only on the amount of abduced pieces of knowledge but in a more holistic way that considers global as well as local graph properties. Moreover our approach considers how well background knowledge integrates into the input during the reasoning process.

Textual Structure. As noted in the introduction, many Winograd Schemas can be solved by identifying expectations evoked by the textual structure of the input, and verifying if these expectations are violated by the semantic content of one or the other reading of the input.

One theory explaining such expectations is Rhetorical Structure Theory (RST) (Mann and Thompson 1988; Taboada and Mann 2006) which describes text organization as relations between parts of text, mostly between pairs of adjacent text spans. Such relations can be explicit in an utterance, e.g., the words 'if' or 'because', but they can be implicit, which creates the challenge of detecting them.

RST argues with similar principles as Relevance Theory, explaining textual structure as *providing relevant knowledge* that can be *integrated readily* into context and also *strengthening or justifying assumptions*. Both theories are likely to be necessary in a system that can disambiguate WSs.

Graph-Based Knowledge Representation. Important works related to our graph knowledge representation are knowledge bases and ontologies for natural language processing such as the Component Library (Barker, Porter, and Clark 2001), Generalized Upper Model (Bateman et al. 2010), and YAGO (Suchanek, Kasneci, and Weikum 2007). These and similar ontologies use formal logic (often Description Logics (Baader et al. 2003)) to categorize and relate linguistic terms, they are systematically engineered to cover a broad range of domains and applications. Contrary to that we use a lightweight graph framework to represent linguistic input and background knowledge, with the aim of studying the formalization of relevance. We hope that the results of this work can be applied also to these more systematic ontologies, as they have natural representations as graphs. As stated by Chaudhri, Dinesh, and Inclezan (2013), to be useful in natural language processing an ontology must be *linguistically motivated*.

Conceptual Blending (Pereira 2008) is an approach that is structurally similar to our knowledge graphs, however Blending has the goal to create *creativity* in AI systems. This is achieved by 'blending' knowledge graphs using associations of concepts that have similar properties, giving rise to 'metaphorical' and 'creative' computational reasoning.

Relevance in Conceptual Blending is formulated as a fitness *with respect to a reasoning goal*, for example the 'horse' and the 'bird' microtheory can be blended in different ways, and if we impose the goal 'flying' then a blend that is compatibly with flying is more relevant.

Knowledge Graphs and Reasoning

Schank aimed to provide a psychological model of how human reasoning works for understanding text. We next define a graph framework inspired by this model and formalize reasoning based on combining nodes of knowledge graphs without violating certain constraints of these graphs.

We simplify the framework to a form that is sufficient for our purposes. Most importantly we distinguish dependencies only by label, not by drawing direction or arrow style.

Knowledge Graphs

We define the knowledge graph data structure based on two vocabularies $\mathcal{C}_{cont}$ and $\mathcal{C}_{dep}$ which are the domains for labels of nodes and dependencies in our knowledge graph, resp.

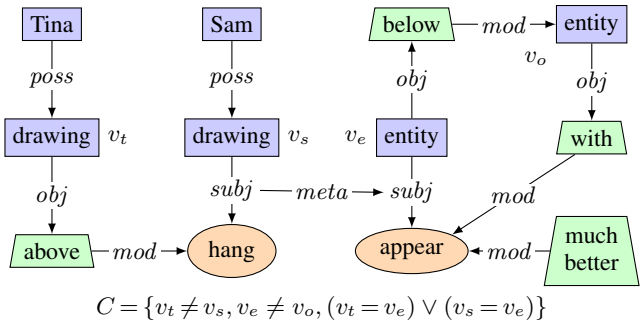

Figure 1: Knowledge graph structure corresponding to (5).

Example 1. *Figure 1 shows as an example the knowledge graph corresponding to input sentence* (5) *(we omit temporal information and interpret 'X's drawing' as 'the drawing owned by X'). Node labels are from the set* $\mathcal{C}_{cont} = \{$Tina, Sam, drawing, entity, hang, appear, above, below, with, much better$\}$. *Some intuitions about this graph: the* obj *dependency between* v_e *and 'below' denotes that* v_e *is the argument of 'below'; the 'below* v_e*' concept modifies* v_o *such that* v_o *denotes 'an entity that is below* v_e*'; moreover* v_e *has a* $subj$ *role in 'appear(ing)' which is modified by 'much better' and by 'with* v_o*'. The* $meta$ *dependency denotes an underspecified textual structure relation.*

In the following we implicitly extend this vocabulary as needed. The dependency vocabulary $\mathcal{C}_{dep} = \{subj, obj, obj2, mod, poss, at, meta\}$ is fixed.

We define an oracle function $compat : 2^{\mathcal{C}_{cont}} \to \{0, 1\}$ that evaluates whether a subset $C \subseteq \mathcal{C}_{cont}$ of the vocabulary contains mutually compatible content. Intuitively $compat$ abstracts from a (possibly intricate) reasoning in an ontological knowledge base that determines whether linguistically distinct concepts can denote the same world concept. For example, a drawing and an entity can be present in one concept node, while a drawing and Sam cannot: they must stay in separate concept nodes.

In Schank's graphs, dependencies occur between nodes and between dependencies, hence we reify dependencies: we represent a dependency as a graph node and two edges.

Definition 1. *A* knowledge graph structure $G = (V, E, l_{cont}, l_{type}, C)$ *on vocabularies* $\mathcal{C}_{cont}$ *and* $\mathcal{C}_{dep}$ *is a directed graph with nodes* V*, edges* $E \subseteq V \times V$*, node labelling functions* $l_{cont} : V \to 2^{\mathcal{C}_{cont} \cup \mathcal{C}_{dep}}$ *and* $l_{type} : V \to 2^{\{\mathbf{act}, \mathbf{obj}, \mathbf{mod}, \mathbf{dep}\}}$*, and a set of reasoning constraints* C *of two forms: inequalities between vertices and disjunctions of equalities between vertices.*

Figure 1 depicts a knowledge graph structure. Here and in the following we show nodes of type **act**, **obj**, and **mod**, as ellipses, rectangles, and trapezes, respectively. Dependencies (nodes of type **dep**) are shown without frame, and we omit arrows into such nodes unless they are $meta$-dependencies. Note in particular the $meta$ dependency between two $subj$ dependencies.

Given a set C of reasoning constraints we denote by $e(C)$ the set of disjunctions of equalities and by $n(C)$ the set of inequalities in C. In our example, $e(C) = \{(v_t = v_e) \vee (v_s = v_e)\}$ and $n(C) = \{v_t \neq v_s, v_e \neq v_o\}$.

We next impose constraints on knowledge graph structures to define knowledge graphs. The constraints ensure that knowledge graphs have certain properties, motivated methodologically (e.g., nodes have only one type, dependencies have only one incoming and one outgoing edge to a concept node) or linguistically (e.g., a limitation of object and possessor dependencies for concept nodes).

Equality constraints are inspired by constraints in Minimal Recursion Semantics (Copestake et al. 2005) which is a formalism for parsing natural language that allows ambiguous representations for unresolved pronouns as in WSs. Inequality constraints arise from syntactic principles of natural language, for example Principle B of Government and Binding (Haegeman 1994) states that a pronoun must not be bound within the same linguistic clause.

The following definition restricts each node $v \in V$ to have exactly one type $l_{type}(v)$. Using this restriction, we denote by $\mathbf{dep}(V) = \{v \in V \mid l_{type}(v) = \{\mathbf{dep}\}\}$ the set of *dependency nodes* and by $\mathbf{con}(V) = \{v \in V \mid l_{type}(v) \in \{\{\mathbf{act}\}, \{\mathbf{obj}\}, \{\mathbf{mod}\}\}\}$ the set of *concept nodes*.

Definition 2. *A* knowledge graph $G = (V, E, l_{cont}, l_{type}, C)$ *on vocabularies* $\mathcal{C}_{cont}$ *and* $\mathcal{C}_{dep}$ *is a knowledge graph structure such that*

(A) for every $v \in V$ *it holds that* $|l_{type}(v)| = 1$*;*
(B) for every $v \in \mathbf{dep}(V)$ *it holds that* $l_{cont}(v) \subseteq \mathcal{C}_{dep}$ *and* $|l_{cont}(v)| = 1$*;*
(C) for every $v \in \mathbf{con}(V)$ *it holds that* $l_{cont}(v) \subseteq \mathcal{C}_{cont}$ *and* $compat(l_{cont}(v)) = 1$*;*
(D) for $r \in \{obj, obj2, poss\}$ *and for every* $v \in V$ *it holds that* $|\{u \in V \mid (u, v) \in E \text{ and } l_{cont}(u) = \{t\}\}| \leq 1$.
(E) for every $v \in \mathbf{dep}(V)$ *it holds that* $|\{u \in \mathbf{con}(V) \mid (u, v) \in E\}| \leq 1$ *and* $|\{u \in \mathbf{con}(V) \mid (v, u) \in E\}| \leq 1$.
(F) for every $u \in \mathbf{con}(V)$*, it holds that there is at most one pair* (v, w)*,* $v \in \mathbf{dep}(V)$*,* $l_{cont}(v) = \{at\}$*,* $w \in \mathbf{con}(V)$ *such that* $\{(u, v), (v, w)\} \subseteq E$.
(G) there is no pair (u, v) *with* $u \in \mathbf{con}(V)$*,* $v \in \mathbf{dep}(V)$*, and* $\{(u, v), (v, u)\} \subseteq E$.
(H) for every pair $u, v \in \mathbf{con}(V)$*,* $u \neq v$ *it holds that* $|\{w \in V \mid \{(u, w), (w, v)\} \subseteq E\}| \leq 1$ *and* $|\{w \in V \mid \{(v, w), (w, u)\} \subseteq E\}| \leq 1$.

Note that Figure 1 is a knowledge graph.

These conditions become useful next where we define a reasoning task that combines nodes in knowledge graphs. (A) ensures single types for nodes. (B) ensures that dependency nodes have a singleton content from $\mathcal{C}_{dep}$. (C) ensures that concept nodes have as content a subset of the vocabulary that can refer to the same object or activity or modifier in the world. (D) ensures that a node can have only a single dependency from an object (obj) second object ($obj2$) and possessor ($poss$). This requirement is related to a linguistic principle known as 'theta criterion' which states that if a word assigns theta roles (types of arguments) then each role must be filled by a unique object (for example the word 'between' requires two arguments of type obj and $obj2$ for tangible or numerical entities). (E) ensures that a dependency node has no more than one incoming and no more than one

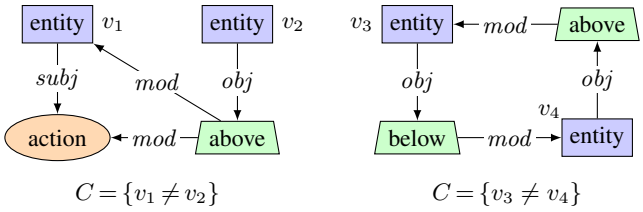

Figure 2: Background Knowledge Graphs related to (5).

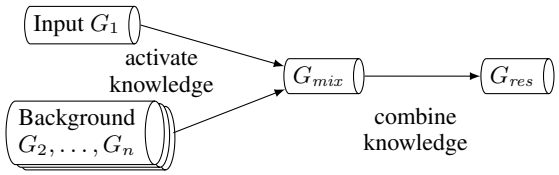

Figure 3: Reasoning with Knowledge Graphs

outgoing edge from (resp., to) a concept node. This causes dependency nodes to be like arcs between concept nodes (as visible in the figure) with the additional possibility of dependencies to dependencies. (F) ensures that a concept is at a single location only. (G) ensures that no concept depends on itself. (H) ensures that two concept nodes are never connected via more than one distinct dependency (in each direction). This avoids redundancies which will become important for realizing relevance in knowledge graphs.

From here on we leave vocabularies implicit.

Reasoning

We next define a notion of reasoning based on activating background knowledge graphs and combining them by collapsing subsets of nodes into single nodes. In the next section we define criteria for comparing all possible graphs resulting from such reasoning, yielding only those graphs that are most relevant wrt. principles of Relevance Theory.

Example 2. *Figure 2 depicts two knowledge graphs that are background knowledge related to our example. The left graph expresses that 'entity v_1 doing something above entity v_2' is interrelated with 'entity v_1 being above v_2'. The right graph expresses that 'entity v_3 being below entity v_4' is interrelated with 'entity v_4 being above v_3'. Note that these graphs does not imply a 'directionality', there are no 'conditions' or 'effects', just multiple dependency chains between concepts.*

Figure 3 gives an overview of our reasoning process: we activate knowledge in G_{mix} and then combine the activated graphs into result graph G_{res}.

Activating Knowledge. We start with a knowledge graph G_1 representing the input and a set $BG_{act} = \{G_2, \ldots, G_n\}$ of *activated knowledge graphs* from a background knowledge collection BG ($BG_{act} \subseteq BG$). For this work it was sufficient to activate knowledge $BG_{act} \subseteq BG$ according to matches of node contents that are more specific than 'entity' or 'action'. For a larger-scale system, methods that rely on salience and semantic distance should be used, for example Distributional Semantics (Padó and Lapata 2007).

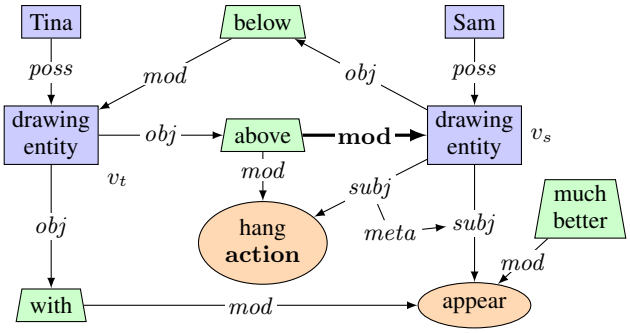

Figure 4: Reasoning: combining graphs from Figure 1 and 2.

Background knowledge is activated because it is somehow related to the input, however some of that knowledge might not be useful for reasoning. Hence we select a subset $BG_{use} \subseteq BG_{act}$ of *used knowledge graphs* from activated knowledge. The next section specifies how this selection is realized.

For combining knowledge we put all graphs in BG_{use} into one graph structure. For that we define a union operator: given two knowledge graphs G_1 and G_2 with disjoint sets of nodes, $G_i = (V_i, E_i, l_{cont_i}, l_{type_i}, C_i)$, $i \in \{1, 2\}$ we obtain $G_1 \cup G_2 = (V_1 \cup V_2, E_1 \cup E_2, l_{cont_1} \cup l_{cont_2}, l_{type_1} \cup l_{type_2}, C_1 \cup C_2)$. Due to disjoint sets of nodes the result is again a knowledge graph. If necessary, we can achieve disjointness by renaming nodes.

Combining Knowledge. We transform a knowledge graph by combining sets of nodes into single nodes. For that we use a function that maps nodes to other nodes.

Definition 3. *Given a knowledge graph structure $G = (V, E, l_{cont}, l_{type}, C)$, a* target function *$target : V \to V$ is a total function such that $target(v) = u$ with $v \neq u$ implies $target(u) = u$.*

A target function induces an equivalence relation over V: nodes that are mapped to themselves are representatives of the equivalence class and all other nodes map to such nodes. We use a function representation because it is more practical for our purposes.

The effect of applying a target function to a knowledge graph is defined next.

Definition 4. *Given a knowledge graph structure $G = (V, E, l_{cont}, l_{type}, C)$ and a target function $target$ wrt. G, we denote by $G[target]$ the* application of $target$ to G *and define $G[target] = (V', E', l_{cont}', l_{type}', C')$ with*

- $V' = \{target(v) \mid v \in V\}$,
- $E' = \{(target(u), target(v)) \mid (u, v) \in E\}$,
- $l_{cont}'(v) = \bigcup\{l_{cont}(u) \mid u \in V,\ target(u) = v\}$,
- $l_{type}'(v) = \bigcup\{l_{type}(u) \mid u \in V,\ target(u) = v\}$, *and*
- $C' = \{c$ *with vertices mapped using* $target \mid c \in C\}$.

The graph $G[target]$ is a knowledge graph structure, however it might not be a knowledge graph (e.g., a vertex might obtain two types). We next restrict $target$ such that

$G[target]$ is again a knowledge graph structure, and define the effect of reasoning constraints.

Reasoning constraints enforce structural properties of knowledge graphs: inequality constraints ensure that two nodes remain distinct nodes during reasoning, while equality constraints ensure that certain nodes are collapsed with others. In our example sentence (5) the word 'another' causes the constraint $v_e \neq v_o$ in Figure 1 while the word 'it' must bind to a predecessor phrase which can either be 'Sam's drawing' or 'Tina's [drawing]', hence we have the constraint $(v_t = v_e) \vee (v_s = v_e)$.

Definition 5. *Given a knowledge graph structure $G = (V, E, l_{cont}, l_{type}, C)$, a target function $target$ wrt. G is a* reasoning function *if*

(a) $G[target]$ is a knowledge graph,
(b) for each inequality constraint $(u \neq v) \in n(C)$ it holds that $target(u) \neq target(v)$, and
(c) for each equality constraint $c \in e(C)$ there is an equality $(u = v)$ in c such that $target(u) = target(v)$.

As an example consider Figure 4 where we combine knowledge graphs. If we disregard the bold **mod** edge and **action** concept then the graph is just a reorganized input graph (Figure 1) with $target(v_o) = v_t$ and $target(v_e) = v_s$. Combining the left graph in Figure 2 with the input graph is possible by combining 'action' with 'hang', and other nodes with nodes containing the same content, which leads to an additional dependency mod between 'above' and node v_s. Now we can see that the right graph from Figure 2 is already contained in the resulting graph, precisely we can combine v_3 with v_s and v_4 with v_t and then nodes containing 'below' and 'above', and this generates no additional edges or nodes. Note that these operations do not violate reasoning constraints, and that in the resulting set of constraints C' we still have $v_t \neq v_s$ but we omit the equivalence constraint because it is satisfied as v_s and v_e becoming the same node.

Observe that the result graph depicted in Figure 4 is a correct solution to the Winograd Schema (5) because in that schema 'it' must refer to Sam's drawing and the graph identifies v_e with v_s.

Finally we formally define a reasoning process based on which we will next formulate criteria of relevance.

Definition 6. *Given input graph G_1 and background knowledge BG, our reasoning process deterministically obtains BG_{act}, then chooses BG_{use} and $target$, and thereby obtain the result graph $G_{res} = G_{mix}[target]$ where*

$$G_{mix} = \bigcup \big(\{G_1\} \cup BG_{use}\big).$$

Relevance (Theory) in Knowledge Graphs

The previous section defined a reasoning process that leaves two important points open: (i) how to select BG_{act} and (ii) how to select $target$. In this section we use concepts from Relevance Theory to *assigning a relevance fitness value* to a reasoning process. This fitness value induces a preference between possible choices for BG_{use} and $target$.

By comparing fitness values wrt. BG_{act} and $target$ we can find the *most relevant* reasoning outcomes for a given input. This approach corresponds well with RT, which states that relevance cannot be measured in absolute terms, but it is always *in comparison with alternatives*.

RT originally is a theory of human cognition of natural language. We next justify and sketch possible formalizations of important principles from RT, then we propose a fitness function based on these ideas.

Nodes in G_{res} that originate from at least one node in the input graph G_1 we call *input nodes* (V_{res}^{in}), while nodes that originate only from nodes in background knowledge graphs we call *background nodes* (V_{res}^{bg}). In our example in Figure 4, the only background node is the bold **mod** dependency node, all other nodes are input nodes because the remaining (seven) nodes from background knowledge are combined with input nodes.

We consider the following formalizations of relevance.

• The amount of nodes from background knowledge that can been combined with input nodes indicates how well background knowledge integrates with the input. If all nodes from a background knowledge graph are combined with input nodes, then that background graph *supports existing knowledge* or *strengthens existing assumptions*. Both is defined as positive cognitive effect in RT.

• Background nodes can form *contextual implications* in the graph, also contributing to positive cognitive effect: they can connect parts of the input graph (as in Figure 4) that are not connected originally. Such connections are like inferences using background and input graph knowledge.

• Background nodes can be close to input nodes or far away in the graph (in terms of the shortest path to some input node). The former nodes are closely related to input, while the latter are more 'far-fetched', they can be seen as *additional assumptions*.

Assuming additional concepts can be necessary to make sense of an input, however this imposes additional *processing effort* and therefore reduces relevance relative to alternatives. In our example, we can combine the right graph in Figure 2 with Figure 1 in a more far-fetched manner: instead of combining v_3 with v_s and v_4 with v_t we could combine v_3 with v_t and not combine v_4 with any input node. In that case our reasoning process makes the *assumption* that there is a third object that is below Tina's drawing.

• Another effect of reasoning with background knowledge is that it can connect nodes from the input graph and thus causes the overall graph to become more connected. To measure how well the result of reasoning matches expectations in background knowledge, and how well-integrated the result of reasoning is, it can therefore be useful to measure the *radius* of the resulting knowledge graph.

The graph radius is the smallest value r such that from some node of the graph we can reach all other nodes traversing less than r edges. Our input graph in Figure 1 has radius 7 (from the left $subj$ node), while the result graph in Figure 4 has radius 5 (from the bold mod node). Recall that dependencies are nodes, so from 'Tina' to 'meta' we traverse 8 edges.

Based on our definition of reasoning process, we next define a fitness function with constant parameters C_{in}^{com}, C_{bg}, C_{bg}^{com}, C_{bg}^{dis}, C^{om}, and C^{rad}.

Definition 7. *Given G_1, BG, BG_{use}, and target as in Definition 5, we define fitness function f_{rel} as*

$$f_{rel}(G_1, BG, BG_{use}, target) = C_{in}^{com} \cdot \sum_{n \in V_{res}^{in}} com(n) + C_{bg} \cdot |V_{res}^{bg}| + C_{bg}^{com} \cdot \sum_{n \in V_{res}^{bg}} com(n) + C_{bg}^{dis} \cdot \sum_{n \in V_{res}^{bg}} dis(n) + C^{om} \cdot |BG_{act} \setminus BG_{use}| + C^{rad} \cdot rad(G_{res})$$

where

$$\begin{aligned} V_{res}^{in} &= \{target(v) \mid v \in V_1\}, \\ V_{res}^{bg} &= V_{res} \setminus V_{res}^{in}, \\ com(n) &= |\{v \in V_{res} \mid target(n) = target(v)\}|, \\ dis(n) &= \textit{the length of the shortest path from } n \\ &\quad \textit{to some node } n' \in V_{res}^{in}, \textit{ and} \\ rad(G_{res}) &= \textit{the radius of graph } G_{res}. \end{aligned}$$

Informally, V_{res}^{in} denotes input nodes, V_{res}^{bg} denotes nodes background nodes, $com(n)$ denotes the number of nodes combined to form node $n \in V_{res}$, and $dis(n)$ denotes the distance of node $n \in V_{res}^{bg}$ to the nearest node $n' \in V_{res}^{in}$.

This fitness function contains all points stated informally before, with (so far) unspecified constant factors as parameters. C_{in}^{com} allows to measure how many nodes were combined to yield input nodes. For background nodes, C_{bg} gives uniform weight to each one, C_{bg}^{com} gives weight proportional to the amount of combined nodes, and C_{bg}^{dis} gives weight proportional to the distance from input nodes. Moreover C^{om} allows for giving a weight to each activated background knowledge graph that was not used, and C^{rad} gives a weight to the radius of the result graph G_{res}.

Note that C_{in}^{com}, C_{bg}, and C_{bg}^{com}can be computed locally for each node of G_{res}, while C_{bg}^{dis} requires consideration of more than one node, C^{rad} is about a property of the whole graph, and C^{om} is not about the graph but about which background knowledge is used to build G_{res}. These locality properties can have significant influence on implementability and computational efficiency of an optimization procedure that computes graphs with optimal fitness. In this work we consider only small inputs to show qualitative applicability of the fitness function, therefore we will only briefly touch on matters of computational efficiency.

Experimental Evaluation

We designed our relevance fitness function based on principles of RT, moreover we know that disambiguation of certain WSs can be explained in terms of relevance.

In this section we perform experiments on such schemas in order to show which parameters lead to a correct disambiguation, and how well our fitness function performs in general, i.e., whether it captures the requirements on disambiguating our example schemas.

For our empirical experiments we selected Winograd Schemas numbered 2, 5, 15, and 17 from (Levesque, Davis, and Morgenstern 2012), encoded them in both of their variants as input graphs, and encoded some relevant background knowledge (including Figure 2). We repeat these schemas as (7)+(8), (5)+(6), (9)+(10), and (11)+(12), respectively.

[Tom]$_t$ threw his schoolbag down to [Ray]$_r$ after [he]$_{t,r?}$ reached the top of the stairs. (7)

[Tom]$_t$ threw his schoolbag down to [Ray]$_r$ after [he]$_{t,r?}$ reached the bottom of the stairs. (8)

The [drain]$_d$ is clogged with [hair]$_h$. [It]$_{d,h?}$ has to be removed. (9)

[The drain]$_d$ is clogged with [hair]$_h$. [It]$_{d,h?}$ has to be cleaned. (10)

There is [a pillar]$_p$ between me and [the stage]$_s$, and I can't see [it]$_{p,s?}$ (11)

There is [a pillar]$_p$ between me and [the stage]$_s$, and I can't see around [it]$_{p,s?}$. (12)

We chose these schemas because they do not violate text structure or world knowledge in their wrong reading, therefore we think Relevance Theory is a major ingredient in solving them.[2]

For each schema we computed the reasoning outcome(s) that were ranked as most relevant by the fitness function f_{rel}. We measured the number of result graphs with correct disambiguation (i.e., graphs where the node corresponding to the ambiguous pronoun is combined with the node of the input that corresponds to the correct answer) versus the number of result graphs with an incorrect disambiguation.

We performed this experiment on the following parameter combinations.

- $C_{in}^{com} \in \{0, 1, 2, 3\}$ varies the importance of combining background knowledge with input nodes.
- $(C_{bg}, C_{bg}^{com}, C_{bg}^{dis}) \in \{(0,0,0), (-1,0,0), (0,0,-1), (0,1,-2), (0,1,-1), (0,2,-1)\}$ varies the importance of several features of background nodes. In particular (0,0,0) omits any cost or benefit, (-1,0,0) gives a uniform cost to every background node, (0,0,-1) imposes a cost corresponding to distance from the nearest input node, (0,1,-1) additionally gives a benefit for combining with other nodes, finally (0,1,-2) and (0,2,-1) vary the ratio between cost and benefit of distance from input nodes and combination with background knowledge.
- $C^{om} \in \{0, -10, -20, -30\}$ varies the cost of not using an activated background knowledge graph.
- $C^{rad} \in \{0, -5, -10, -15\}$ gives cost to the graph radius.

These parameter ranges were established from estimates of parameter importance and in preliminary experiments. The seemingly natural setting $(C_{bg}, C_{bg}^{com}, C_{bg}^{dis}) = (0, 1, 0)$ was excluded because it facilitates the use of background knowledge that is neither combined with other background knowledge nor with input knowledge.

The above parameter combinations yield 384 overall parameter combinations and we have 8 sentences (2 for each schema), yielding 3072 overall experimental runs.

We encoded the reasoning process in Answer Set Programming (ASP) (Lifschitz 2008; Brewka, Eiter, and

[2]There can be two stairs, a plumber might remove a clogged drain, and there can be an object blocking the view to the pillar.

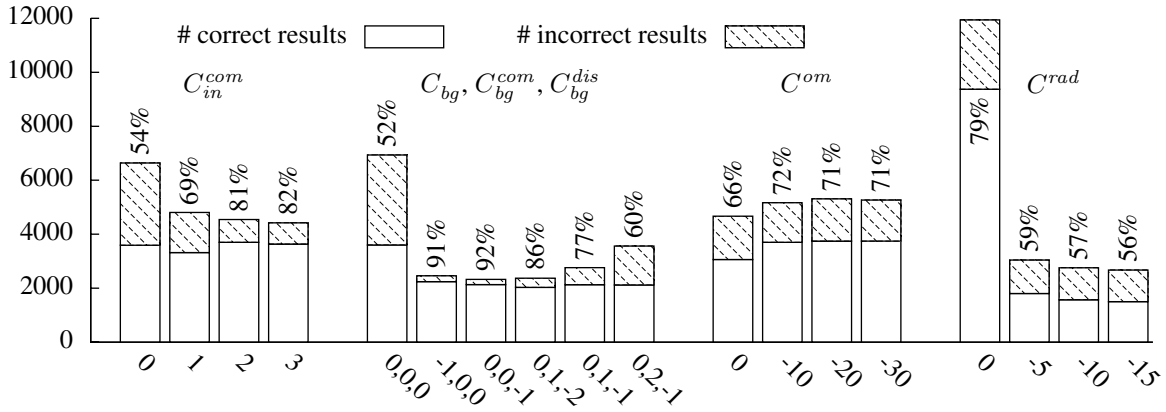

Figure 5: Experimental results (for each parameter group we accumulated over all combinations of remaining parameters).

Truszczynski 2011) which is a logic programming formalism suitable for representing knowledge and guess-and-check computations with integer optimization. Encodings, graph visualizations, and results are available online.[3]

In our experiments we used the solver clingo 4.2.1 (Gebser, Kaufmann, and Schaub 2013) with a timeout of 1 hour for finding the optimal value and 1 hour for enumerating a maximum of 25 graphs of optimum cost. Note that our encodings are not tuned for good performance, hence some parameter combinations and inputs cause timeouts and we only consider results from runs without timeouts. Such timeouts happened only for inputs (7) and (8), due to a high number of activatable background knowledge graphs. To gain confidence in our results, we checked that all trends we report in the following are similar if we use a timeout of only 20 min, hence timeouts do not invalidate the following discussion.

Results

Figure 5 shows results for each of the four parameter groups described previously, accumulated over all possible combinations of the other three parameter groups. We display the number of enumerated reasoning graphs, split into correctly and incorrectly disambiguated graphs, we also show the percentage of correct disambiguations.

We aim for a relevance fitness function that has the following properties: (i) firstly it gives higher fitness to graphs that contain the correct disambiguation, and (ii) it select as few as possible best results. The benefit of (i) is obvious, while (ii) is desireable for reasons of relevance: a low total number of results means that few assumptions needed to be taken for achieving these results, and few assumptions are necessary for subsequent reasoning.

From Figure 5 we can observe the following.

- Increasing C_{in}^{com} improves the correctness and reduces the number of result graphs.
- Giving weight to the second group of parameters $(C_{bg}, C_{bg}^{com}, C_{bg}^{dis})$ is important for correctness and for reducing the number of result graphs. The best correctness results are achieved with (-1,0,0), (0,0,-1), and (0,1,-2).
- A nonzero C^{om} increases correctness and increases the number of results (due to encouraging usage of background graphs).
- Giving weight to C^{rad} reduces correctness from 79% to 59% and drastically reduces the number of results.

These accumulated results give an overview of the impact of our fitness function constants. We next look into details.

Table 1 shows the best and worst individual parameter combinations. Each row is the result of 8 runs (one for each sentence of each schema).

In the upper part of the table we first show the 11 best combinations, they yield 100% correct answers and only 10 answers for 8 inputs. We can observe that C_{in}^{com} and C^{rad} are never 0, furthermore the combinations (0,0,0) and (0,2,-1) do not appear in the second column, which indicates that these parameter values are not favorable for correctness. C^{om} seems to be least important. The table row with 11 correct answers and 100% correctness actually contains 30 different parameter configurations, these combinations are not shown for space reasons, but we note that these combinations contain neither zero constants for C_{in}^{com}, C^{om}, and C^{rad}, nor combinations (0,0,0) or (0,2,-1) for the other constants. This suggests that all possible parameter values except (0,0,0) and (0,2,-1) and zero values contribute to successful disambiguation.

In the lower part of the table we show the 8 worst settings. (C_{bg},C_{bg}^{com},C_{bg}^{dis}) is either (0,0,0) which gives no weight to background nodes, or (0,1,-1), which gives cost to distance from input nodes but also gives the same amount of benefit for combination with other background knowledge nodes. C_{in}^{com} is zero in all but configuration. C^{om} and C^{rad} vary across their possible values. The total number of solutions (correct plus incorrect) is higher in the lower part of the table, except for two rows with 7 incorrect and 4 correct solutions: in these rows the parameters make graph radius the dominating cost and optimal fitness is achieved by not using any background knowledge (which is undesired and also leads to bad correctness).

In summary we see that all coefficients of f_{rel} are important, and many parameter values and combinations achieve correct disambiguation with few reasoning result. On the

Conclusion and Future Work

In order to formalize important concepts from Relevance Theory we introduced a formal simplification of Roger Schank's framework for knowledge graphs. We started from this framework because it promised an easy formulation of principles from RT as properties of graphs. Moreover, our knowledge graphs have similar properties to other graphs used for representing knowledge.

Therefore we hope that our work can inspire applications of Relevance Theory also in other graph-based reasoning formalisms.

Negative Results. Preliminary experiments showed that certain graph parameters are not useful: minimizing the number of *bridges* (edges whose removal disconnects the graph) does not yield promising results because the input graph might already be without any bridges. Also, maximizing the number of dependencies per node encourages buildup of additional dependencies between input nodes (think: contextual implications) but this measure can introduce redundancies in the graph that do not violate basic graph conditions and certainly do not follow the intended notion of relevance.

Possible Extensions. An important possible extension of our approach are graphs that act as *constraints*, i.e., they invalidate a reasoning result if a specific part of them *can* match the result graph. Preliminary experiments show that adding only one background knowledge graph with such capabilities increases the correctness of many parameter combinations tested in this work. Due to prohibitively high computation times we conducted only preliminary experiments.

Possible extensions of our relevance fitness function are the Cheeger constant (a graph parameter that measures *bottlenecks* in a graph; it is mainly used in research about social or computer networks) and a variable cost for unused activated graphs, depending on such graphs' size.

Winograd Schemas contain short sentences and they are meant to be interpreted without additional context. Therefore wrt. processing effort we mainly considered effort of assuming additional entities, a characterization that is shared by RT and by Hobbs et al. (1993). Future work should also consider salience of concepts and semantic distance between concepts as factors that contribute to processing effort.

Obtaining Knowledge Graphs. We here considered only knowledge graphs and abstracted from the process of *parsing natural language* to create knowledge graphs — certainly a challenging task by itself. Most existing parsing systems resolve ambiguities during parsing, a notable exception is Minimal Recursion Semantics (Copestake et al. 2005) which inspired equality constraints in this work. For obtaining and processing knowledge graphs several related works exist, e.g., the Boxer system (Bos 2008) which is based on Discourse Representation Theory, work by Baral and Dzifcak (2012) who interpret natural language and inferring unknown annotations using inverse lambda calculus, and the approaches of Chen et al. (2013) who combine existing open knowledge bases in a system for human-robot interaction.

Probabilistic approaches are not included in this work, in a general and robust system such methods will be necessary, and metrics relevant to probabilistic NLP will become relevant for evaluating such a system, for example MUC (Message Understanding Conference) metrics.

Computational Efficiency. We largely disregarded the efficiency of reasoning in our experiments and discussion. Due to the high complexity class of our reasoning method which is a typical guess & check & optimize task, reasoning efficiency will certainly become an important topic in practice. Several possibilities for tuning performance exist, the most obvious being an optimization of the ASP encoding, using general principles as described, e.g., by Balduccini and Lierler (2012). Moreover there is the possibility of using a hybrid reasoning formalism such as HEX-programs (Eiter et al. 2005) that combine ASP with domain-specific C++ code (e.g., for graph processing). Finally it is possible to realize the reasoning method from this paper in a formalism that is independent from ASP.

Incremental Progress. While our experiments indicate that certain parameter combinations lead to correct disambiguation, they are limited because they have been performed on a small set of examples. Levesque, Davis, and Morgenstern (2012) pointed out that *incremental progress* is possible in the WSC, by creating libraries of questions that can be solved by children, up to questions solvable by university-educated people. They also propose using a limited vocabulary, which will make testing more objective, and avoid solutions that are targeted to certain sentences.

For this paper we created a few background knowledge graphs from which several become activated and used in multiple of our test sentences. Nevertheless we are convinced that for achieving truly general results, it will be *nec-*

essary to create larger-scale testsuites on standard vocabularies. (Otherwise background knowledge used in experiments might just be tuned to achieve the right experimental outcome, making the experimental results meaningless.)

Creating such a corpus of Winograd Schema on a limited vocabulary contains several research challenges such as vocabulary selection, building the schemas, and evaluating empirically whether each schema is correctly disambiguated by a significant majority of human subjects.

Generalized Multi-Context Systems

Shahab Tasharrofi, Eugenia Ternovska
Simon Fraser University, email: {sta44,ter}@cs.sfu.ca

Abstract

Multi-context systems (MCSs) define a versatile framework for integrating and reasoning about knowledge from different (heterogeneous) sources. In MCSs, different types of non-monotonic reasoning are characterized by different semantics such as equilibrium semantics and grounded equilibrium semantics [Brewka and Eiter, 2007].

We introduce a novel semantics of MCSs, a supported equilibrium semantics. Our semantics is based on a new notion of support. The "strength" of supports determines a spectrum of semantics that, in particular, contains the equilibrium and grounded equilibrium semantics. In this way, our supported equilibrium semantics generalizes these previously defined semantics. Moreover, the "strength" of supports gives us a measure to compare different semantics of MCSs.

Introduction

Plato defined knowledge as justified true beliefs but it took thousands of years before this philosophical standpoint was used to form the intuitionistic view of Brouwer and the S4 provability logic of Godel. Since then, the progress towards more justified belief system have accelerated. Artemov (Artemov 1995) introduced Logic of Proofs (LP) as a formalization that internalizes justifications for statements and several justification logics were defined based on LP by Brezhnev (Brezhnev 2001). Knowledge representation and reasoning (KRR) field has also both benefited from and contributed to this direction. Fitting (Fitting 2005) defined an epistemic semantics for LP and Cabalar (Cabalar 2011) used LP to define causal logic programming under stable model semantics. Inspired by the utility that justification systems bring to true logical statements in general and to non-monotonic logic in particular, this paper uses justifications to remove unintended models of multi-context systems (MCSs) (Brewka and Eiter 2007) in a new semantics that we call *supported*. A MCS is a collection of contexts that are linked using bridge rules. Each context has its own way of representing knowledge (i.e., its own syntax and semantics). Bridge rules define how knowledge can be transferred between contexts. In MCSs, a model has the form of a collection of belief sets (called a *belief state*). The semantics of MCSs that inters us here are as follows.

Copyright © 2014, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

1. *Equilibrium semantics (ES)* defines intended models as exactly those belief states that, if viewed operationally, remain unchanged after first applying bridge rules and then applying contexts, hence the name of an equilibrium.
2. *Minimal equilibrium semantics (MES)* defines intended models as those equilibriums that are also minimal.
3. *Grounded equilibrium semantics (GES)* defines intended models as the minimal equilibriums of a positive MCS obtained by *reducing* the original MCS. Reducing MCSs is similar (both methodically and intent-wise) to the procedure Gelfond and Lifschitz (Gelfond and Lifschitz 1988) use to define stable model semantics. Unfortunately, this also means that GES is not applicable to MCSs with non-reducible logics, that is logics for which the reduction procedure cannot be applied.

The above semantics are motivated by everyday reasoning about a collection of contexts or agents. In MCSs, some knowledge is shared between different knowledge bases, while some knowledge is kept private/confidential.

Note that that justifications and, in particular, avoiding self-justifications was the main motivation behind the introduction of grounded equilibrium semantics for MCSs (Brewka and Eiter 2007). However, grounded equilibrium semantics (GES) is defined over MCSs in which all contexts are reducible. Thus, even one non-reducible context is enough to render GES non-applicable. Below, example 1 demonstrates this point.

The main goal of this work is to extend MCSs with the notions of justifications and support so that

- a spectrum of semantics for MCSs is obtained by varying one parameter, the support;
- the existing semantics of MCSs are in that spectrum.

We relate variations in support with the level of selectivity of the semantics, and argue that intermediate points in the spectrum are just as useful as the previously known semantics, – ES, MES, GES. We also show the usefulness of our new justification-aware semantics in diagnosis of MCSs.

Recall that normal answer set programs are sets of rules of form $h \leftarrow b_1, \cdots, b_k, \textbf{not}\ b_{k+1}, \cdots, \textbf{not}\ b_n$ such that $h, b_1, \cdots, b_n$ are first order literals (i.e., negated or non-negated atoms with variables). Also, recall that S is a stable model of a normal answer set program P if and only if S is consistent and deductively closed under the positive program obtained by reducing P according to S.

Example 1. *Let $M := (C_1, C_2, C_3)$ be*[1] *a multi-context system with $C_i := (L_i, kb_i, br_i)$ (for $i \in \{1, 2, 3\}$), L_1, L_2 be the logic of normal answer set programs under stable model semantics, L_3 be first-order logic (with $BS_3 := \{\{\}, \{comedian(jk)\}\}$ as possible belief sets), and kb_i, br_i be as follows:*

$$kb_1 := \left\{ \begin{array}{l} forbes400(bg). \\ wealthy(X) \leftarrow forbes400(X). \\ wealthy(X) \leftarrow celebrity(X). \end{array} \right\}$$
$$br_1 := \{celbrity(X) \leftarrow C_2 : famous(X).\}$$
$$kb_2 := \left\{ \begin{array}{l} actor(bp). \\ famous(X) \leftarrow actor(X). \end{array} \right\}$$
$$br_2 := \left\{ \begin{array}{l} famous(X) \leftarrow C_1 : wealthy(X). \\ famous(X) \leftarrow C_3 : comedian(X). \end{array} \right\},$$
$$kb_3 := \{\}$$
$$br_3 := \{\bot \leftarrow C_3 : comedian(X), \textbf{not}\ C_2 : famous(X).\}$$

with X ranging over the four possibilities of "bg" (stands for Bill Gates), "bp" (stands for Brad Pitt), "jk" (stands for Jimmy Kimmel), and "aj" (stands for Average Joe).

Note that MCS M can only use the equilibrium semantics because context C_3 is not reducible. According to equilibrium semantics, M has equilibriums $S_1, \cdots, S_6$ as follows:

for $i \in \{1, \cdots, 6\} : S_i := (bs_1^i, bs_2^i, bs_3^i)$ where,

$$bs_1^1 := \left\{ \begin{array}{l} forbes400(bg), wealthy(bg), wealthy(bp), \\ celebrity(bg), celebrity(bp) \end{array} \right\},$$
$$bs_1^2 := bs_1^1 \cup \{wealthy(aj), celebrity(aj)\},$$
$$bs_1^3 := bs_1^4 := bs_1^1 \cup \{wealthy(jk), celebrity(jk)\},$$
$$bs_1^5 := bs_1^6 := bs_1^2 \cup bs_1^3,$$

$$bs_2^1 := \{actor(bp), famous(bg), famous(bp)\},$$
$$bs_2^2 := bs_2^1 \cup \{famous(aj)\},$$
$$bs_2^3 := bs_2^4 := bs_2^1 \cup \{famous(jk)\},$$
$$bs_2^5 := bs_2^6 := bs_2^2 \cup bs_2^3,$$

$$bs_3^1 := bs_3^2 := bs_3^3 := bs_3^5 := \{\},$$
$$bs_3^4 := bs_3^6 := \{comedian(jk)\}.$$

If the names of this example are to be taken literally, among all the six equilibrium models above, only S_4 is a reasonable belief state. This is because, first, "Average Joe," by definition, is not famous, wealthy, or a celebrity, and, second, "Jimmy Kimmel" is a famous comedian and a wealthy celebrity.

Note that, in Example 1, grounded equilibrium semantics is not applicable because context C_3 uses the non-reducible first-order logic. However, since kb_3 is empty, one might wonder what would have happened if L_3 was a reducible logic. Example 2 considers that situation.

Example 2. *In Example 1, let M be as before except that L_3 is the reducible logic of normal answer set programs under stable model semantics. Then, equilibrium models of M are as before (i.e., $S_1, \cdots, S_6$) but, now, M also has exactly one grounded equilibrium: S_1.*

[1] We use := to represent "denotes" or "equals by definition".

Note that, as we discussed before, in Example 1, S_4 is the only reasonable equilibrium model. However, as we saw in Examples 1 and 2, neither the equilibrium semantics nor the grounded equilibrium semantics can capture the set of intended models. We saw that equilibrium semantics accepts too many equilibriums, i.e., all of $S_1, \cdots, S_6$, and grounded equilibrium semantics (even if definable) rejects our intended equilibrium model S_4.

Summary of the Paper – First, this paper defines a novel semantics for MCSs that we call supported equilibrium semantics. We show that our semantics generalizes both the equilibrium semantics and the grounded equilibrium semantics under a natural instantiation of justification functions for contexts. For instance, we show that, for our running Example 1, depending on how justification functions are instantiated, our supported equilibrium semantics can either work similar to equilibrium semantics and accept all equilibrium $S_1, \cdots, S_6$, or it can work similar to grounded equilibrium semantics and accept only S_1.

Second, this paper also shows that our supported equilibrium semantics characterizes many interesting cases that cannot be captured by either the equilibrium semantics or by the grounded equilibrium semantics. For instance, we show that under a very natural and easy instantiation of justification functions, our supported equilibrium semantics accepts both equilibrium models S_1 and S_4 of MCS M in Example 1. That is, using such natural justifications, supported equilibrium semantics is neither as relaxed as equilibrium semantics that accepts all $S_1, \cdots, S_6$, nor as restrictive as grounded equilibrium semantics that rejects our intended equilibrium model S_4. In this sense, supported equilibrium semantics properly generalizes its predecessors and better captures our intended equilibrium models.

Finally, the last section of this paper is dedicated to a short discussion on a plausible application of supported equilibrium semantics to detect and repair faulty MCSs. There, we discuss how supported equilibrium semantics helps us to remove equilibrium model S_1 of MCS M from Example 1. This type of debugging and repairing has not previously been possible in MCSs, and its future formal investigation will help MCSs be more suited to modelling practical KRR applications.

Contributions

Our contributions in this paper are as follows:

Supported Equilibrium Semantics – We introduce a novel semantics for multi-context systems by adding the concept of support to all logics and then extending the semantics of equilibrium models so that the concept of support is respected when choosing intended equilibria of a MCS.

Unifying Equilibrium Semantics with Grounded Equilibrium Semantics – We show that our new semantics of supported equilibria naturally extends both the equilibrium semantics and the grounded equilibrium semantics. That is, we show that, by carefully choosing supports of logics, both equilibrium semantics and grounded equilibrium semantics become special cases of supported equilibrium semantics.

Broadening Applications of MCSs – Our supported equilibrium semantics extends the applicability of MCSs to ap-

plications in which some/all of justifications cannot be revealed due to privacy, confidentiality or other reasons. This is achieved by allowing contexts to justify their beliefs at varying degrees, and by designing a semantics that works independently of how detailed justifications are. Of course, the more justifications are provided, the better our semantics becomes.

Better Diagnosis and Repair – We show that supported equilibrium semantics paves the way for better diagnoses and repairs in a faulty MCS.

Background

This section briefly reviews multi-context systems using the exposition of (Fink, Ghionna, and Weinzierl 2011) and (Brewka and Eiter 2007). We also use the two following notations here and in other places throughout this paper:

Notation 1 (Negating a Set). *For a set of belief literals X, we use "***not** *X" to denote a set that contains the negation of literals in X, i.e.,* **not** $X := \{\textbf{not}\ b \mid b \in X\}$.

Notation 2 (Un-pairing). *For a pair $P := (X, Y)$, we use* $\mathrm{fst}(P)$ *to denote X and* $\mathrm{snd}(P)$ *to denote Y.*

In MCSs (Brewka and Eiter 2007), a *logic* L is a triple $L := \langle KB_L, BS_L, ACC_L\rangle$, where KB_L is a set of knowledge bases (syntactic part of L), BS_L is a set of belief sets (semantic part of L), and $ACC_L : KB_L \mapsto 2^{BS_L}$ maps each knowledge base to a set of acceptable belief sets (the semantics of L). A *multi-context system MCS* $:= (C_1, \cdots, C_n)$ is a collection of contexts $C_i := (L_i, kb_i, br_i)$ with logic L_i, knowledge base $kb_i \in KB_{L_i}$ and bridge rules br_i. In MCSs, bridge rule $r \in br_i$ has the following form:

$$(i:s) \quad \leftarrow \quad (c_1:p_1), \cdots, (c_j:p_j), \ \textbf{not}\ (c_{j+1}:p_{j+1}), \cdots, \textbf{not}\ (c_m:p_m). \tag{1}$$

where $hd(r) := s$; $body^+(r) := \{(c_k : p_k) \mid 1 \le k \le j\}$; $body^-(r) := \{(c_k : p_k) \mid j+1 \le k \le m\}$; and, $body(r) := body^+(r) \cup (\textbf{not}\ body^-(r))$.

A *belief state* $S := (S_1, ..., S_n)$ is a collection of belief sets, i.e., $S_i \in BS_{L_i}$. Also, we use $X(S)$ for the disjoint union of beliefs in all S_i's, i.e., $X(S) := \{(i : b) \mid 1 \le i \le n \text{ and } b \in S_i\}$. A bridge rule r of form (1) is *applicable* wrt. S, denoted by $S \models body(r)$, iff $p_l \in S_{c_l}$ for $1 \le l \le j$ and $p_l \notin S_{c_l}$ for $j < l \le m$. We define $app_i(S) := \{hd(r) \mid r \in br_i \wedge S \models body(r)\}$ to obtain heads of all applicable bridge rules of context C_i. Belief state S is an *equilibrium* of *MCS* if, for all i, $S_i \in ACC_{L_i}(kb_i \cup app_i(S))$.

Logic L is *monotone* if, for all $kb, kb' \in KB_L$, (1) $ACC(kb)$ is a singleton set $\{S\}$, and, (2) if $ACC(kb) = \{S\}$, $ACC(kb') = \{S'\}$, and $kb \subseteq kb'$ then $S \subseteq S'$. Also, L is *reducible* if (1) subset $KB^*_L \subseteq KB_L$ exists s.t. $L^* := \langle KB^*_L, BS_L, ACC_L\rangle$ is monotone, and, (2) reduction function $red_L : KB_L \times BS_L \mapsto KB^*_L$ exists s.t. a. $red_L(kb, S) = kb$ if $kb \in KB^*_L$, b. $red_L(kb, S') \subseteq red_L(kb, S)$ if $S \subseteq S'$, and, c. $S \in ACC_L(k)$ iff $ACC_L(red_L(k, S)) = \{S\}$.*Context* $C := (L, kb, br)$ *is reducible* if L is reducible and $red_L(kb \cup H, S) = red_L(kb, S) \cup H$ for all $H \subseteq \{hd(r) \mid r \in br\}$. MCS M is reducible if all of its contexts are reducible.

A reducible MCS $M := (C_1, \ldots, C_n)$ is *definite* if all bridge rules r of M are positive, i.e., $body^-(r) = \emptyset$, and, for all i, $kb_i \in KB^*_{L_i}$. Definite MCSs guarantee monotonic inference and, thus, always have a unique minimal equilibrium (Brewka and Eiter 2007). Also, for reducible MCS $M := (C_1, \cdots, C_n)$, reduction of M under belief state S, denoted by M^S, is a definite MCS $M' := (C^S_1, \cdots, C^S_n)$ where $C^S_i := (L_i, red_i(kb_i, S_i), br^S_i)$ and $br^S_i := \{hd(r) \leftarrow body^+(r) \mid r \in br_i \text{ and } S \models body(r)\}$. Finally, S is a *grounded equilibrium* of reducible MCS M if S is the unique minimal equilibrium of the M^S. For non-reducible MCSs, grounded equilibria are not defined.

Note that other semantics for MCSs and their extensions (such as managed MCSs (Brewka et al. 2011)) exist, but are not considered here because they are not relevant to this paper.

Generalized MCSs

Examples 1 and 2 showed a case where both equilibrium and grounded equilibrium semantics fail to capture our intended models. This section first defines justification functions that justify beliefs of an acceptable belief set with other beliefs of that belief set and formulas in the knowledge base. For example, the belief that a product is unavailable for sale is justified by a combination of other beliefs and formulas as follows. Among the beliefs that contribute towards justifying unavailability of this product, we can mention the belief that all instance of this product in the store are marked as "sold" and that this product is also unavailable in the warehouse. Moreover, a formula also contributes as a justification of unavailability of this product: it says that if a product is available for sale, then it should be either in the warehouse or in the store without being labeled as "sold."

Secondly, in this section, we lift the notion of justification from a particular acceptable belief set in a particular logic to contexts in general, and then to multi-context systems. We show the naturality of our definitions using our running example and leave the formal expressiveness results to the next section.

Support for Logics

In order to define supported equilibrium semantics, we need to introduce the concept of support at the level of logics. To this end, we define *justifications* for acceptable belief sets and, then, extend them to *support for logics*. While we use very natural definitions, we also heavily use our running example to give more intuitions about our definitions.

Consider logic $L := \langle KB, BS, ACC\rangle$, belief set $bs \in BS$, and knowledge base $kb \in KB$ such that bs is an acceptable belief set for kb in L. By a *justification* for bs, we mean a possible explanation of why belief in bs are believed.

Definition 1 (Justification). *Let $L := \langle KB, BS, ACC\rangle$, $kb \in KB$ and $bs \in ACC(kb)$. Then, function $j : bs \mapsto (\mathcal{P}(bs) \times \mathcal{P}(kb))$ is called a* justification *for bs if j is non-circular, i.e., a well-ordering $<_{bs}$ on beliefs in bs exists such that, for all $b, b' \in bs$ with $b \in \mathrm{fst}(j(b'))$, we have $b <_{bs} b'$.*

A justification function as in Definition 1 provides possible explanations for belief sets in a non-circular way. In the

following, Example 3 shows a natural justification function in the context of our running example.

Example 3. *Consider multi-context system M from Example 1 and equilibrium models $S_1, \cdots, S_6$. By definition of equilibrium models, we know that, for $i \in \{1,2,3\}$ and $j \in \{1,\cdots,6\}$, belief set bs_i^j is an acceptable belief set for knowledge base $kb_i \cup app_i(S_j)$, i.e., $bs_i^j \in ACC_i(kb_i \cup app_i(S_j))$. In this example, we give two natural justification functions j_1 and j_2 for two belief sets bs_1^1 and bs_1^2 respectively. Note that, by Definition 1, each j_i (non-circularly) maps bs_1^i to a pair consisting of a subset of bs_1^i and a subset of $kb_1 \cup app_1(S_i)$, i.e., $j_i : bs_1^i \mapsto (\mathcal{P}(bs_1^i) \times \mathcal{P}(kb_1 \cup app_1(S_i)))$. Our j_i's are as follows:*

$$
\begin{aligned}
&j_{1,2}(forbes400(bg)) := (\{\}, \{forbes400(bg)\}),\\
&j_{1,2}(wealthy(bg)) := (\{forbes400(bg)\},\\
&\qquad \{wealthy(bg) \leftarrow forbes400(bg)\}),\\
&j_{1,2}(wealthy(bp)) := (\{celebrity(bp)\},\\
&\qquad \{wealthy(bp) \leftarrow celebrity(bp)\}),\\
&j_2(wealthy(aj)) := (\{celebrity(aj)\},\\
&\qquad \{wealthy(aj) \leftarrow celebrity(aj)\}),\\
&j_{1,2}(celebrity(bg)) := (\{\}, \{celebrity(bg)\}),\\
&j_{1,2}(celebrity(bp)) := (\{\}, \{celebrity(bp)\}),\\
&j_2(celebrity(aj)) := (\{\}, \{celebrity(aj)\}).
\end{aligned}
$$

Note that j_1 and j_2 agree on their shared domain, i.e., bs_1^1 and that they both have very intuitive meanings. For instance, $j_1(forbes400(bg)) = (\{\}, \{forbes400(bg)\})$ means that, our belief in $forbes400(bg)$ is independent of all other beliefs and is justified only by a fact from the knowledge base, i.e., $forbes400(bg)$. It is noteworthy that, here, $forbes400(bg)$ appears once as a belief and another time as a formula. Thus, $forbes400(bg)$ does not constitute a self-justification because, for self-justifications to occur, a belief should (directly or indirectly) depend on itself (as a belief).

In Example 3, justification coincides with the consequence relation. That is, if $j_i(b) = (bs, kb)$, $bs \subseteq bs'$, $kb \subseteq kb'$, and $bs' \in ACC_1(kb')$ then $b \in bs'$. However, we want to emphasize that, despite the proximity of the two notions of consequence and justification, the latter is much more flexible than the former. Therefore, as shown later in this paper, the same logic can have many different justification functions (unlike consequence relation which is closely tied to the semantics of a logic). Moreover, since justifications are more flexible, as this paper shows, they can be used to characterize a range of different semantics for the same MCS (which would have been impossible using consequence relation because of their rigidity).

Now, we use justifications to define the support for a logic. Intuitively, $Sup_L(kb, bs)$ denotes a (usually non-exhaustive) set of possible *justifications* for belief set bs.

Definition 2 (Support for a Logic L). *Let $L := \langle KB_L, BS_L, ACC_L\rangle$, $kb \in KB_L$ and $bs \in BS_L$. Then, $Sup_L(kb, bs)$ is a set of justifications for bs according to kb such that if $bs \notin ACC_L(kb)$ then $Sup_L(kb, bs) = \emptyset$.*

Example 4 applies Definition 2 to our running example:

Example 4. *Continuing Example 1, we define Sup_{L_1} to be such that $Sup_{L_1}(kb_1, bs_1^2) = \emptyset$ (because $bs_1^2 \notin ACC_1(kb_1)$) and $Sup_{L_1}(kb_1 \cup app_1(S_2), bs_1^1) = \{j_2, j_3\}$ where j_2 is from Example 3 and $j_3 : bs_1^2 \mapsto (\mathcal{P}(bs_1^2) \times \mathcal{P}(kb_1 \cup app_1(S_2)))$ is as below:*

$$
\begin{aligned}
&j_3(wealthy(bg)) := (\{celebrity(bg)\},\\
&\qquad \{wealthy(bg) \leftarrow celebrity(bg)\}),\\
&j_3(b) := j_2(b) \quad (\textit{for } b \in bs_1^2 \setminus \{wealthy(bg)\}).
\end{aligned}
$$

As discussed before, justifications do not uniquely correspond to a logic L of a context. Moreover, as seen in Example 4, different justification functions contribute towards defining different supports for a logic. Among all possible supports for a logic, two trivial but important ones are the *unit support* and the *empty support* (defined below). Unit and empty supports are definable for all logics and, as will be seen later on, they respectively form the minimum and the maximum of a lattice on supports for a logic.

Definition 3 (Unit and Empty Supports). *Consider logic L and two supports uSup_L, eSup_L for L such that, for all kb and bs: (1) $\mathrm{eSup}_L(kb, bs) = \emptyset$, and, (2) $\mathrm{uSup}_L(kb, bs) = \{u^{bs}\}$ where, for all $b \in bs$, $u^{bs}(b) = (\{\}, \{\})$. Also, we call uSup_L and eSup_L respectively as the* unit support for L *and the* empty support for L.

Note that, neither the unit support nor the empty support for a logic does not provide any information about the internal knowledge base. As we show later on, the unit and empty support for a logic define the two ends of an spectrum in which the unit support is the most relaxed support for a logic and empty support is the most rigid support for a logic. In other words, we show later on in this paper that (1) unit support for a logic corresponds to the case where all equilibriums are supported, and, (2) empty support corresponds to the case that no equilibriums is supported.

While empty and unit supports are definable for all logics, they do not give us any insight into why something is (or is not) believed. Thus, one might wonder if more insightful notions of support can be developed for interesting KR logical frameworks. Here, we emphasize that, for many interesting logical frameworks, such as many non-monotonic logics, a more rigid notion of support has already been developed (Lifschitz 2010; Tasharrofi 2013). The following example uses a well-established notion of support for normal logic programs in combination with MCS M from Example 1 to show how supports provide insight into a knowledge base.

Example 5. *Consider context C_1 of Example 1. Since kb_1 is a normal logic program under answer set semantics, one can use a support for logic L of C_1 that is based on the notion of support as defined in (Lifschitz 2010). Using this support function, both justification functions j_1 and j_3 from Examples 3 and 4 belong to $Sup_L(bs_1^1, kb_1 \cup app_1(S_1))$.*

Support for Contexts

Using the definition of supports on the level of logic, we define support on the level of contexts as in Definition 4 that follows. Unlike supports for logics that worked with syntactic (knowledge base formulas) and semantic (beliefs) objects simultaneously, in Definition 4, supports at the level of contexts work solely on semantic objects (beliefs).

Definition 4 (Support for Contexts). *Consider MCS $M := (C_1, \cdots, C_n)$, its context $C_i := \langle L_i, kb_i, br_i \rangle$, and its belief state $S := (S_1, \cdots, S_n)$. Also, let Sup_{L_i} be the support function for logic L_i and recall that $X(S) := \{(i : b) \mid b \in S_i\}$. Support of belief set S_i (from context C_i) under S, denoted by Sup_i^S, is the set of functions $f : S_i \mapsto \mathcal{P}(X(S))$ that are computed by taking a function $g \in Sup_{L_i}(kb_i \cup app_i(S), S_i)$ and tracing the reason for the inclusion of the knowledge that comes from bridge rules. More formally, a function f is included in Sup_i^S if and only if functions $g \in Sup_{L_i}(kb_i \cup app_i(S), S_i)$ and $R : S_i \mapsto \mathcal{P}(br_i)$ exist such that, for all $b \in S_i$, we have:*

$$f(b) := \{i : b' \mid b' \in \mathrm{fst}(g(b))\} \cup \bigcup_{r \in R(b)} body^+(r).$$

and $R(b) \subseteq \{r \mid r \in br_i \text{ and } S \models body(r)\}$ is a minimal subset of applicable bridge rules that justifies the knowledge that comes from bridge rules, i.e., for all formulas $k \in (\mathrm{snd}(g(b)) \setminus kb)$, a rule $r \in R(b)$ exists with $hd(r) = k$.

Note that, in Definition 4, if $\mathrm{snd}(g(b)) \setminus kb = \emptyset$ for some belief b, then $R(b) = \emptyset$. Intuitively, it means that support from other contexts is required only when existing knowledge of a context is not sufficient for supporting a belief. Following example applies the notion of support at the context-level to our running Example 1.

Example 6. *Consider MCS M of Example 1 and equilibrium model S_2 of M. Also, assume that support for logic of C_1 is as in Example 5. Using that support, let us compute one of the functions $f \in Sup_1^{S_2}$. According to Definition 4, such a function f supports beliefs in bs_1^2. Also, by Definition 4, to construct such a function f, we need function $g \in Sup_{L_1}(kb_1 \cup app_1(S_2), bs_1^2)$. By Example 4, we know $Sup_{L_1}(kb_1 \cup app_1(S_2), bs_1^2) = \{j_2, j_3\}$, thus either $g = j_2$ or $g = j_3$. In this example, we take $g = j_2$.*

By Definition 4, to construct f, formulas that are justified (generated) by bridge rules should be justified. In our example, these are formulas of form $celebrity(X)$. Fortunately, each of these formulas appear as the head of has exactly one bridge rule. Therefore, the minimal set $R(b)$ in the case of each of these formulas contains exactly one rule with that belief in its head. For example, when $b = celebrity(aj)$, $R(b)$ only contains rule "$celebrity(aj) \leftarrow C_2 : famous(aj)$". Thus, f is as follows:

$$f(celebrity(X)) = \{2 : famous(X)\} \text{ (for all } X),$$
$$f(wealthy(X)) = \{1 : celebrity(X)\} \text{ (for } X \neq bg),$$
$$f(wealthy(bg)) = \{1 : forbes400(bg)\},$$
$$f(forbes400(bg)) = \emptyset.$$

The numbers 1 and 2 in the function f above refer to contexts C_1 and C_2 respectively.

Example 6 shows how support functions can be extended beyond the boundaries of knowledge bases and belief sets of a logic and into the beliefs from the belief sets of other contexts. According to Definition 4 and as shown in Example 6, this task is achieved by following bridge rules of a context.

Supported Equilibrium Semantics

Now, we use supports at the level of contexts to define supported equilibrium semantics for MCSs. In the following, Definition 5 gives our main notion of a *supported equilibrium*. Informally speaking, a belief state is called a supported equilibrium if all beliefs are well-justified, i.e., they are justified and nothing justifies itself (either directly or indirectly). Similar to Definition 1, self-justifications are avoided by requiring the existence of a well-ordering on the beliefs.

Definition 5 (Supported Equilibrium). *A belief state $S := (S_1, \cdots, S_n)$ of MCS is a* supported equilibrium w.r.t. *$(Sup_{L_1}, \cdots, Sup_{L_n})$ if functions $f_1 \in Sup_1^S, \cdots, f_n \in Sup_n^S$ and well-founded strict partial ordering $<$ on $X(S)$ exist s.t. if $p \in S_i$ and $(j : q) \in f_i(p)$ then $(j : q) < (i : p)$.*

First, note that Definition 5 does not put any special requirement on contexts and works for all contexts and all supports. Therefore, unlike grounded equilibrium semantics of (Brewka and Eiter 2007), introspection in supported equilibrium semantics does not come at the cost of excluding non-reducible contexts.

Second, note that Definition 5 tests a belief state for being supported but not for being an equilibrium. So, one might reasonably suspect that a belief state S might exist such that S is a supported equilibrium (according to Definition 5) but not an equilibrium (according to the original definition of equilibrium semantics (Brewka and Eiter 2007)). However, the following Theorem 1 states that if S is a supported equilibrium then it has to be an equilibrium as well. Therefore, the term "supported equilibrium" is indeed an appropriate and reasonable name for belief states that satisfy the condition of Definition 5.

Theorem 1 (Supported Equilibria $\subseteq$ Equilibria). *Let $M := (C_1, \cdots, C_n)$ and also let $S := (S_1, \cdots, S_n)$ be a supported equilibrium of M w.r.t. $(Sup_{L_1}, \cdots, Sup_{L_n})$. Then, S is also an equilibrium of M.*

Proof. Assume that S is not an equilibrium of M. Then, context C_i should exist such that $S_i \notin ACC(kb_i \cup app_i(S))$. Therefore, by Definition 2, we know that $Sup_{L_i}(kb_i \cup app_i(S), S_i) = \emptyset$. Thus, by Definition 4, $Sup_i^{L_i}$ is also empty. Hence, by Definition 5, S cannot be a supported equilibrium of M which contradicts our assumption. So, S has to be an equilibrium of M. □

Now, let us return to our running example and see if supported equilibrium semantics can be introspective enough to reject equilibrium model S_2 of Example 1 as not supported.

Example 7. *Consider MCS M and equilibrium model S_2 of Example 1. In Example 6, we saw that $Sup_1^{L_1}$ contains two support functions for belief set bs_1^2 of S_2. We also computed support function $f \in Sup_1^{L_1}$. For S_2 to be a supported equilibrium, by Definition 5, functions $f_i \in Sup_i^{L_i}$ (for $i \in \{1, 2, 3\}$) should be found so that beliefs in bs_i^2 ($i \in \{1, 2, 3\}$) are justified and nothing justifies itself. In this example, we show that, indeed, if f_1 is the support function f from Example 6, then a self-justification is inevitable.*

In order to do so, we take f_1 to be function f from Example 6 and show that ordering $<$ cannot exist. We know that $(1 : celebrity(aj)) \in f_1(wealthy(aj))$ and $(2 : famous(aj)) \in f_1(celebrity(aj))$. Thus, ordering $<$ should satisfy $(2 : famous(aj)) < (1 : celebrity(aj)) < (1 : wealthy(aj))$. Now, we look at the possible supports for belief $famous(aj)$ in bs_2^2. According to C_2, belief $famous(X)$ can have three possible supports: $actor(X)$, $comedian(X)$ or $wealthy(X)$. However, for $X = aj$, the only possibility is $wealthy(X)$. Thus, inevitably, we have $(1 : wealthy(aj)) \in f_2(famous(aj))$ and, therefore, ordering $<$ should also satisfy $(1 : wealthy(aj)) < (2 : famous(aj))$ that contradicts the previous constraint on $<$.

Hence, if f_1 is function f from Example 6, ordering $<$ cannot exist and a self-justification inevitably occurs. The reader can check that choosing f_1 differently does not rectify the situation either. So, S_2 is not a supported equilibrium w.r.t. support functions $(Sup_{L_1}, Sup_{L_2}, \mathrm{uSup}_{L_3})$.

Example 7 demonstrates how supported equilibrium semantics avoids undesirable equilibrium models. Moreover, Example 7 shows that supported equilibrium semantics can also single out unfounded beliefs. In Example 7, one can check that all beliefs in S_2 are founded except those about "Average Joe". Even more importantly, Example 7 shows that supported equilibrium semantics allows us to trace back the reason for inclusion of all beliefs in a belief state.

Moreover, recall that grounded equilibrium semantics was not applicable to MCS M from Example 1. Thus, up to now, it was not possible to avoid unintended equilibrium models such as S_2 for MCSs such as M. However, as Example 7 shows, supported equilibrium semantics both (1) applies to M, and, (2) rejects unintended equilibrium S_2 as not supported. Hence, supported equilibrium semantics can indeed express cases that are not expressible using either the equilibrium model semantics or the grounded equilibrium model semantics. It should also be noted that Example 7 concerned a very simple MCS in which all contexts except one were reducible. However, as shown in the next section, the cases that supported equilibrium semantics can express (but equilibrium semantics or grounded equilibrium semantics cannot) are not limited to these easy cases. In the next section, we show that supported equilibrium semantics generalizes and unifies a spectrum of different semantics that can be ordered according to their selectivity.

Degree of Selectivity in Supports

In the previous sections, we defined supported equilibrium semantics and showed that all supported equilibriums are indeed also an equilibrium while vice versa is not necessarily true. That is, as shown in Example 7, there exist equilibriums that are not supported. Moreover, in various parts of this paper, we noted that supported equilibrium semantics is a unifying semantics that can define a spectrum of different semantics ordered according to their flexibility and/or selectivity. In this section, we want to further elaborate on the relationship between different semantics of a MCS.

In this section, we partially order different supports for logics and show that this ordering directly corresponds to the degree of selectivity in supported equilibrium semantics. That is, if support S is less than support S' (according to the ordering in this section), then supported semantics w.r.t. S' is more selective than supported semantics w.r.t. S.

We first define an ordering over justification functions:

Definition 6 (Ordered Justifications). *Let bs be a belief set for a logic L and j_1, j_2 be two justification functions for bs. Then, we say that j_1* is less selective than *j_2, denoted by $j_1 \leq j_2$, if, for all $b \in bs$, we have:*

$$\mathrm{fst}(j_1(b)) \subseteq \mathrm{fst}(j_2(b)) \text{ and } \mathrm{snd}(j_1(b)) \subseteq \mathrm{snd}(j_2(b)).$$

Intuitively, $j_1 \leq j_2$ means that j_1 requires less reasons than j_2 for supporting beliefs b in a belief set. Therefore, since supported equilibriums disallow self-justifying loops, requiring more reasons makes such a loop more probable and, so, shrinks the set of supported equilibriums.

Definition 7 (Ordered Supports). *Let $L := \langle KB, BS, ACC\rangle$ be a logic and Sup_L, Sup'_L be two supports for logic L. Then, we say that Sup_L* is less selective than *Sup'_L, denoted by $Sup_L \leq Sup'_L$ if, for all $kb \in KB$, $bs \in BS$, and $j' \in Sup'_L(kb, bs)$, a justification $j \in Sup_L(kb, bs)$ exists such that $j \leq j'$.*

Informally speaking, Definition 7 says that S_1 is a less selective support than S_2 if and only if, for all justification functions in S_2, a less selective justification function in S_1 can always be found. Hence, again, if $S_1 \leq S_2$ then using S_1 leads to less circularity and thus more supported equilibriums. The following theorem formalizes this reasoning:

Theorem 2. *Let $M := (C_1, \cdots, C_n)$ be a MCS and $S := (S_1, \cdots, S_n)$ be a supported equilibrium of M w.r.t. supports $(Sup_1, \cdots, Sup_n)$. Also, let supports $Sup'_1, \cdots, Sup'_n$ be such that $Sup'_i \leq Sup_i$ (for $1 \leq i \leq n$). Then, S is also a supported equilibrium of M w.r.t. supports $(Sup'_1, \cdots, Sup'_n)$.*

Proof. Let ordering $<$ and functions $f_i \in Sup_i^S$ witness S being a supported equilibrium. Since $f_i \in Sup_i^S$, by Definition 4, functions $g_i \in Sup_i(kb_i \cup app_i(S), S_i)$ and $R_i : S_i \mapsto \mathcal{P}(br_i)$ exist such that, for all $b \in S_i$: (1) $R_i(b)$ is a minimal subset of applicable bridge rules in br_i (with respect to S) that satisfies $\{hd(r) \mid r \in R_i(b)\} \supseteq \mathrm{snd}(g_i(b)) \setminus kb_i$, and, (2) $f_i(b) = \mathrm{fst}(g_i(b)) \cup \bigcup_{r \in R_i(b)} body^+(r)$.

Now, since $Sup'_i \leq Sup_i$, functions $g'_i \in Sup'_i(kb_i \cup app_i(S), S_i)$ exist such that $g'_i \leq g_i$. Also, construct R'_i such that $R'_i(b) = \{r \mid r \in R_i(b) \text{ and } hd(r) \in (\mathrm{snd}(g'_i(b)) \setminus kb_i)\}$. It is easy to check that $R'_i(b)$ satisfies minimality conditions of Definition 4 and, so, functions $f'_i \in Sup'^S_i$ exist such that $f'_i(b) = \mathrm{fst}(g'_i(b)) \cup \bigcup_{r \in R'_i(b)} body^+(r)$.

Therefore, in order to prove that S is supported w.r.t. $(Sup'_1, \cdots, Sup'_n)$, we only need to show that functions f'_i are non-circular. Note that, since $R'_i(b) \subseteq R_i(b)$ and $\mathrm{fst}(g'_i(b)) \subseteq \mathrm{fst}(g_i(b))$, we have $f'_i(b) \subseteq f_i(b)$ (for all b). Hence, the same ordering $<$ also shows the non-circularity of functions f'_i because:

$$(j : b') \in f'_i(b) \Rightarrow (j : b') \in f_i(b) \Rightarrow (j : b') < (i : b).$$

□

Theorem 2 shows that our ordering on supports is indeed relevant to our supported equilibrium semantics in the sense that greater supports are related to more selective semantics. The following proposition shows that our ordering relation on supports has a minimum and a maximum that respectively coincides with our unit and empty supports.

Proposition 1 (Least and Greatest Supports). *For all logics L and supports Sup_L, we have:* $\mathrm{uSup}_L \leq Sup_L \leq \mathrm{eSup}_L$.

Proof. Showing $Sup_L \leq \mathrm{eSup}_L$ is easy because $\mathrm{eSup}_L(kb, bs) = \emptyset$. Showing $\mathrm{uSup}_L \leq Sup_L$ is also easy because function $u^{bs} \in \mathrm{uSup}_L(kb, bs)$ is less than all $j \in Sup_L(kb, bs)$. This is because $\mathrm{fst}(u^{bs}(b)) = \emptyset \subseteq \mathrm{fst}(j(b))$ and $\mathrm{snd}(u^{bs}(b)) = \emptyset \subseteq \mathrm{snd}(j(b))$. □

According to Proposition 1, unit support is the most flexible support. In the next section, we show that if all logics use the unit support then supported equilibrium semantics coincides with equilibrium semantics. That is, equilibrium semantics is, in fact, a semantics in which beliefs are believed without really knowing why. On the other hand, we will also show in the next section that grounded equilibrium semantics is a particular case of supported equilibrium semantics in which having detailed justifications for beliefs are extremely important.

Generalizing Normal and Grounded Equilibrium Semantics

One of the promises of this paper was that our new supported equilibrium semantics generalizes both of the original semantics for multi-context systems, i.e., the equilibrium semantics and the grounded equilibrium semantics. In this section, we give Theorems 3 and 5 that, respectively, prove that equilibrium semantics and grounded equilibrium semantics are both special cases of supported equilibrium semantics (just using different support functions).

Theorem 3. *Let $M := (C_1, \cdots, C_n)$ be a MCS and $S := (S_1, \cdots, S_n)$ be a belief state of M. Then, S is an equilibrium of MCS if and only if S is a supported equilibrum of MCS w.r.t.* $(\mathrm{uSup}_{L_1}, \cdots, \mathrm{uSup}_{L_n})$.

Proof. ($\Leftarrow$) Directly follows Theorem 1.
($\Rightarrow$) Since S is an equilibrium model of M, we have that $S_i \in ACC(kb_i \cup app_i(S))$ for all $1 \leq i \leq n$. Therefore, by Definition 3, we know that $\mathrm{uSup}_{L_i}(kb_i \cup app_i(S), S_i) = \{u^{S_i}\}$. Now, by Definition 4, $Sup_i^S = \{f^{S_i}\}$ where $f^{S_i}(b) := \emptyset$ for all $b \in S_i$. Hence, we take $(f_1, \cdots, f_n) \in (Sup_1^S \times \cdots \times Sup_n^S)$ such that $f_i := f^{S_i}$. Now, by Definition 5, S is a supported equilibrium because functions $f_1, \cdots, f_n$ do not induce any circular justification. □

Theorem 3 shows that supported equilibrium semantics w.r.t. unit supports naturally extends equilibrium semantics. Previously, we discussed that unit support is associated with a complete black-box view of contexts since it does not provide any information about why something is believed. Hence, by Theorem 3, we know that equilibrium semantics indeed corresponds to the view of contexts as black-boxes.

Next, we show that, if support functions are chosen carefully, grounded equilibrium semantics can also be defined in terms of supported equilibrium semantics. In order to achieve our goal, we first characterize the unique minimal equilibrium of definite MCSs and use this definition to characterize the grounded equilibrium semantics in terms of supported equilibrium semantics.

Definition 8 (Monotonicity-based Support). *Let $L := \langle KB, BS, ACC\rangle$ be a monotone logic, $kb \in KB$ be a knowledge base and $bs \in BS$ be the unique acceptable belief set of kb, i.e., $\{bs\} = ACC(kb)$. Also, let $<$ be a total and well-founded ordering on kb. A function $j_< : bs \mapsto (\mathcal{P}(bs) \times \mathcal{P}(kb))$ is said to be a* monotonicity-based justification *according to ordering $<$ if, for all $b \in bs$, we have $j_<(b) := (bs_1, kb_2)$ where kb_1, kb_2, bs_1 and bs_2 are so that:*

- *either $kb_1 = bs_1 = \emptyset$ or $kb_1 \in KB$, $bs_1 \in BS$ and $\{bs_1\} = ACC(kb_1)$,*
- *$kb_2 \in KB$, $bs_2 \in BS$ and $\{bs_2\} = ACC(kb_2)$,*
- *formulas $k_1, k_2 \in kb$ exist such that $k_1 \leq k_2$, $kb_1 = kb_{<k_1}$, $kb_2 = kb_{\leq k_2}$, and, for all k' with $k_1 < k' \leq k_2$, we have $kb_{<k'} \notin KB$,*
- *$b \notin bs_1$ but $b \in bs_2$.*

We also define the monotonicity-based support of L, *denoted by* mSup_L, *as follows:*

If $\{bs\} \neq ACC(kb)$ then $\mathrm{mSup}_L(kb, bs) = \emptyset$;
Otherwise, $\mathrm{mSup}_L(kb, bs)$ is the set of monotonicity-based justifications $j_<$ according to ordering $<$.

In the following, Theorem 4 shows that, for definite multi-context systems, supported equilibrium semantics and grounded equilibrium semantics coincide.

Theorem 4. *Let $M := (C_1, \ldots, C_n)$ be a definite MCS and $S := (S_1, \cdots, S_n)$ be a belief state of M. Then, S is a supported equilibrium of M w.r.t.* $(\mathrm{mSup}_{L_1}, \cdots, \mathrm{mSup}_{L_n})$ *if and only if S is a grounded equilibrium of M.*

Proof. ($\Leftarrow$) Let S be a grounded equilibrium of M. By Proposition 1 of (Brewka and Eiter 2007), we know that $\{S_i\} = ACC_{L_i}(kb_i^\infty)$ where $kb_i^\infty := \bigcup_\alpha kb_i^\alpha$ and kb_i^α is defined as follows:

$$kb_i^\alpha := \begin{cases} kb_i & \text{if } \alpha = 0, \\ kb_i^\beta \cup app_i(E^\beta) & \text{if } \alpha = \beta + 1, \\ \bigcup_{\beta<\alpha} kb_i^\beta & \text{if } \alpha \text{ is a limit ordinal.} \end{cases}$$

where, for all ordinals α, we have $E^\alpha := (E_1^\alpha, \cdots, E_n^\alpha)$ and $\{E_i^\alpha\} = ACC(kb_i^\alpha)$. So, for ordinals α and β, if $\alpha < \beta$ then $E_i^\alpha \subseteq E_i^\beta$ (for all i). Thus, for all $k \in kb_i^\infty$ (respectively, for all $b \in S_i$), by $rank_i^{kb}(k)$ (respectively, by $rank_i^{bs}(b)$), we denote the minimum ordinal α such that $k \in kb_i^\alpha$ (respectively, $b \in E_i^\alpha$). Now, define orderings $<_i$ (for $i \in \{1, \cdots, n\}$) on kb_i^∞ to be any total ordering that respects the ranks of knowledge in kb_i^α's, i.e., for $k_1, k_2 \in kb_i^\infty$, we have $k_1 <_i k_2$ if $rank_i^{kb}(k_1) < rank_i^{kb}(k_2)$.

Next, we show that functions $f_1 \in \mathrm{mSup}_1^S, \cdots, f_n \in \mathrm{mSup}_n^S$ exist such that $f_1, \cdots, f_n$ avoid self-justification. In order to do that, consider support functions $g_i \in \mathrm{mSup}_{L_i}(kb_i^\infty \cup app_i(S), S_i)$ (for $i \in \{1, \cdots, n\}$) that are

generated according to orderings $<_i$ (respectively). Now, construct functions $f_i \in \mathrm{mSup}_i^{L_i}$ using g_i's so that, for $b \in S_i$, we have:

$$f_i(b) := \{(i : b') \mid b' \in \mathrm{fst}(g_i(b))\} \cup \bigcup_{r \in R_b} body^+(r),$$

where R_b is a minimal subset of applicable bridge rules of C_i such that, for each $k \in (\mathrm{snd}(g_i(b)) \setminus kb_i)$, there is a rule $r \in R$ with $hd(r) = k$ and $E_i^{rank_i^{kb}(k)-1} \models body(r)$. Note that $rank_i^{kb}(k) - 1$ is indeed an ordinal because, if $k \notin kb_i$, $rank_i^{kb}(k)$ is always a successor ordinal.

It can be easily checked that, for $i \in \{1, \cdots, n\}$, we have $f_i \in \mathrm{mSup}_i^{L_i}$. We just need to show that ordering $<^*$ exists such that $(i : p) \in f_j(q)$ implies $(i : p) <^* (j : q)$. Define $<^*$ as follows:

$$(i : p) <^* (j : q) \Longleftrightarrow \begin{cases} \text{either } i = j \text{ and } p \in g_i(q), \\ \text{or, } rank_i^{bs}(p) < rank_j^{bs}(q). \end{cases}$$

We leave it to the reader to check that $<^*$ is a well-founded ordering. Now, if $(i : p) \in f_j(q)$, we know that either $i = j$ and $p \in \mathrm{fst}(g_j(q))$ or $(i : p) \in body^+(r)$ for a rule $r \in app_i(S)$ with $hd(r) \in \mathrm{snd}(g_j(q))$. In the former case, by construction of $<^*$, we have $(i : p) <^* (j : q)$ as required. In the latter case, let $\alpha := rank_j^{bs}(q)$. By construction of $\mathrm{snd}(g_j(q))$, we know that α is a successor ordinal and that r is applicable under $E^{\alpha-1}$. Thus, $p \in E_i^{\alpha-1}$. Hence, $rank_i^{bs}(p) \leq \alpha - 1 < \alpha = rank_j^{bs}(q)$ and, so, by construction of $<^*$ and as required, $(i : p) <^* (j : q)$. Hence, S is a supported equilibrium of M.

($\Rightarrow$) Since S is a supported equilibrium, functions $f_i \in \mathrm{mSup}_i^{L_i}$ and well-ordering $<_{X(S)}$ exist such that $(i : p) \in f_j(q)$ implies $(i : p) <_{X(S)} (j : q)$. Also, by Definition 4, we know that each f_i is constructed according to some $g_i \in \mathrm{mSup}_{L_i}(kb_i \cup app_i(S), S_i)$. Also, since M is a definite MCS, it has a unique minimal equilibrium. Let $E := (E_1, \cdots, E_n)$ be that minimal equilibrium.

By Theorem 1, we know that S is an equilibrium of M. Thus, we only need to show that S is minimal. Assuming otherwise means that i and p exist such that $p \in S_i$ but $p \notin E_i$. Choose a minimal such i and p w.r.t. ordering $<_{X(S)}$. By Definition 8, $f_i(p) \supseteq \bigcup_{r \in R} body^+(r)$ where R satisfies $\{hd(r) \mid r \in R\} \supseteq (\mathrm{snd}(g_i(p)) \setminus kb_i)$. Now, since $(i : p)$ is minimal w.r.t. $<_{X(S)}$, if $(j : q) \in f_i(p)$ then $q \in E_j$. Thus, for all $r \in R$, we have $E \models body(r)$ and, so, $app_i(E) \supseteq \{hd(r) \mid r \in R\} \supseteq (\mathrm{snd}(g_i(p)) \setminus kb_i)$. Therefore, $(kb_i \cup app_i(E)) \supseteq \mathrm{snd}(g_i(p))$. Now, assume that bs is the unique acceptable belief set of $\mathrm{snd}(g_i(p))$. By Definition 8, $p \in bs$. Moreover, since L_i is monotone and $\{E_i\} = ACC(kb_i \cup app_i(E))$, we have that $E_i \supseteq bs$ and, henceforth, $p \in E_i$. This contradicts our assumption that $p \notin E_i$. Therefore, S is a minimal equilibrium and, since M has only one minimal equilibrium, $S = E$. □

Theorem 4 shows that, for definite MCS, grounded equilibrium semantics can be defined in terms of supported equilibrium semantics. In the following, we use monotonicity-based support of M and Theorem 4 to show that, indeed, grounded equilibrium semantics can always be defined in terms of supported equilibrium semantics.

Definition 9 (Reducibility-based Supports). *Let $L := \langle KB, BS, ACC\rangle$ be a reducible logic. Also, let $kb \in KB$ and $bs \in ACC(kb)$. Moreover, let $L^* := \langle KB^*, BS, ACC\rangle$ be the monotone part of logic L. The* reducibility-based support of L, *denoted by* $\mathrm{rSup}_L(kb, bs)$, *is the set of functions $f : bs \mapsto (\mathcal{P}(bs) \times \mathcal{P}(kb))$ such that:*

$$\exists f' \in \mathrm{mSup}_{L^*}(red_L(kb, bs), bs) \text{ s.t.} \\ \forall b \in bs : \ f(b) = (\mathrm{fst}(f'(b)), \mathrm{snd}(f'(b)) \cap kb).$$

Needless to say that $\mathrm{rSup}_L(kb, bs) = \emptyset$ *if* $bs \notin ACC(kb)$.

The following lemma suggests that the difference between monotonicity-based supports and reducibility-based supports disappear when we move to the supports to the level of contexts.

Lemma 1. *For reducible MCS $M := (C_1, \cdots, C_n)$ and belief state $S := (S_1, \cdots, S_n)$ of M, let $C_i' := (L_i^*, red_{L_i}(kb_i, S_i), br_i^*)$ where L_i^* is the monotone part of L_i and br_i^* is the reduct of br_i under S. Then, for all i, $\mathrm{mSup}_i^S = \mathrm{rSup}_i^S$.*

Theorem 5. *Let $M := (C_1, \ldots, C_n)$ be a reducible MCS and $S := (S_1, \cdots, S_n)$ be a belief state of M. Then, S is a grounded equilibrium of M if and only if S is a supported equilibrium of M w.r.t. $(\mathrm{rSup}_{L_1}, \cdots, \mathrm{rSup}_{L_n})$.*

Proof. ($\Rightarrow$) Let S be a ground equilibrium of M. Then, S is the unique grounded equilibrium of M^S and, hence, a supported equilibrium of M w.r.t. $(\mathrm{mSup}_{L_1^*}, \cdots, \mathrm{mSup}_{L_n^*})$ (by Theorem 4 and where L_i^*'s are the monotone part of L_i's). Therefore, $f_i^* \in \mathrm{mSup}_i^S$ and strict well-ordering $<$ exist such that $p \in S_i \wedge (j : q) \in f_i(p) \Rightarrow (j : q) < (i : p)$. By Lemma 1, $f_i \in \mathrm{rSup}_i^S$. Thus, S is a supported equilibrium of M w.r.t. $(\mathrm{rSup}_1, \cdots, \mathrm{rSup}_n)$.

($\Leftarrow$) Let S be a supported equilibrium of M. Then, by Lemma 1, S is also a supported equilibrium of M^S (using the same support functions and well-ordering). Therefore, S is the unique grounded equilibrium of M^S (by Theorem 4). Hence, S is a grounded equilibrium of M. □

Theorem 5 shows that supported equilibrium semantics naturally extends grounded equilibrium semantics. We also showed previously in Theorem 3 that supported equilibrium semantics also naturally extends equilibrium semantics of MCSs. Thus, our supported equilibrium semantics indeed extends and unifies both the equilibrium semantics and the grounded equilibrium semantics.

Application: Better Diagnoses

In this section, we discuss one of possible applications of supported equilibrium semantics for MCSs: the detailed diagnosis of MCSs in the presence of supports.

Recall the example of shops and warehouses from the beginning of the section on generalized MCSs. There, a product was believed to be unavailable for sale because (1) the product was believed not to be in the warehouse, (2) all

the available instances of that product in the store were believed to be "sold," and, (3) our knowledge base asserted that a product can be available only if it is available in the warehouse or if it is available in the store and not marked as "sold." Now, consider an extension of this example in which this product is also believed to be on route from factory to warehouse and our knowledge asserts that a product cannot be both unavailable and on route to warehouse. Here, using supports to trace back the reason for conflict, a more meaningful diagnosis can be obtained: to change our knowledge so that we also believe a product is available if it is on route from factory to warehouse. Note that our diagnosis here proposes a change to the knowledge base of a context; a diagnosis that was impossible without using justifications.

In (Bögl et al. 2010) and (Eiter et al. 2010), authors rightly argue that, due to their distributed behavior and complexity, MCSs are prone to two types of errors: those that originate inside a context and those that originate in the interaction between contexts. Moreover, the authors introduce *inconsistency explanations* and *diagnoses* to repair inconsistent MCSs. For MCS M, an inconsistency-explanation is a pair (E_1, E_2) so that $E_1, E_2 \subseteq br_M$ which, informally speaking, means that if all bridge rules in E_1 are kept and all bridge rules in E_2 are non-applicable then M is inconsistent. Thus, (E_1, E_2) explains why M is inconsistent: because bridge rules in E_1 are all applicable or because bridge rules in E_2 are all non-applicable. Also, authors of (Eiter et al. 2010) study the dual notion of diagnoses (D_1, D_2) which means that excluding bridge rules in D_1 and excluding enough conditions from the body of bridge rules in D_2 makes M consistent. Hence, a diagnosis tells us a way to restore the consistency of M.

The authors of (Eiter et al. 2010) study inconsistency explanations and diagnoses and prove their duality. However, diagnoses and inconsistency explanations only take bridge rules into consideration and cannot deal with inconsistencies that arise from errors internal to a knowledge base. However, we now know that supported equilibrium semantics provides the right means to look inside the contexts of a MCS. Therefore, a mistake can be traced back to its source via justifications. In this section, we consider an example of how better repair is achievable through support functions and leave the full treatment of this subject to a future research.

Moreover, and even more importantly, supported equilibrium semantics enables us to focus on incorrectness of MCSs rather than their inconsistency. It should be clear that inconsistency and incorrectness are different notions. For example, consider MCS M from Example 1. M has two equilibrium models and, thus, is consistent. However, M accepts unintended equilibrium model S_2 and, thus, is incorrect. Similarly, one could argue that some inconsistent multi-context systems are indeed correct. For instance, a tour of American cities that passes each city exactly once might not exist. The non-existence of such a path might make a MCS inconsistent but it does not make it incorrect.

Example 8. *Consider MCS M of Example 1 and its equilibrium model S_1. We know that S_1 is a supported equilibrium model of M w.r.t. the same support functions as in Example 7. According to S_1, "Jimmy Kimmel" is not famous, not wealthy and not a celebrity which is contradictory to the real world. So, we want to guarantee that M should assert $celebrity(jk)$. Under this assumption, M is incorrect because it allows S_1 to be supported. Thus, M is consistent but not correct (because it does not represent what it is intended to represent). Now, using support functions, we understand that one possible repair for our MCS is to guarantee in C_3 that "Jimmy Kimmel" is a comedian. In this case, a non-circular chain of justifications would guarantee that $celebrity(jk)$, $wealthy(jk)$ and $famous(jk)$ will all be true. Thus, we would add knowledge $comedian(jk)$ to the knowledge base of C_3 to repair this example and disallow S_1 from being a supported equilibrium.*

Hence, supported equilibrium semantics enables us to focus on correctness (rather than consistency), and better repair MCSs (by proposing internal changes to contexts).

Conclusion and Future Directions

In this paper, we introduced the notion of justifications and supports to MCSs and invented the novel semantics of supported equilibria for MCSs. Moreover, we showed that supported equilibrium semantics is useful in two important ways: (a) from the theoretical aspect, supported semantics generalizes the two main semantics proposed for multi-context systems, i.e., the equilibrium semantics and the grounded equilibrium semantics, and, (b) from the application point of view, supported equilibrium semantics provides the means to look inside the contexts of MCSs and to better diagnose and repair faulty MCSs. Hence, we believe that supported equilibrium semantics is the most suitable semantics available for MCSs.

Moreover, in this paper, we only argued about two very specific supports, i.e., the trivial unit supports and the reducibility-based supports. We also discussed that supported equilibrium semantics allows the inclusion of many more possible supports that, from the viewpoint of selectivity degree, lie between these two semantics. We believe that many other useful supports exist that have not been investigated in this paper. For example, an interesting and unanswered question about supported equilibrium semantics is to find necessary and/or sufficient conditions under which it is guaranteed that supported equilibria of a MCS will form an anti-chain. Answering such a question gives us natural ways to define a semantics similar to stable model semantics for arbitrary new languages.

Abstract

Angry Birds is a popular video game where the task is to kill pigs protected by a structure composed of different building blocks that observe the laws of physics. The structure can be destroyed by shooting the angry birds at it. The fewer birds we use and the more blocks we destroy, the higher the score. One approach to solve the game is by analysing the structure and identifying its strength and weaknesses. This can then be used to decide where to hit the structure with the birds.

In this paper we use a qualitative spatial reasoning approach for this task. We develop a novel qualitative spatial calculus for representing and analysing the structure. Our calculus allows us to express and evaluate structural properties and rules, and to infer for each building block which of these properties and rules are satisfied. We use this to compute a heuristic value for each block that corresponds to how useful it is to hit that block. We evaluate our approach by comparing the suggested shot with other possible shots.

Introduction

Qualitative spatial representation and reasoning has numerous applications in Artificial Intelligence including robot planning and navigation, interpreting visual inputs and understanding natural language (Cohn and Renz 2008). In recent years, plenty of formalisms for reasoning about space were proposed (Freksa 1992; Frank 1992; Renz and Mitra 2004). An emblematic example is the RCC8 algebra proposed by Randell *et al*. (1992). It represents topological relations between regions such as "x overlaps y", or "x touches y"; however, it is unable to represent direction information such as "x is on the right of y" (Balbiani, Condotta, and del Cerro 1999). The Rectangle Algebra (RA) (Mukerjee and Joe 1990; Balbiani, Condotta, and del Cerro 1999), which is a two-dimensional extension of the Interval Algebra (IA) (Allen 1983), can express orientation relations and at the same time represent topological relations, but only for rectangles. If we want to reason about topology and direction relations of regions with arbitrary shapes, we could for example combine RCC8 and RA, which was analysed by (Liu, Li, and Renz 2009). However, if we only consider the minimum bounding rectangles (MBR) of regions, RA is expressive enough to represent both direction and topology.

What is common in basically all qualitative spatial representations that have been proposed in the literature, and in particular for two-dimensional calculi such as the RA, is that the represented world is assumed to be represented from a birds-eye view, that is from above like a typical map. This is particularly remarkable since qualitative representation and qualitative reasoning are usually motivated as being very close to how humans represent spatial information. But humans typically don't perceive the world from a birds-eye view, the "human-eye view" is to look at the world sideways! When looking at the world sideways, the most important feature of the world is the distinction of "up" and "down" and the concept of gravity. What goes up must come down, everything that is not supported by something and is not stable will invariably fall to the ground. This gives a whole new meaning to the concept of consistency which is typically analysed in the context of qualitative spatial reasoning: a qualitative representation Θ is consistent if there is an actual situation θ that can be accurately represented by Θ. But if any possible θ is not stable and would fall apart under gravity, then Θ cannot be consistent.

In this paper we are concerned with the human-eye view of the world, i.e., we want to be able to have a qualitative representation that takes into account gravity and stability of the represented entities.

Ideally, we want a representation that allows us to infer whether a represented structure will remain stable or whether some parts will move under the influence of gravity or some other forces (e.g. the structure is hit by external objects). Additionally, if the structure is regarded as instable, we want to be able to infer the consequences of the instability, i.e., what is the impact and resulting movement of the instable parts of the structure. Gravity and stability are essential parts of our daily lives and any robot or AI agent that is embedded in the physical world needs to be able to reason about stability. Obvious examples are warehouse robots who need to be able to safely stack items, construction robots whose constructions need to be stable, or general purpose household robots who should be able to wash and safely stack dishes. But in the end, any intelligent agent needs to be able to deal with stability, whenever something is picked up, put down or released. While this problem is clearly of

general interest, the motivating example we use in this paper is the popular Angry Birds game. There we have a two-dimensional snapshot of the world, ironically in the human-eye view and not the birds-eye view, and inferring how objects move and fall down under gravity and other forces is of crucial importance when trying to build an AI agent that can successfully play the game.

The Rectangle Algebra is not expressive enough to reason about the stability or consequences of instability of a structure in a human-eye view. While it is possible to some degree, we could simply impose that a structure can only be consistent if each rectangle is supported from below, this is only a necessary condition, it is clearly not sufficient. For example, in Fig. 1(a) and (b), assume the density of the objects is the same and object 2 is on the ground. The RA relation between object 1 and object 2 in these two figures are both <start inverse, meet inverse>, but obviously the structure in Fig. 1(a) is stable whereas object 1 in (b) will fall. In order to make such distinctions, we need to extend the granularity of RA and introduce new relations that enable us to represent these differences. In this paper, we introduce an *Extended Interval Algebra* (EIA) which contains 27 relations instead of the original 13. We use the new algebra as a basis for an *Extended Rectangle Algebra* (ERA), which is obtained in the same way as the original RA. Depending on the needs of an application, we may not need to extend RA to 27 relations in each dimension. Sometimes we only need the extended relations in one axis. Thus, the extended RA may include 13×27, 27×13 or 27×27 relations depending on the requirement of different tasks.

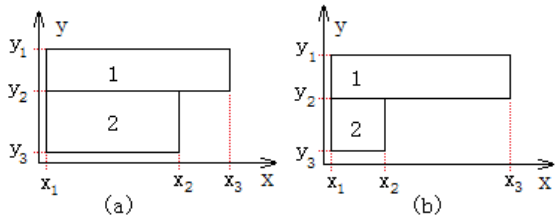

Figure 1: Two structures with the same RA relation (si,mi)

In the following, we will introduce EIA and ERA and then develop a rule-based reasoning method that allows us to infer the stability of a structure and the consequences of the detected instability. Our method is focused towards our target application, namely, to build an agent that can play the Angry Birds game automatically and rationally. This requires us to identify a target that will make a given stable structure maximally instable and will lead to the greatest damage to the structure. In order to do so, we take a stable structure (typically everything we see is by default stable) and for each possible target object we remove the object and analyse the consequences of the structure minus this object. Other applications may require a slightly different method, but the basic stability detection we develop is a general method. The results of our evaluation show that the agent based on this method is able to successfully detect stability and to infer the consequences of instability.

Interval Algebra and Rectangle Algebra

Allen's Interval Algebra defines a set $\mathcal{B}_{int}$ of 13 basic relations between two intervals (see Fig.2). It is an illustrative model for temporal reasoning. The set of all relations of IA is the power set $2^{\mathcal{B}_{int}}$ of $\mathcal{B}_{int}$. The composition ($\circ$) between basic relations in IA is illustrated in the transitivity table in Allen [1983]. The composition between relations in IA is defined as $R \circ S = \cup\{A \circ B : A \in R, B \in S\}$.

Relation	Illustration	Interpretation
X b Y Y a X	X Y	X takes place before Y
X m Y Y mi X	X Y	X meets Y(*i* stands for *inverse*)
X o Y Y oi X	X Y	X overlaps with Y
X s Y Y si X	X Y	X starts Y
X d Y Y di X	X Y	X during Y
X f Y Y fi X	X Y	X finishes Y
X = Y	X Y	X is equal to Y

Figure 2: The 13 basic relations of the Interval Algebra

RA is an extension of IA for reasoning about 2-dimensional space. The basic objects in RA are rectangles whose sides are parallel to the axes of some orthogonal basis in 2-dimensional Euclidean space (see Fig. 1). The basic relations of RA can be denoted as $\mathcal{B}_{rec} = \{(A, B)|A, B \in \mathcal{B}_{int}\}$. The composition between basic RA relations is defined as $(A, B) \circ (C, D) = (A \circ C, B \circ D)$.

The Extended Rectangle Algebra (ERA)

In order to express the stability of a structure and reason about the consequences of the instability in a situation which observes physical rules, we extend the basic relations of IA from 13 relations to 27 relations denoted as $\mathcal{B}_{eint}$ (see Fig.3). The relations consider the importance of the centre of mass of an object for its stability, which corresponds to its centre point for rectangular objects.

Definition 1 (The extended IA relations). *We introduce the centre point of an interval as a new significant point in addition to the the start and end points. For an interval a, denote centre point, start point and end point as c_a, s_a and e_a, respectively.*
1. The 'during' relation has been extended to 'left during', 'centre during' and 'right during' (ld, cd & rd).

- *"x ld y" or "y ldi x" :* $s_x > s_y, e_x \leq c_y$
- *"x cd y" or "y cdi x":* $s_x > s_y, s_x < c_y, e_x > c_y, e_x < e_y$
- *"x rd y" or "y rdi x" :* $s_x \geq c_y, e_x < e_y$

2. The 'overlap' relation has been extended to 'most overlap most', 'most overlap less', 'less overlap most' and 'less overlap less'(mom, mol, lom &lol).

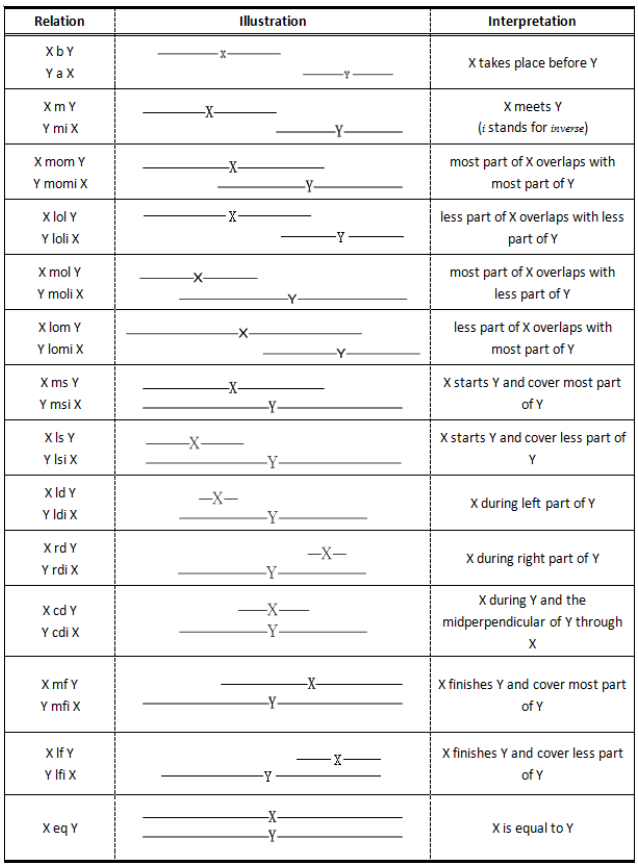

Figure 3: The 27 basic relations $\mathcal{B}_{eint}$ of the extended IA

- *"x mom y" or "y momi x"* : $s_x < s_y, c_x \geq s_y, e_x \geq c_y, e_x < e_y$
- *"x mol y" or "y moli x"* : $s_x < s_y, c_x \geq s_y, e_x < c_y$
- *"x lom y" or "y lomi x"* : $c_x < s_y, e_x \geq c_y, e_x < e_y$
- *"x lol y" or "y loli x"* : $c_x < s_y, e_x > s_y, e_x < c_y$

3. The 'start' relation has been extended to 'most start' and 'less start' (ms & ls).

- *"x ms y" or "y msi x"* : $s_x = s_y, e_x \geq c_y$
- *"x ls y" or "y lsi x"* : $s_x = s_y, e_x > s_y, e_x < c_y$

4. Similarly, the 'finish' relation has been extended to 'most finish' and 'less finish' (mf & lf).

- *"x mf y" or "y mfi x"* : $s_x > s_y, s_x \leq c_y, e_x = e_y$
- *"x lf y" or "y lfi x"* : $s_x > c_y, s_x < e_y, e_x = e_y$

Denote the set of relations of extended IA as the power set $2^{\mathcal{B}_{eint}}$ of the basic relation set$\mathcal{B}_{eint}$. Denote the set of relations of extended RA as the power set $2^{\mathcal{B}_{erec}}$ of the basic relation set$\mathcal{B}_{erec}$. The composition table of EIA and ERA is straightforward to compute.

Note that EIA can be expressed in terms of INDU relations (Pujari, Kumari, and Sattar 2000) if we split each interval x into two intervals x_1 and x_2 that meet and have equal duration. However, this would make representation of spatial information very awkward and unintuitive. There is also some similarity with Ligozat's general intervals (Ligozat 1991) where intervals are divided into zones. However, the zone division does not consider the centre point.

Inferring stability using ERA rules

In the example in Figure 1 we have seen a simple case where a situation is instable. However, since instability is not a concept which is contained in ERA itself, but is rather a consequence of certain ERA cases, compositional reasoning which is typically used in qualitative spatial reasoning is not helpful for determining instability. Instead, we express standard physical stability rules using ERA relations and use rule-based reasoning to infer stability.

For our analysis we assume that the centre of mass of all objects we represent is at the centre of their MBR. This is always the case for circles and rectangles with a uniform density, even if the rectangles are not parallel to the ground. This covers most objects used in Angry Birds, with the exception of triangular shaped objects and non-structurally significant objects. The MBRs of all Angry Birds objects are obtained using the object recognition module of the basic Angry Birds game playing software that is provided by the organisers of the Angry Birds AI competition (AIBIRDS). In order to get the real shapes of objects, we used an improved version of the object recognition module (Ge et al. 2014), which will be added to the basic software package soon. This module also detects the ground, which is important for stability analysis. In accordance with Ge and Renz (2013) we call rectangles that are equivalent to their MBRs *regular* rectangles and otherwise *angular* rectangles. Figure 4 gives an overview of the different kinds of angular rectangles that Ge and Renz distinguish. The distinctions are mainly whether rectangles are fat or slim, or lean to the left or right. Interestingly, these distinctions can be expressed using ERA relations by comparing the projections of each of the four edges of the angular rectangle with the projections of the corresponding MBR.

We first translate all objects we obtain using the object recognition modules into a set of ERA constraints Θ. Since all these objects are from real Angry Birds scenes, all ERA constraints in Θ are basic relations and the identified objects are a consistent instantiation of Θ. This is a further indication that compositional reasoning is not helpful for determining stability. The next step is that we extract all contact points between the objects. This is possible for us to obtain since we have the real shapes of all objects. The contact points allow us to distinguish different types of contact between two objects, which we define as follows:

Definition 2 (Contact Relation). *Two rectangles R_1 and R_2 can contact in three different ways:*

- *If one corner of R_1 contacts with one edge of R_2, then R_1 has a* point to surface contact *with R_2, denoted as $CR(R_1, R_2) = ps$*
- *If one edge of R_1 contacts with one edge of R_2, then R_1 has a* surface to surface contact *with R_2, denoted as $CR(R_1, R_2) = ss$*
- *If one corner of R_1 contacts with one corner of R_2, then R_1 has a* point to point contact *with R_2, denoted as $CR(R_1, R_2) = pp$*

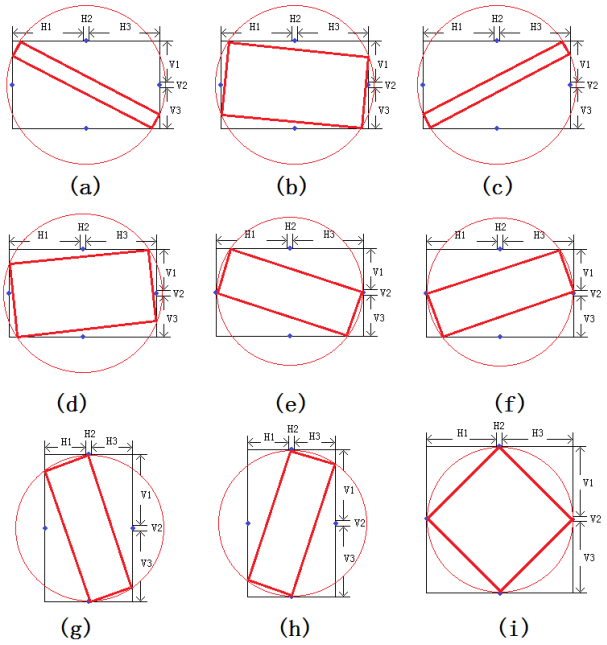

Figure 4: 9 types of angular rectangles (Ge and Renz 2013)

- *If R_1 does not touch R_2, then R_1 has* no contact *with R_2, denoted as $CR_{R_1,R_2} = n$*

Definition 3 (Contact Dimension). *The* contact dimension *expresses in which dimension (horizontal or vertical) two rectangles R_1 and R_2 contact each other. Specifically, if $CR(R_1, R_2) \in \{ps, ss, pp\}$, then:*

- *R_1 and $_2$* contact horizontally *(denoted as $CD(R_1, R_2) = hc$), if $ERA(R_1, R_2) \in (\{m, mi\}, U_{EIA})$, where $\mathcal{U}_{EIA}$ is the set of all EIA relations.*
- *In all other cases R_1 and R_2* contact vertically*, denoted as $CD(R_1, R_2) = vc$.*

If $CR(R_1, R_2) = n$, then $CD(R_1, R_2) = n$, too.

Stability of Regular Rectangles

We start with stability for regular rectangles as the rules are obvious consequences of Newtonian physics. Throughout this paper, we will never consider what is happening *above* an object when determining its stability. As an example how this can influence stability, refer again to Figure 1(b). Suppose we put a very heavy object 3 on object 1, then object 1 might be stable if the combined centre of mass of objects 1 and 3 is above object 2. Since this requires numerical calculations and cannot be obtained qualitatively, we will always ignore these cases, and consequently will only be able to obtain an approximation of stability. We therefore call our stability concept *ERA-stability*. ERA-stability is based on the simple physical rule that an object is stable and will not topple if the vertical projection of the centre of mass of an object falls into the area of support base.

Given a set of ERA-constraints Θ and a consistent instantiation θ, where the centre of mass of all elements $x \in \theta$ coincides with the centre of the MBR of x. ERA-stability for regular rectangles $x \in \theta$ is determined recursively using the following rules, until no more objects are determined ERA-stable:

A regular rectangle $x \in \theta$ is ERA-stable, if one of the following rule applies:

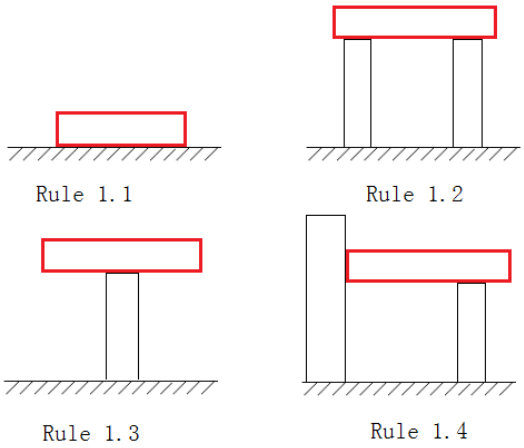

Figure 5: Examples for ERA-stable cases of regular rectangles

Rule 1.1: x lies on the ground.

Rule 1.2: $\exists y, z \in \theta$ such that y and z are both ERA-stable and $CD(y, x) = CD(z, x) = vc$: $ERA_x(x, y) \in \{momi, moli, lomi, loli, msi, lsi, ldi\} \wedge ERA_x(x, z) \in \{mom, mol, lom, lol, mfi, lfi, rdi\}$.

Rule 1.3: $\exists y \in \theta$ such that y is ERA-stable and $CD(y, z) = vc$: $ERA_x(x, y) \in \{ms, mf, msi, ls, mfi, lf, cd, cdi, ld, rd, mom, momi, lomi, mol\}$.

Rule 1.4: $\exists y, z \in \theta$ such that y and z are both ERA-stable, $CD(x, y) = hc$ and $CD(x, z) = hc$: $((ERA_x(x, y) \in \{mi\} \wedge ERA_x(x, z) \in \{mom, mol, lom, lol, mfi, lfi, rdi\}) \vee (ERA_x(x, y) \in \{m\} \wedge ERA_x(x, z) \in \{momi, moli, lomi, loli, msi, lsi, ldi\}))$

Rule 1.2 covers the cases where the vertical projection of the mass centre of an object is located between two ERA-stable supporters y and z. Rule 1.3 covers the cases where it is located above the contact area of an ERA-stable supporter y. Rule 1.4 covers cases where x is horizontally contacting with an ERA-stable object on one side and has an ERA-stable supporter on the other side. Fig. 5 shows examples of the four ERA-stable cases for a regular rectangle. In all four rules x is always ERA-stable.

Stability of Angular Rectangles

The case of angular rectangles is more complicated than regular rectangles, but it follows the same physical rule that if an object is stable, the vertical projection of the centre of mass must falls into a support area. While the support area

for regular rectangles is defined by two supporting objects, for angular rectangles it can be defined by the ground, acting as a supporting object, and one supporting object. Angular rectangles always have a momentum to become regular rectangles. The rectangles in Figure 4(a,b,e) have a momentum in counter-clockwise direction, the rectangles in Figure 4(c,d,f) have a momentum in clockwise direction. The three rectangles in the bottom row probably never occur in reality as the top point has to be exactly above the bottom point and we ignore these cases. The momentum means that an angular rectangle always needs support to prevent it from becoming a regular rectangle. In cases where the bottom point of an angular rectangle is supported, for example by the ground, the second support must always be on the opposite side of the centre of mass. This leads to the following rules, which again are applied recursively, until no more objects are determined ERA-stable:

An angular rectangle $x \in \theta$ is ERA-stable, if one of the following rule applies:

Rule 1.5: $\exists y, z \in \theta$ such that y and z are both ERA-stable and $CD(y,x) = CD(z,x) = vc$: $ERA_x(x,y) \in \{momi, moli, lomi, loli, msi, lsi, ldi\} \wedge ERA_x(x,z) \in \{mom, mol, lom, lol, mfi, lfi, rdi\}$.

Rule 1.6: $\exists y \in \theta$ such that y is ERA-stable and $CD(y,x) = vc$ and $CR(x,y) = ss$: $ERA_x(x,y) \in \{ms, mf, msi, ls, mfi, lf, cd, cdi, ld, rd, mom, momi, lomi, mol\}$.

Rule 1.7: $\exists y, z \in \theta$ such that y and z are both ERA-stable and $CD(y,x) = hc$ and $CD(z,x) = vc$: $((ERA_x(x,y) \in \{mi\} \wedge ERA_x(x,z) \in \{mom, mol, lom, lol, mfi, lfi, rdi\}) \vee (ERA_x(x,y) \in \{m\} \wedge ERA_x(x,z) \in \{momi, moli, lomi, loli, msi, lsi, ldi\}))$.

Rule 1.8: $\exists y, z \in \theta$ such that y and z are both ERA-stable and $CD(y,x) = CD(z,x) = hc : ERA_x(x,y) \in \{m\} \wedge ERA_x(x,z) \in \{mi\}$

The principle of Rule 1.5 is similar to Rule 1.2 which tests if the centre of mass falls between two vertical supporters. Rule 1.6 is similar to Rule 1.3, the difference is that it requires the two objects to be surface-to-surface contact, otherwise the angular rectangle will topple. The supporter in this case also needs sufficient support to remain stationary. Rule 1.7 is a similar rule as Rule 1.4 which describes horizontal support for angular rectangles. Rule 1.8 describes a different property of angular rectangles, which is an angular rectangle can remain stable with the support of two horizontally contacting objects on both left and right sides. This is because the two objects on the sides can provide upward frictions to support the angular rectangle. Fig. 6 shows example cases of the above four rules where angular rectangles are ERA-stable.

All these rules only consider objects as support that are already stable. Cases where two rectangles are stable because they support each other are not considered. Applying rules 1.1-1.8 recursively to all objects in θ until no more objects are detected as ERA-stable identifies all ERA-stable objects. If all objects in θ are ERA-stable, then θ is ERA-stable. The recursive assignment of ERA-stability to objects

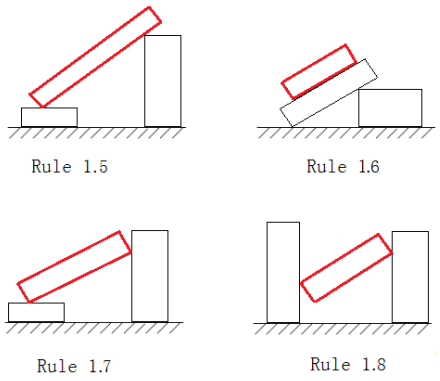

Figure 6: ERA-stable cases of angular rectangles

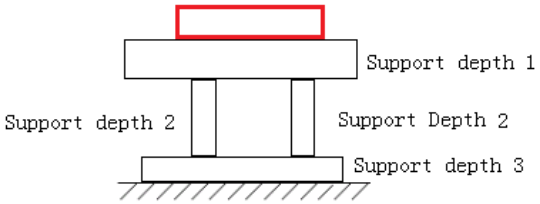

Figure 7: Illustration of support structure

allows us to build a *stability hierarchy*. Regular objects that lie on the ground are objects of *stability level* 1. Then, objects that are stable because they are supported by an object of stability level ℓ and possible objects objects of stability level smaller than ℓ are considered to be of level $\ell + 1$. Conversely, we could define the *support depth* of a target object (see Figure 7). Those object that are directly responsible for the ERA-stability of a target object x as they support it have support depth 1. Objects that are directly responsible for the ERA-stability of an object y of support depth ℓ as they support it have support depth $\ell + 1$. This can be calculated while recursively determining stability of objects. The support level can be helpful in order to separate the support structure of an object from the larger structure, or when determining which object could cause the most damage to a structure when destroyed.

Applying ERA-stability to identify good shots in Angry Birds

The goal of the Angry Birds game is to shoot birds using a slingshot in a way that all pigs are killed with the fewest number of used birds. The pigs are typically supported by complicated structures that have to be destroyed in order to kill the pigs. Instead of shooting at a pig directly, it might be better to destroy the whole structure that supports the pig. This could be optimised by using the support structure we defined in the previous section.

Another useful substructure is the shelter of the pigs. The

reason is straightforward, if a pig is not reachable, there must be some objects that protect it; these objects form the sheltering structure of the pigs. Destroying the sheltering structure can either kill the pig or make the pig directly reachable to the bird. We define the sheltering structure of a pig as the closest objects that protect the pig from a direct hit from each direction. Specifically, a sheltering structure of an object (usually a pig) consist of left, right and top sheltering objects. In order to obtain the sheltering structure of a certain object, the first step is to get the closest object from the left side of the queried object; then, get the supportee list of the object (similar process as getting the supporter list); after that, get the right closest object with its supportee list. The next step is to check if the two supportee lists have objects in common. If so, pick the one with smallest depth as the roof object of the sheltering structure; if not, there is no sheltering structure for the queried object. If a roof object is found, also put the supportees of both the left and right closest objects with smaller depth than the roof object into the sheltering structure. Finally, put the supporters of both left and right closest objects which are not below the queried object into the sheltering structure. This can also be described using rules expressed in ERA (actually RA is sufficient).

The integration of the rules to evaluate a shot

With the rules described above, we are able to dynamically analyse the possible consequences after a shot has been made. In order to predict the final consequence of an external influence on the structure (usually the impact from a bird), the direct consequence and its following subsequences should be analysed in detail. Funt (1987) suggested a similar method to simulate the consequence of a structure with a changed object which assumes that the changed object disappears and chooses the most significant instable object to simulate the consequence.

In the following, we analyse different cases of how a structure can be impacted from an external force and, in particular, what other objects will be affected by an impact to the target object. We separately analyse *regular rectangles* and *angular rectangles*, each of which can be affected in four different ways. First we consider the four cases where the affected objects are regular rectangles:

Case 1: The target object is directly hit by another object. The direct consequence to the hit object will be one of three types: **destroyed, toppling, remaining stationary**. Empirically, the way to determine the consequence of the hit depends on the height and width ratio of the target. For example, if an object hits a target with the height and width ratio larger than a certain number (such as 2), the target will fall down. And this ratio can be changed to determine the conservative degree of the system. In other words, if the ratio is high, the system tends to be conservative because many hits will have no influence on the target. Moreover, if the external object affects a target with the height and width ratio less than one, the target itself will remain stable temporarily because the system will also evaluate its supporter to determine the final status of the target. After deciding the direct consequence of the hit, the system should be able to suggest further consequences of the status change of the direct target. Specifically, if the target is destroyed, only its supportees will be affected. If the target falls down, the case will be more complex because it may influence its supporters due to the friction, as well as its supportees and neighbours. If the target remains stable temporarily, it will also influence its supporters, and its supporters may again affect its behaviour. Algorithm 1 demonstrates the evaluation process of an object that has been hit by another object.

Algorithm 1 Direct hit estimation

```
1:  PROCEDURE Hit(Object o)
2:  o ∈ pendingList
3:  if o ∈ affectedList then
4:     pendingList.remove(o)
5:     Exit()
6:  end if
7:  if o.isRegular then
8:     if o.affectedMethod = "Hit" then
9:        if o.isDestroyed then
10:          affectedList.add(o)
11:          pendingList.add(supporteesOf(o))
12:       else if !o.isDestroyed then
13:          if o.height/o.width > threshold then
14:             affectedList.add(o)
15:             pendingList.add(supporteesOf(o))
16:             pendingList.add(supportersOf(o))
17:          else
18:             pendingList.add(supportersOf(o))
19:          end if
20:       end if
21:    end if
22: end if
23: pendingList.remove(o)
```

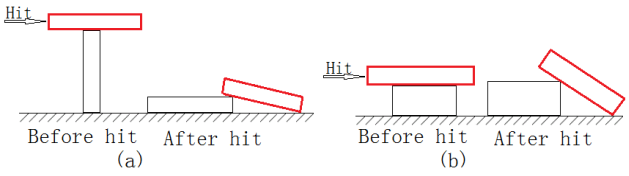

Figure 8: Two examples for case 2.

Case 2: The supportee of the target object topples down. The target object's stability is also determined by its height to width ratio, but the number should be larger (about 5) as the influence from a supportee is much weaker than from a direct hit. If the target is considered as instable, it will fall down and affect is neighbours and supporters; otherwise, it will only influence its supporters (see Fig. 8).

Case 3: The supporter of the target object topples down. Here a structure stability check process (applying Rules 1.1 - 1.4) is necessary because after a supporter falls,

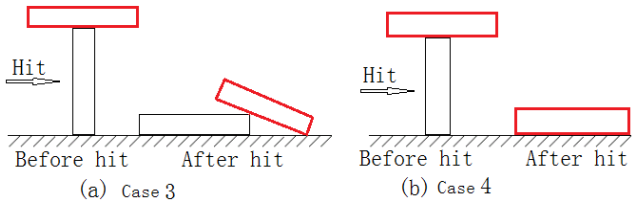

Figure 9: Examples for Cases 3&4

the target may have some other supporters and if the projection of its mass centre falls into the areas of its other supporters, it can stay stable. Then, if the target remains stable, it will again only affect its supporters due to the friction; otherwise, it may fall and affect its supporters, supportees and neighbours (see Fig. 9(a)).

Case 4: The supporter of the target is destroyed. This is more like a sub case of the previous one. If the target cannot remain stable after its supporter is destroyed, it may fall and affect its supporters, supportees and neighbours (see Fig. 9(b)).

Next we consider the four cases where the target objects are angular rectangles:

Case 5: The target object is directly hit. As analysed in Section *Inferring stability using ERA rules*, angular rectangles can be classified into 9 classes. If we only consider the direction of the objects, there only exists 3 classes, which are *"lean to left"*,*"lean to right"* and *"stand neutrally"*. Assume the hit is from left to right. Then if a *"lean-to-left"* object is hit and the force is strong enough, the object will rotate around the lowest pivot, i.e. the lowest corner of the object. However, in the Angry Birds game, before the force becomes sufficient to make the object rotate, the object will be destroyed first. Thus, the two possibilities here are either the target object affects its supporters or it is destroyed and affects its supportees. The case of *"lean-to-right"* object is the same as above. For a *"stand-neutrally"* object, it cannot stand by itself and at least one *point-to-surface* touched supporter on each side is necessary. If it is hit from left, there will be no friction applied to its left supporter, thus it will either be destroyed or affect its right supporter.

Case 6: The supportee of the target object topples down. Angular objects will not topple due to the fall of their supportees. Because their supporters restrict their spatial location. And therefore only the supporters will be affected. For *"stand-neutrally"* objects, if the friction given by their supportees is from left to right, the left supporters will not be affected, and vice-versa for the right supporter.

Case 7: The supporter of the target object topples down. First check the stability using Rules 1.5 - 1.8. If the object still has sufficient support, it only affects its supporters, otherwise it will rotate and affect its supportees, other supporters and neighbours.

Case 8: The supporter of the target object is destroyed. Again, a stability check is applied first. However if it remains stable, it will not affect its supporters because no friction applies to the target from the destroyed supporter. If it is not stable, than it will affect its supportees, other supporters and neighbours.

By applying these cases recursively for each potential target object, we obtain a list of objects that are affected when hitting a particular target object. Then, with all the affected objects in a list, the quality of the shot can be evaluated by calculating a total heuristic value depending on the affected objects. The scoring method is defined as follows and is based on experimenting with different heuristic values: if an affected object belongs to the support structure or the sheltering structure of a pig, 1 point will be added to this shot; and if the affected object is itself a pig, 10 points will be added to the shot. After assigning scores to shots at different possible target objects, the target with the highest score is expected to have the largest influence on the structures containing pigs when it is hit. The heuristic value roughly corresponds to the number of affected objects plus a higher value for destroyed pigs. Then, based on different strategies, the agent can choose either to hit the reachable object with highest heuristic value or generate a sequence of shots in order to hit the essential support object of the structure.

We first extract the ERA relations between all objects and then match the rules for all relevant combinations of objects. Thus, the process of evaluating the significance of the targets is straightforward and fast.

Planning in Angry Birds

The previous analysis only looks at the effects of one shot, while taking into account reachability of target objects. Reachability is calculated using the impact different bird types have on different block types. For example, a yellow bird can hit through 2 layers of wood, a blue bird can go through 2 layers of ice, etc. We can use this knowledge to reason about the reachability of a bird and roughly estimate the damage of the direct consequence of a shot. Ideally, we would like to plan a sequence of shots. Due to the inability to accurately predict the state after a shot (we can currently only predict affected objects), successful planning of shot sequences seems very hard.

However, in order to demonstrate how planning in Angry Birds could work, we have implemented one special case of planning, which can be used when the shot with highest score is not reachable due to some blocks in the path. We can identify which blocks are on the trajectory and block the target. Then a planner could be used to generate a shot to first clear the blocks in the path and then hit the primary target with the second shot. Specifically, the planner will first check if the highest-ranked shot is reachable. If not, it will retrieve the block objects in the calculated trajectory. Then it will search for a shot that can affect most of the objects in the block list. Finally, the planner will suggest using the first shot to clear the blocks if applicable. However, as we cannot exactly simulate the consequence of a shot, sometimes the first shot may lead to an even worse situation. Initial experi-

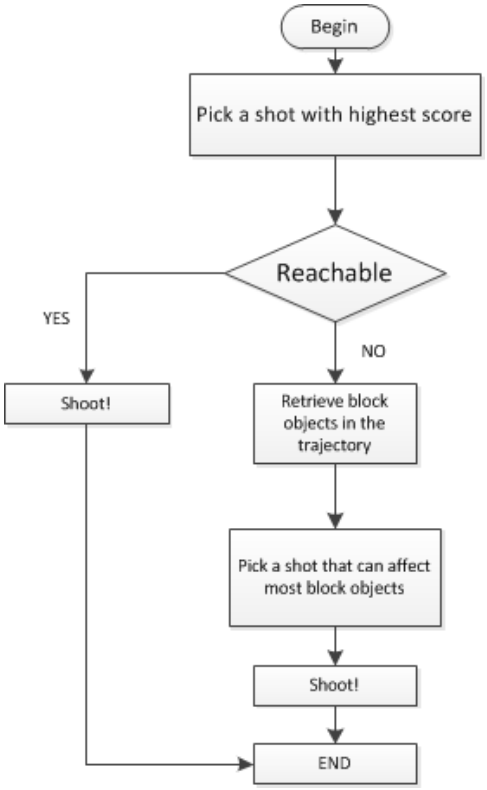

Figure 10: Process of the proposed two step planner

ments we did with this method showed good results though. Fig.10 shows the process of the planner.

Evaluation

We evaluate our approach by applying it to the first 21 Poached Eggs levels, which are freely available at chrome.angrybirds.com. These levels are also used to benchmark the participants of the annual Angry Birds AI competition. We take each level and calculate the heuristic value of all reachable objects and rank them according to the heuristic value. We then fire the bird at each of the reachable objects and record the actual game score resulting from each shot. We reload the level before each shot, so each bird always fires at the initial structure. We restricted our analysis to initial shots only, as we found that it is not possible to consistently obtain the same intermediate game state simply by repeating the same shot. However, our method works equally well for intermediate game states.

The results of our evaluation are shown in Table 1 where we listed for each of the 21 levels how many reachable objects there are, the resulting game scores of shooting at the four highest ranked reachable objects, as well as the rank of the object that received the highest game score. It turns out that in about half of the levels (10 out of 21), our method correctly identified the best object to hit. In a further 5 cases, the second highest ranked object received the highest score, in 2 cases the 3rd highest ranked object. On average there are about 7.8 reachable objects. The average score of the shooting at the highest ranked object over all 21 levels is about 21,700, shooting at the second ranked object gives an average of about 16,700 and the third ranked object an average of about 13,100. This clearly demonstrates the usefulness of our method in identifying target objects.

Table 1: Evaluation on first 21 levels. #RO is the number of reachable objects, S1, S2, and S3 are the scores obtained when shooting at the highest, second-highest and third highest ranked object. HS is the rank of the reachable object with the highest score.

Level	#RO	S1	S2	S3	Time(s)	HS
1	6	29030	30370	27330	1.34	2
2	7	16240	6040	11250	1.06	1
3	5	5410	41850	6790	0.77	4
4	2	36890	1850		1.45	1
5	6	22380	66240	16800	5.11	2
6	10	1610	6770	7710	1.83	4
7	10	46200	6230	6210	3.81	1
8	7	17310	17310	6010	1.08	4
9	9	14030	10140	13210	5.37	1
10	9	22920	3860	5920	3.88	1
11	10	57110	22640	9680	6.60	1
12	6	26570	15010	21800	3.47	1
13	8	12200	12650	14460	4.02	3
14	10	30330	28590	37670	2.43	7
15	9	16880	17550	4580	3.97	2
16	11	15090	22430	23860	4.24	3
17	12	48850	12240	19850	7.18	1
18	10	9460	14590	3240	3.02	2
19	2	5870	3290		5.83	1
20	8	7420	8170	6820	4.46	2
21	8	14270	4650	7170	12.70	1

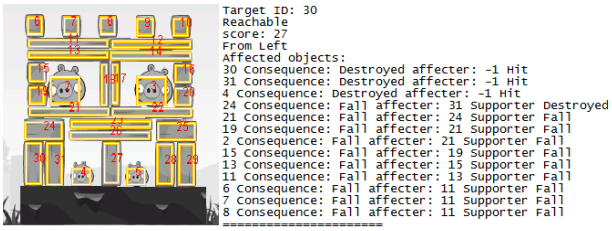

Figure 11: Level 1-16 in Chrome Angry Birds and agent output for this level

However, the resulting game score is not always a good measure, as shots can have unexpected side effects that lead to higher scores than expected. These side effects are typically unrelated to the stability of a structure and, hence, are not detected by our method. As an example, consider level 16 where the second and third ranked objects resulted in a higher score than the first ranked object. Figure 11 shows the level and output of our stability analysis. Our method predicts that shooting at object 30 will kill the two pigs on the left and result in the toppling of the left half structure.

Figure 12 shows the actual result after the recommended shot has been made. We can see that the prediction of the system is very accurate in this case. The left two pigs are

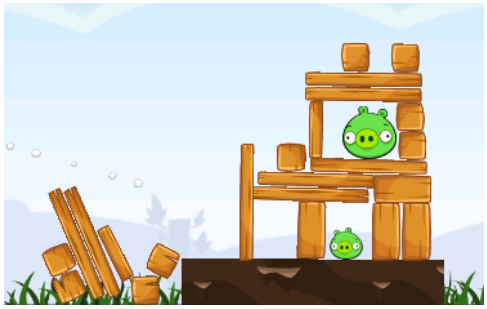

Figure 12: Actual result for the recommended shot

killed and the left part of the structure toppled. However, the shots at the second and third ranked objects each killed three pigs and therefore obtained higher scores. It turns out that two of the three pigs were killed when they bounced to the wall without actually destroying much of the structure (see Figure 13). Therefore, the next shot is much less likely to solve the level as more of the structure remains. So the shot at the highest ranked object first is likely still the best shot overall as the second shot can easily solve the level. This example nicely shows that Angry Birds requires even more sophisticated methods to correctly predict the outcome of shots.

Figure 13: Actual result for the 3rd ranked shots

Related Work

Qualitative spatial representation and reasoning has been applied to some physical systems to do common sense reasoning (Klenk et al. 2005). Physical reasoning has two important theories, namely kinematics and dynamics(Forbus 1988). Kinematics mainly concerns about the position of objects which may change continuously over time and the shape which is strictly rigid and static over time (Davis 2008). However it considers less about the forces between objects and the type of motions. These features make kinematics easy to be formulated, on the other hand models using kinematics are usually limited by the context and appear to be less expressive. The CLOCK Project (Forbus, Nielsen, and Faltings 1991) is a typical success which uses a variety of techniques but mainly kinematics to represent and reason about the inner motions of a mechanical clock. Under some given environments and constraints, this approach can successfully analyse the mechanisms; however, as this system requires restricted constraints such as the exact shape of the parts and the range of the motion, it may not be applicable in the cases with high degrees of freedom such as the world of Angry Birds.

In contrast, dynamics takes force analysis into account which allows reasoning about more complex motions and the transfer of motion. However, the limitation is that precisely predicting a consequence of a motion in an arbitrary environment is almost impossible due to uncertainty. However, it is possible to reason about some simpler physical features of a structure, such as stability. Fahlman (1973) implemented a stability verification system dealing with the stability of blocks with simple shapes (e.g. cuboid). This system can produce qualitative output to determine whether a structure is stable without external forces, but it requires some quantitative inputs (e.g. magnitude of forces and moments). The stability check in our work is partially inspired by this system, however without quantitative inputs about forces, we use a purely qualitative way to analyse the probability of the balance of forces and moments in a structure. Although our approach may produce a few false predictions in very complex cases, it is a good estimation of humans' reasoning approach. Our work also focuses on reasoning about the impacts of external forces (a hit from an external object) on a structure, which has not been discussed much in previous work.

Additionally, a method for mapping quantitative physical parameters (e.g. mass, velocity and force) to different qualitative magnitudes will be very useful for the situation where the input information is often incomplete. (Raiman 1991) developed a formalization to define and solve *order of magnitude equations* by introducing comparison operators such as $\approx$ (in the same magnitude) and $\ll$ (far less than). Raiman's method is of particular significance for our approach, for example, we will be able to infer that a hit from 1×1 block will not change the motion state of a 100×100 block with the same density.

Discussion and Future Work

In this paper we have introduced an extended rectangle algebra useful for representing and reasoning about stability under gravity and other properties of 2-dimensional structures. By splitting some basic interval relations into more detailed ones, we obtained 27 interval relations in each dimension that can express the physical relations between rectangular objects more precisely. Our algebra is very useful when representing a human-eye view of the physical world, rather than the birds-eye view which is surprisingly common in qualitative spatial representation and reasoning. A nice example of a two-dimensional human-eye view of the world is Angry Birds, where we can represent the world using the new algebra.

In addition to representing what we see using the extended interval algebra, we also used it for defining some useful structural rules regarding properties such as stability, reachability, support, and shelter that allow us to perform rule-based reasoning about these properties. We tested the usefulness of our rules by designing an agent that performs a struc-

tural analysis of Angry Birds levels. Based on these rules, we predict for each block the consequences if it gets hit and calculate a heuristic value that determines the usefulness to hit the block. We then shoot at the block with the highest value that is reachable with the current bird. Our evaluation shows that our method is very successful in determining good target objects and good shots.

Despite its success, some parts of our method offer significant room for improvement. For example, our current motion analysis can only vaguely predict which objects may be affected by a shot, i.e., we do not have accurate predictions about a possible successor state at this stage. Because of this, we currently cannot plan ahead and evaluate sequences of shots in advance. Also we only consider stability of an object with respect to its supporters, but not with respect to objects that are on top of it, which means we do not analyse the interactions between substructures. In the future, we will try to design a feedback loop between the dynamic analysis and ERA, specifically, so we can use the results of the dynamic analysis to restrict a range of possible subsequent positions of an object and use ERA rules to suggest several possible successor cases. Then we can use dynamic analysis again to check the stability of these cases and finally decide on desirable successor states. Moreover, we will find a method to determine useful substructures in order to increase the reliability of the dynamic analysis.

Abstract

Diagnostic problem solving involves a myriad of reasoning tasks associated with the determination of diagnoses, the generation and execution of tests to discriminate diagnoses, and the determination and execution of actions to alleviate symptoms and/or their root causes. Fundamental to diagnostic problem solving is the need to reason about action and change. In this work we explore these myriad of reasoning tasks through the lens of artificial intelligence (AI) automated planning. We characterize a diversity of reasoning tasks associated with diagnostic problem solving, prove properties of these characterizations, and define correspondences with established automated planning tasks and existing state-of-the-art planning systems. In doing so, we characterize a class of planning tasks with epistemic and ontic goals which we show can be compiled into non-epistemic planning, allowing state-of-the-art planners to compute plans for such tasks. Furthermore, we explore the effectiveness of using the conditional planner Contingent-FF with a number of diagnostic planning tasks.

1 Introduction

Automated diagnosis seeks to determine what is wrong with a system, prompted by some observations of egregious behaviour. As our world becomes increasingly instrumented with sensors – our street corners, our homes, our cars, and even our bodies – and as the infrastructure that controls our power, communication, and transportation systems grows in complexity, we must rely on computers to monitor the state of these systems and to oversee their operation. Unfortunately, these systems can and do malfunction, resulting in diagnostic problems of such enormous complexity that they confound human reasoning.

Diagnostic Problem Solving (DPS) refers to the myriad of reasoning tasks associated with the diagnosis, testing, and repair of a system. In this work we advocate for a *purposeful view of diagnostic problem solving*. While a naïve approach to DPS suggests that we generate candidate diagnoses, identify a unique diagnosis through testing, and then treat or repair, we instead observe that identifying candidate diagnoses may be unnecessary or perhaps only necessary to the extent that it informs an appropriate course of action to be selected – a course of action that may result in the realization of further tests to discriminate diagnoses, or to alleviate the symptoms or potential root causes, potentially without actually identifying a unique root cause.

Example 1 *Consider a run-of-the-mill flashlight that is not emitting light. A common response is to turn the flashlight on and off a few times. If it's still malfunctioning, the most likely hypothesis is that the batteries are dead, but it could also be the case that the bulb is burned out, or that there is a loose connection somewhere. That's three candidate diagnoses, and there could be more. A typical course of action would be to open up the flashlight, take out the batteries, put in new ones, re-assemble the flashlight and turn it on again. If the flashlight emits light, you'll likely be happy, recycle the batteries and consider yourself "done." Your purpose was* not *to diagnose the flashlight, but rather to get it working again. A more careful examination of what went on shows that the course of action you took, together with the happy outcome that the flashlight is now "working," served to eliminate the hypothesis that the bulb was burned out, and it tightened the connection, effectively* repairing *the connection regardless of whether it was faulty or not. This changed the space of hypotheses under consideration. What is equally interesting is that this sequence of actions neither confirmed nor refuted the hypothesis that the batteries were dead. The cause of the faulty behaviour could have been the result of a loose connection which got fixed in the process of changing the batteries. Those batteries you recycled could still be OK! What's also noteworthy is that if after executing the procedure the flashlight had not emitted light, you would still be left with the hypotheses that the original batteries were dead or that the bulb was broken, but you would also have the further (granted, unlikely) hypothesis that the new batteries were also dead.*

The above seemingly simple DPS scenario illustrates the need for reasoning about action and change as well as reasoning about knowledge, and in particular what an agent comes to know about aspects of the world (symptoms and diagnoses in this case) based upon the execution of both world-altering and sensing actions. It is also suggestive of the somewhat subordinate role the actual candidate diagnoses may play in the resolution of a system failure scenario.

In this paper, we explore this purposeful view of diag-

Copyright © 2014, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

nostic problem solving through the lens of AI automated planning. Our motivation for doing so is pragmatic. We are interested in characterizing the fundamental knowledge representation and reasoning tasks that underlie DPS in its many guises, but we wish to do so in a manner that supports establishing its correspondence with the state of the art in AI automated planning theory and practice. There have been tremendous advances in AI automated planning systems over the last decade and a number of highly optimized planning systems exists. Further there have been significant recent advances in non-classical planning such as conformant or contingent planning that support planning with incomplete information and/or with sensing. A major contribution of this paper is to show that many purposeful DPS tasks that have been heretofore unsolvable can be realized in varying measure through recent advances in state-of-the-art AI planning systems. Our characterization not only allows us to solve certain problems now, but it provides the insight and understanding that will support the realization of these and isomorphic tasks as computational machinery in planning improves in the coming years.

Characterizing diagnostic problem solving tasks in terms of planning builds upon a large body of research that includes research on topics as varied as reasoning about knowledge and action (e.g., Scherl and Levesque 2003; Petrick and Bacchus 2002), planning with epistemic goals (e.g., Herzig, Lang, and Marquis 2003; Aucher and Bolander 2013), and conformant (e.g., Palacios and Geffner 2009), contingent (e.g., To, Pontelli, and Son 2011), and classical (e.g., Helmert 2006) planning. We discuss this related research later in the paper.

In Section 2 we introduce the mathematical formalisms upon which our work rests. In Section 3 we introduce the notion of a diagnosis that we use here, and contrast it to other forms of diagnosis discussed in the literature. With a definition of diagnosis in hand, in Section 4 we present the notion of a diagnostic plan, establish its correspondence to known planning paradigms, and establish properties of various forms of diagnostic plans. In Section 5 we introduce a notion of epistemic diagnostic planning – planning to determine a particular diagnosis, or to discriminate diagnoses. We define compelling classes of epistemic goals and then show that it is possible to use state-of-the-art non-epistemic planners to plan for such epistemic goals, by providing a sound and complete translation of such epistemic tasks to conditional planning. In Section 6 we turn our attention to the realization of our newly established diagnostic planning tasks via existing planning systems. We conclude with some reflections on our work, its relationship to other work and prospects for future work.

2 Preliminaries

In this section we introduce a planning language that will allow us to define various kinds of planning tasks which we then will show can model interesting DPS tasks. In particular, we define a common language for deterministic (classical), conformant, and conditional planning.[1] The planning language we present below builds on the ADL planning language (Pednault 1989), and considers extensions for uncertainty about the initial state and conditional plans that have been presented in a similar way by other researchers (e.g., Palacios and Geffner 2006; To, Pontelli, and Son 2011).

2.1 Dynamical Systems

Dynamical systems can be formally described in many ways. In this paper we model them as transition systems, which we represent with a standard planning language. As such, transitions occur as the result of actions described in terms of preconditions and effects, and the domain is finite (i.e., there is a finite number of system configurations). Formally, a dynamical system is a tuple $\Sigma = (F, A, \Omega, I)$, where F is a finite set of fluent symbols, A is a set of deterministic actions, Ω is a set of sensing actions, and I is a set of clauses over F that defines a set of possible initial states. If $p \in F$, then p and $\neg p$ are *fluent literals*. If ℓ is a literal, we denote its complement by $\overline{\ell}$; thus, $\overline{p} = \neg p$ and $\overline{\neg p} = p$. Every action $a \in A$ is defined by a precondition $prec(a)$, which is a conjunction of fluent literals, and $\mathit{eff}(a)$, a set of conditional effects of the form $C \rightarrow L$, where C is a conjunction of fluent literals and L is a fluent literal. We sometimes write the unconditional effect $\rightarrow L$ as simply L, and use $true$ to denote an empty precondition. Each sensing action, on the other hand, is defined by its precondition $prec(a)$, which is a conjunction of fluent literals, and $obs(a)$, which is the fluent literal that is observed by the sensing action.

A *system state* s is a set of fluent symbols, which intuitively defines all that is true in a particular state of the dynamical system. For a system state s, we define $M_s : F \rightarrow \{true, false\}$ as the truth assignment that assigns the truth value $true$ to p if $p \in s$, and assigns $false$ to p otherwise. We say a state s is *consistent* with a set of clauses $\mathcal{C}$, if $M_s \models c$, for every $c \in \mathcal{C}$.

We denote by S_0 the set of planning states consistent with the clauses of the initial state I. We say a dynamical system has a *complete initial state* iff $|S_0| = 1$; i.e., I has only one model. Σ has an *incomplete initial state* iff $|S_0| > 1$. We formalize the notion of conditional plans through *action trees* as follows.

Definition 1 (Action Tree) *Given a system $\Sigma = (F, A, \Omega, I)$, an action tree T is:*

- *ϵ (the empty tree); or*
- *aT', where $a \in A$, and T' is an action tree; or*
- *$a(T', T'')$, where $a \in \Omega$ and T' and T'' are action trees.*

We denote by $\mathcal{T}_\Sigma$ the set of action trees in Σ. Furthermore, we say that an action a is *executable* in a state s if $M_s \models$

[1] A paradigm related to conditional planning is *contingent planning*. Although originally understood to define the same class of problems as conditional planning, current research in contingent planning frequently sees contingent planning as an incremental process in which planning is intertwined with execution (see e.g., Brafman and Shani 2012). We thus stick here to conditional planning to emphasize that we are looking for a conditional plan in an offline manner.

$prec(a)$. If $a \in A$ is executable in a state s, we define its successor state as $\delta(a, s) = (s \setminus Del) \cup Add$, where Add contains a fluent f iff $C \rightarrow f$ is an effect of a and $M_s \models C$. On the other hand Del contains a fluent f iff $C \rightarrow \neg f$ is an effect of a, and $M_s \models C$.

Now we define how to compute the set of states that result from executing an action tree. To that end, we define the relation $\vdash_\Sigma$: $\mathcal{T}_\Sigma \times 2^F$ such that $(T, S) \vdash_\Sigma (T', S')$ intuitively means that if the agent is in any of the states in S, then performing one step of T results in being in some state in S', with action tree T' remaining. Formally,

- $(aT, S) \vdash_\Sigma (T, S')$ if a is executable in every state in S, and $S' = \{\delta(a, s) \mid s \in S\}$.
- $(a(T', T), S) \vdash_\Sigma (T, S')$ if a is executable in every state in S and $S' = \{s \in S \mid M_s \models obs(a)\}$ or $S' = \{s \in S \mid M_s \not\models obs(a)\}$.

We use $\vdash$ instead of $\vdash_\Sigma$ when the transition system is obvious from the context. We denote by $\vdash^*$ the reflexive and transitive closure of $\vdash$. This allows us to define what states result from executing an action tree in the initial state of a transition system.

Definition 2 (Resulting State) *Given a transition system Σ, state s is a resulting state from executing action tree T in Σ iff $(T, S_0) \vdash^* (\epsilon, S')$ and $s \in S'$.*

2.2 Classical, Conformant, and Conditional Planning

Below we define classes of planning tasks that have been studied extensively by the planning community. Deterministic (classical) planning is the most standard form of planning in which there is a unique initial state, and hence knowledge about the state of the world is always complete. In conformant planning, on the other hand, there is uncertainty but no observability, and actions that change the state of the world are deterministic; hence solutions to these tasks are sequences of actions. Finally, in conditional planning,[2] there is uncertainty about the initial state and the agent may observe the world through sensing actions. The resulting plan in this case is typically an action tree.

Definition 3 (Classes of Planning Tasks) *Given a set of literals G, and a system $\Sigma = (F, A, \Omega, I)$ we define the following classes of planning tasks:*

- (Σ, G) *is a* deterministic *or* classical *planning task if I defines a complete initial state and $\Omega = \emptyset$.*
- (Σ, G) *is a* conformant *planning task if I does not define a complete initial state and $\Omega = \emptyset$.*
- (Σ, G) *is a* conditional *planning task if I does not define a complete initial state and $\Omega \neq \emptyset$.*

Definition 4 (Plan) *Action tree T is a plan for planning task (Σ, G) iff for every state s_f that may result from the execution of T in Σ it holds that $M_{s_f} \models G$.*

[2]Early literature in conditional planning (e.g. Pryor and Collins 1996) assumed complete observability of the world. However, the current standard in the planning community—under which state-of-the-art solvers are developed—is to consider sensing actions as the only mechanism to observe the world (e.g. To, Pontelli, and Son 2011).

When T is a plan for a deterministic task, then we say T is a *deterministic plan*. Analogously, we use the terms *classical plan*, *conformant plan*, and *conditional plan*.

3 Characterizing Diagnoses

Automated diagnosis has long been a problem of interest to the AI community. Well-publicized early work focused on expert systems approaches as exploited in the medical diagnosis expert systems MYCIN (Shortliffe and Buchanan 1975). In the mid-1980's AI researchers turned their attention to model-based diagnosis. Early work in this area included Geneserth's DART system (Genesereth 1984), as well as GDE, the General Diagnosis Engine by de Kleer and Williams (de Kleer and Williams 1987) among others. In 1987 Reiter published his seminal paper formalizing the notion of *consistency-based diagnosis* and *minimal diagnosis*, which were predicated on a so-called first principles model of the normative behaviour of a system (Reiter 1987). This characterization defined a diagnosis to be a minimal set of components that must be designated as *abnormal* in order for observations of system behaviour to be logically consistent with the model (axiomatization) of the system. The exploitation of fault models and other aspects of system behaviour and function necessitated a more stringent characterization of diagnosis in terms of *abduction* (e.g., (Console and Torasso 2006), (Poole 1994)) in which faults or other explanations were posited in order to *entail* or otherwise explain observations. Such abductive diagnoses were originally conceived to work with fault models, rather than normative models, in order to entail faulty behaviour. de Kleer, Mackworth, and Reiter published a follow-on to Reiter's 1987 paper in 1992 that combined aspects of abductive and consistency based diagnosis into kernel diagnoses (de Kleer, Mackworth, and Reiter 1992). All of these characterizations of diagnosis related to static systems, described using a triple $(SD, COMPS, OBS)$ – the system description, a finite set of components to be diagnosed, and an observation. There was no notion of system dynamics – just a single state.

The systems we are concerned with in this paper include not only these static descriptions but also a rich theory of action that supports diagnostic planning in its many guises. We begin with a definition of such a diagnostic system.

- SD, the system description, a set of propositional sentences;
- $COMPS$, the components, a finite set of constants;
- OBS, the observation, a conjunction of ground literals:
- $\Sigma = (F, A, \Omega, I)$, a dynamical system that describes actions relevant to diagnostic problem solving tasks associated with the system described by SD.

We illustrate these with a simple example.

Example. Consider a flashlight, comprised of a battery and a switch. If the switch is on and both the battery and switch are operating normally, then light will be emitted. This fact can be described by the following logical formula, which is included in the system's description SD:

$$on \wedge \neg AB(battery) \wedge \neg AB(switch) \supset light.$$

a	$prec(a)$	Effect/Observation
$turn\text{-}on$	$\neg on$	on
$change\text{-}battery$	$true$	$\neg AB(battery)$
$fix\text{-}switch$	$true$	$\neg AB(switch)$
$sense\text{-}light$	$true$	$light$

Table 1: Preconditions and direct effects of the actions in our flashlight example.

The set of system components is simply defined by $COMPS = \{battery, switch\}$.

Now we assume the flashlight can be operated by a human user. The available actions are: turn on the switch, change the battery, and fix the switch. In addition, we have the ability to observe whether or not there is light in the room. The dynamics of these actions is described using a transition system Σ, where $F = \{on, AB(switch), AB(battery), light\}$, $A = \{turn\text{-}on, change\text{-}battery, fix\text{-}switch\}$, and $\Omega = \{sense\text{-}light\}$. The effects of the actions are described using our planning language as shown by Table 1. §

In general, the action theory described by Σ supports reasoning about actions to test, repair, or eradicate egregious behaviour in a system. On the other hand, the system description describes complex interactions between the components of the system.

Our notion of *diagnostic system*, which we define formally below, intuitively integrates the system description SD with the dynamics of the world described by Σ. In doing so, we need to address the so-called *ramification problem* – the problem of characterizing the indirect effects of actions. To see why this is, in our example, observe that performing the action $turn\text{-}on$ may have the indirect effect of $light$, under the condition $\neg AB(battery) \wedge \neg AB(switch)$.

The ramification problem is a well-studied problem in the KR community (e.g., Lin 1995; McCain and Turner 1995; Thielscher 1995; Sandewall 1996; Pinto 1999; Strass and Thielscher 2013) and has also been previously studied in the specific context of DPS (e.g., McIlraith 1997; McIlraith 2000; McIlraith and Scherl 2000). For the purposes of this paper, we adopt an existing solution to the ramification problem that compiles the indirect effects of actions into additional direct effects of actions proposed both by Pinto (1999) and in variation most recently by Strass and Thielscher (2013). The solution is predicated on augmentation of the constraints, SD, that additionally captures the causal relationship between fluents. These causal relationships have historically been captured via an explicit causal relation in the constraints (e.g., Lin 1995; McCain and Turner 1995) or by the augmentation of SD with a causal graph structure that ranges over the literals in SD (e.g., McIlraith 2000).

Example (continued). In our flashlight example, we consider the following ramification constraint, which is extracted directly from SD.

$$on \wedge \neg AB(battery) \wedge \neg AB(switch) \textbf{ causes } light.$$

a	New Effect
$turn\text{-}on$	$\neg AB(battery) \wedge \neg AB(switch) \rightarrow light$
$change\text{-}battery$	$on \wedge \neg AB(switch) \rightarrow light$
$fix\text{-}switch$	$on \wedge \neg AB(battery) \rightarrow light$

Table 2: Additional effects of actions in our example theory.

From there, we use Pinto's algorithm (1999) to compute additional effects for the actions in our theory. Some of the resulting effects are shown in Table 2. §

Now we provide a formal definition for a diagnostic system.

Definition 5 (Diagnostic System) *Given SD, $COMPS$, OBS, and $\Sigma = (F, A, \Omega, I)$, as defined above, a diagnostic system Σ_{SD} is a tuple (F', A', Ω, I') where:*

- *F' contains the elements in F and in $Vars(SD)$, the propositional variables in SD, and ground fluents of the form $AB(c)$ for every $c \in COMPS$;*
- *A' contain the same actions in A but augmented, following Pinto (1999), with conditional effects to address the ramification problem that emerges from the integration of Σ and SD;*
- *$I' = I \cup SD \cup OBS$.*

Note that the initial state I' contains both the system's description and the observation. In our example, we could have that $I = \{on\}$ and that $OBS = \{\neg light\}$. By including SD in I' we enforce that states consistent with I' have at least one abnormal component. Note that an alternative means of characterizing a diagnostic system is to treat ramifications as further actions that are triggered by the direct effects of actions.

We now formally define the notion of diagnosis, which we borrow from de Kleer, Mackworth, and Reiter (1992)'s, in which we posit a minimal subset of components that must be behaving abnormally in order to account for the observation in the initial state of our dynamical system. To facilitate explication, we appeal to a characterization of diagnosis in terms of abnormal components; however the work in this paper is applicable to a diversity of definitions of diagnoses or hypotheses and need not rely on the use of distinguished components. The generalization is straightforward. Recall that I', of Σ_{SD}, includes our observation, OBS of (potentially egregious) behaviour.

Definition 6 (Diagnosis) *Given a diagnostic system Σ_{SD}, $\Delta \subseteq COMPS$ is a diagnosis iff*

$$I' \cup \bigcup_{c \in \Delta} AB(c) \cup \bigcup_{c' \in COMPS \setminus \Delta} \neg AB(c')$$

is satisfiable.

Definition 7 (Minimal Diagnosis) *Δ is a minimal diagnosis of Σ_{SD} if Δ is a diagnosis and no other proper subset Δ' of Δ is a diagnosis.*

In previous work, we examined diagnosis of dynamical systems with respect to a narrative of observations that

evolved over a period of time. We characterized the notion of an *explanatory diagnosis* in the situation calculus (Sohrabi, Baier, and McIlraith 2010; McIlraith 1998) and relatedly the notion of an *explanation* in a planning-inspired propositional language (Sohrabi, Baier, and McIlraith 2011). These definitions of diagnosis and explanation conjecture a set of zero or more assumptions together with a sequence of actions to account for the observations. These definitions of diagnosis and explanation are not at odds with what is proposed here. Indeed, a diagnosis, Δ would hold in the final state of an explanatory diagnosis, with OBS as the final observation of the narrative of observations used to construct the explanatory diagnosis. The generation of explanatory diagnosis looks back in time to conjecture what happened based on past observations. Observations going forward are integrated with the diagnostic plans.

4 Diagnostic Planning

While automated diagnosis remains a well-studied area of research, we argue for a purposeful view of diagnosis. In particular, rather than generating candidate diagnoses and performing tests to identify a unique diagnosis, after which a course of action (amelioration/treatment) is determined, we argue that the determination of a unique diagnosis is generally not an end in itself and that a pragmatic view of DPS should focus on acting.

One argument in support of this viewpoint is that in many settings there are a limited number of courses of action that can achieve a particular goal. These actions/plans induce an equivalence class of diagnoses for which a particular course of action is relevant. For example, many families of bacterial infection require treatment with the same antibiotic and we need not completely discriminate the nature and location of the infection before treating. Similarly, if a photocopier is malfunctioning, despite the ability to perform an in-depth diagnosis, the first course of action is often to turn the machine off and on, resolving a large family of faults simultaneously without the need for time-consuming, and time-wasting in this case, differential diagnosis.

All of the diagnostic planning tasks we examine take the same general form. The dynamical model of the system, Σ_{SD}, is augmented with additional information about the initial state, the goal state and some constraints that need to be enforced throughout execution of the plan. In this section, we provide a general formulation of a diagnostic plan. We discuss the diversity of diagnostic tasks that can be achieved via the specification of different initial conditions, goals, and constraints, and the complexity of plan existence in some of these different settings. While the types of plans we are interested in here change the state of the world, we are also interested in plans that are designed to change our state of knowledge without necessarily changing (much of) the world. In the section that follows, we look at epistemic goals – planning to know whether or not a diagnosis is true, to refute a diagnosis, or to discriminate a collection of candidate diagnoses.

Definition 8 (Diagnostic Plan) *Given a diagnostic planning task* $(\Sigma_{SD}, Init, \Phi, G)$ *where*

- $\Sigma_{SD} = (F, A, \Omega, I)$*, is the diagnostic system;*
- $Init$*, is a set of logical formulae that provide additional information about the initial state;*
- Φ*, is a logical formula representing additional state constraints that must be enforced throughout the plan; and*
- G*, is a set of literals that prescribe the diagnostic planning goal,*

and where $Init \cup I \cup \Phi$ *is satisfiable.*

Action tree T *is a diagnostic plan for the diagnostic planning task* $((F, A, \Omega, I \cup Init), G)$ *under the constraint of* Φ *iff* T *is a plan for the planning task* $((F, A, \Omega, I \cup Init), G)$*, and for every* S *such that* $(T, S_0) \vdash^* (T', S)$ *it holds that* $M_s \models \Phi$*, for every* $s \in S$*.*

4.1 Properties of Diagnostic Plans

As evident from the definition presented, our characterization of a diagnostic plan is coupled to our previously defined classes of planning tasks. These classes differ with respect to the completeness of their initial states and whether they exploit sensing of any form. Such characteristics have implications with respect to the complexity of planning.

The following are the complexity classes of the decision problem for the different planning tasks.

Theorem 1 (Diagnostic Planning w/ Complete Info.) *Given a diagnostic planning problem* $(\Sigma_{SD}, Init, \Phi, G)$*, if* $I \cup Init \cup \Phi$ *defines a complete initial state and if* $\Omega = \emptyset$ *then this is a* classical *planning task and deciding whether there exists such a plan is PSPACE-complete.*

This result follows from Bylander's result on the complexity of deterministic planning (Bylander 1994).

Theorem 2 (Diagnostic Planning without Sensing) *Given a diagnostic planning problem* $(\Sigma_{SD}, Init, \Phi, G)$*, if* $\Omega = \emptyset$ *but* $I \cup Init \cup \Phi$ *does not define a complete initial state then this is a* conformant *planning problem and deciding whether there exists such a plan is EXPSPACE-complete.*

This follows from Haslum's result on the complexity of conformant planning (Haslum and Jonsson 1999). Finally,

Theorem 3 (Diagnostic Planning with Sensing) *Given a diagnostic planning problem* $(\Sigma_{SD}, Init, \Phi, G)$*, if* $I \cup Init \cup \Phi$ *does not define a complete initial state and* $\Omega \neq \emptyset$ *then this is a* conditional *planning problem and deciding whether there exists such a plan is 2-EXPTIME-complete.*

This follows from Rintanen's results on the complexity of conditional planning (Rintanen 2004).

4.2 The Many Guises of Diagnostic Planning

Our characterization of a diagnostic plan encompasses a diversity of DPS scenarios. Here we informally explore some of these varied scenarios in order to illustrate the broad utility of our characterization. Each scenario is realized by varying the $Init$ and G and can be performed with or without sensing as the scenario necessitates, and with commensurate implications regarding the type of planner.

Eradicate egregious behaviour By setting $Init = \emptyset$ and $G = \neg OBS$ we can plan to eradicate behaviour without

first explicitly computing a diagnosis. If sensing is permitted, sufficient information will be garnered to select an appropriate course of action. Such information may or may not entail a unique diagnosis as illustrated in some of the previous examples. Without sensing, a conformant plan will be generated (where possible) that will work regardless of what is wrong with the system.

Fix the system, given a diagnosis Given a diagnosis Δ, $Init = \{AB(c) \mid c \in \Delta\} \cup \{\neg AB(c) \mid c \in COMPS \setminus \Delta\}$ and $G = \bigwedge_{c \in \Delta} \neg AB(c)$. When a unique diagnosis has been determined, this can be added to the initial state and a plan generated accordingly. In such a case I may transform or be transformable into a classical planning problem, greatly diminishing the computational effort involved in generating a plan. $Init$ may also be used to capture the set of candidate diagnoses. (E.g., *The car won't start because it's either out of gas or the battery is dead.*) Even in a scenario such as this one, the best plan may require no sensing since this candidate diagnosis set may dictate the same "fix" – call for road-side assistance.

Assume a diagnosis and fix it or eradicate behaviour We can also use the planner to do what-if planning. Whereas the previous scenario used $Init$ to add facts to the initial state, it is often compelling to *assume* a particular likely diagnosis and generate a plan that will work predicated on the assumption being correct. (E.g., *Assume the battery is dead and fix it.*) A subset of candidate diagnoses may similarly be assumed.

Discriminate between different diagnoses Given two diagnoses Δ_1 and Δ_2, return a plan to determine which one of Δ_1 or Δ_2 may be causing the egregious behaviour. We require a notion of *epistemic goals*, which we define below, to formalize this as a planning problem.

Our definition of diagnostic plan also supports the enforcement of (safety) constraints. There are a number of compelling uses for such constraints, particularly in cases where a diagnosis is being assumed. In such a scenario, the user may wish to prescribe avoidance of things that would be fatal should the assumptions be flawed (e.g., giving penicillin to a patient with allergies). Constraints of this form can often be compiled away so as not to add to the difficulty of planning. Finally, the user can exercise flexibility in eliminating sensing actions to generate conformant rather than contingent plans, or to enforce Φ by eliminating the actions that would result in its violation.

5 Epistemic Diagnostic Planning

In the previous section we examined tasks to achieve some state of the world. Here we wish to generate plans to achieve epistemic goals. For example, we may wish to generate a plan to *know* a particular diagnosis (*E.g., I know Ralph has meningitis.*), to discriminate between diagnoses (*E.g., I know Ralph has one and only one of meningitis, strep-A, or influenza.*), or to eliminate a diagnosis (*E.g, I've eliminated the possibility that Ralph has strep-A.*).

The notion of planning and reasoning to achieve a state of knowledge dates back to work by Moore (1985). Scherl and Levesque (2003) later integrated Moore's approach with Reiter's solution to the frame problem (1991). More recently, epistemic planning has been discussed in the context of dynamic epistemic logic (e.g, (Herzig, Lang, and Marquis 2003; Andersen, Bolander, and Jensen 2012).

Currently, there are no competitive planning systems that implement the possible world semantics. There are a few systems that however implement the idea of *knowledge-level planning* (Demolombe and Pozos Parra 2000; Petrick and Bacchus 2002), in which the knowledge of the agent is explicitly represented as propositions of the language (e.g., using a fluent KF to represent that the agent knows F). These planners are capable of carrying out a limited, but still reasonably expressive form of reasoning about knowledge. A few systems like PKS (Petrick and Bacchus 2002) and the web-service composition planner by Pistore et al. (2005) adopt the approach of *planning at the knowledge level* to implement these ideas. Planning at the knowledge level may achieve good performance in many planning benchmarks however, their ability to reason about knowledge is limited. Along the same lines, Palacios and Geffner (2009) proposed a compilation technique that maps contingent planning into knowledge-level deterministic tasks. As expected, their translation is compact, sound, and complete for only a certain class of problems (Palacios and Geffner 2009).

While many simple epistemic diagnostic planning tasks can indeed be mapped into knowledge-level planning domains we propose an alternative compilation into conditional planning with sensing actions. Our motivation is practical since this enables computing diagnoses with a variety of existing planning systems.

Our translation still takes a somewhat impoverished view of the world, choosing not to appeal to rich modal theories of knowledge and belief in favour of adopting the stance of planning at the so-called *belief level*. In this view, the state of the system captures the agent's beliefs about the world. Specifically, in the initial state, we assume that the agent knows any formula ϕ that is such that for every s consistent with I it holds that $M_s \models \phi$. Similarly, when the agent performs actions, the agent knows all formulae that hold in all states that it could reach. Formally, given a set of states S, and a formula ϕ, we say that:

$$K(\phi, S) \text{ iff } M_s \models \phi \text{ for each } s \in S,$$

where the intuitive meaning of $K(\phi, S)$ is that the agent knows ϕ when the set of states it is possibly in is S.

With this definition in hand we are ready to define our notion of planning with epistemic goals.

Definition 9 (Epistemic Plan) *Let $\Sigma = (F, A, \Omega, I)$ be a transition system and S_0 be the set of all plan states consistent with I. Then,*

- *T is a plan for $\mathsf{Know}(\phi)$ iff for every S such that $(T, S_0) \vdash^* (\epsilon, S)$ it holds that $K(\phi, S)$,*
- *T is a plan for $\mathsf{KnowWhether}(\phi)$ iff for every S such that $(T, S_0) \vdash^* (\epsilon, S)$ it holds either $K(\phi, S)$ or $K(\neg\phi, S)$, and*
- *T is a plan for $\mathsf{Discriminate}(\phi, \psi)$ iff for every S such that $(T, S_0) \vdash^* (\epsilon, S)$ it holds either $K(\phi \wedge \neg\psi, S)$ or $K(\neg\phi \wedge \psi, S)$.*

Under this definition it is simple to prove that T is a plan for ϕ if and only if T it is an epistemic plan for $\mathsf{Know}(\phi)$. This is compatible with our notion of planning at the belief level: the knowledge of the agent is captured by the set of states the agent is at. This also means that if one wants a plan for $\mathsf{Know}(\phi)$, then one can obtain such a plan by querying a regular conditional planner for the goal ϕ. However, it is not immediately straightforward how to obtain plans for the other types of epistemic goals using a conditional planner. For example, using the non-epistemic goal $\phi \vee \neg\phi$ instead of $\mathsf{KnowWhether}(\phi)$ would not work since $\phi \vee \neg\phi$ is tautological and therefore achieved by every action tree.

Interestingly, it *is* possible to treat all types of epistemic goals as ontic planning. Below we propose a simple compilation which maps our notion of planning with epistemic goals to ontic conditional planning.

5.1 From Epistemic Planning to Conditional Planning

Given an epistemic goal of the form $\mathsf{KnowWhether}(\phi)$, the main idea underlying this compilation is to add an additional fluent $kw\text{-}\phi$ that can be used to replace the epistemic goal $\mathsf{KnowWhether}(\phi)$.

To simplify the presentation we will assume, for now, that the goal is $\mathsf{KnowWhether}(L)$, where L is a literal, and that as usual $\Sigma = (F, A, \Omega, I)$ is the transition system. The compiled planning problem is $\Sigma' = (F', A', \Omega, I)$, and F' and A' are generated by performing the following steps:

1. Let F' be $F \cup \{kw\text{-}L\}$.
2. Add to A' all actions in A plus actions $kw\text{-}act\text{-}pos\text{-}L$ and $kw\text{-}act\text{-}neg\text{-}L$, whose preconditions are, respectively, L and $\overline{L}$. Both actions have a single effect, $kw\text{-}L$.
3. For each action a in A' that contains either $C \rightarrow L$ or $C \rightarrow \overline{L}$ as a conditional effect, for some C different from $\{true\}$, we add the unconditional effect $\neg kw\text{-}L$ to a.

Note that Step 2 generates actions that add the fact $kw\text{-}L$. These actions can only be performed if the set of states the agent believes it is in, say, S, is such that $K(L, S)$ or $K(\neg L, S)$ (i.e., the agent knows whether L is true). Step 3 handles the case in which there may be "loss of knowledge" due to a conditional effect of an action. To see this, imagine a system with a single action A which is always executable and which has conditional effect $p \rightarrow L$. Assume I is such that the set of states consistent with I is $\{\{p\}, \{\}\}$. Even though the agent knows whether L in the states of I, it is not the case anymore after performing A, since the set of resulting states is $\{\{p, L\}, \{\}\}$.

We now prove that our proposed translation is sound and complete, in the senses defined below.

Theorem 4 (Completeness) *Let $\Sigma = (F, A, \Omega, I)$ be a transition system, and let Σ' be defined as above. If T is a plan for $(\Sigma, \mathsf{KnowWhether}(L))$ then there exists a plan T' for $(\Sigma', kw\text{-}L)$ which differs from T only in that it contains actions of the form $kw\text{-}act\text{-}pos\text{-}L$ or $kw\text{-}act\text{-}neg\text{-}L$ at the end of each of T''s branches.*

Proof. We note that if there exists an action tree T that is a plan for $(\Sigma, \mathsf{KnowWhether}(L))$ then we can construct a plan T' for $(\Sigma', kw\text{-}L)$ by simply adding an additional $kw\text{-}act\text{-}pos\text{-}L$ or $kw\text{-}act\text{-}neg\text{-}L$ as the final action in each branch of the tree. Such actions are executable at that point since it holds that $K(L, S)$ or $K(\neg L, s)$, where S is the set of states reached by that branch. ■

Theorem 5 (Soundness) *Let $\Sigma = (F, A, \Omega, I)$ be a transition system, and let Σ' be defined as above. If T is a plan for $(\Sigma', kw\text{-}L)$ then, by removing all actions of the form $kw\text{-}act\text{-}pos\text{-}L$ or $kw\text{-}act\text{-}neg\text{-}L$ from T we obtain an action tree that is a plan for $(\Sigma, \mathsf{KnowWhether}(L))$.*

Proof. Let T be a plan for $kw\text{-}L$. Take any S_f that results from the execution of a branch of T; i.e., such that $(T, S_0) \vdash^* (\epsilon, S_f)$. Observe that $kw\text{-}L \in S_f$. Now let (kT', S) be the configuration visited by the execution of the branch in which kwL is added for the last time (here k is either $kw\text{-}act\text{-}pos\text{-}L$ or $kw\text{-}act\text{-}neg\text{-}L$). In other words, let S be such that $(T, S_0) \vdash^* (kT', S) \vdash (T_1, S_1) \vdash (T_2, S_2) \vdash^* (T_n, S_n)$, with $T_n = \epsilon$, $S_n = S_f$, and such that for all $i \in \{1, \ldots, n\}$, $kw\text{-}L \in S_i$. Because k is executable in S, either $K(L, S)$ or $K(\neg L, S)$ holds. Furthermore, because S and S_1 differ in at most $kw\text{-}L$, it also holds that either $K(L, S_1)$ or $K(\neg L, S_1)$ holds. Now assume that it holds that $K(L, S_i)$ or $K(\neg L, S_i)$ for some $i \geq 1$. Since $kwL \in S_{i+1}$ the action that was performed in S_i to yield S_{i+1} was either an action that does not change the truth value of L or changes it unconditionally (in other words, it is not an action modified by Step 3 of the compilation). In either case it holds either $K(L, S_{i+1})$ or $K(\neg L, S_{i+1})$. We conclude that $K(L, S_n)$ or $K(\neg L, S_n)$, which means that T achieves $\mathsf{KnowWhether}(L)$. We observe now that if we remove all occurrences of $kw\text{-}act\text{-}pos\text{-}L$ or $kw\text{-}act\text{-}neg\text{-}L$ we obtain a plan that also achieves $\mathsf{KnowWhether}(L)$. ■

Now consider the epistemic goal $\mathsf{Discriminate}(L_1, L_2)$, where L_1 and L_2 are literals. The compilation follows the same intuitions from above. We generate a new transition system $\Sigma' = (F', A', \Omega, I)$, where and F' and A' are computed by performing the following steps:

1. Let F' be $F \cup \{disc\text{-}L_1\text{-}L_2\}$.
2. Add to A' all actions in A plus actions $disc\text{-}act\text{-}1\text{-}L_1\text{-}L_2$ and $disc\text{-}act\text{-}2\text{-}L_1\text{-}L_2$, whose preconditions are $\{L_1, \overline{L_2}\}$ and $\{\overline{L_1}, L_2\}$, respectively. Both actions have a single effect, $disc\text{-}L_1\text{-}L_2$.
3. For each action a in A' that contains $C \rightarrow L_1$, $C \rightarrow \overline{L_1}$, $C \rightarrow L_2$, or $C \rightarrow \overline{L_2}$ as a conditional effect, for some C, we add the unconditional effect $\neg disc\text{-}L_1\text{-}L_2$ to a.

This translation is also sound and complete. The proofs are similar to the ones presented above.

Theorem 6 (Completeness) *Let $\Sigma = (F, A, \Omega, I)$ be a transition system, and let Σ' be defined as above. If T is a plan for $(\Sigma, \mathsf{Discriminate}(L_1, L_2)))$ then there exists a plan T' for $(\Sigma', disc\text{-}L_1\text{-}L_2)$ which differs from T only in that it contains actions of the form $disc\text{-}act\text{-}1\text{-}L_1\text{-}L_2$ or $disc\text{-}act\text{-}2\text{-}L_1\text{-}L_2$ at the end of each of T''s branches.*

Theorem 7 (Soundness) *Let $\Sigma = (F, A, \Omega, I)$ be a transition system, and let Σ' be defined as above. If T is a plan for $(\Sigma', \mathsf{Discriminate}(L_1, L_2))$ then, by removing all*

actions of the form $disc\text{-}act\text{-}1\text{-}L_1\text{-}L_2$ *or* $disc\text{-}act\text{-}2\text{-}L_1\text{-}L_2$ *from* T *we obtain an action tree that is a plan for* $(\Sigma, \mathsf{Discriminate}(L_1, L_2))$.

Extending the Compilation to Formulae We have discussed how to compile goals of the form $\mathsf{KnowWhether}(L)$ and $\mathsf{Discriminate}(L_1, L_2)$, for the case of literals. To extend our compilation to general formulae we can use a pre-compilation step in which, for each formula ϕ involved in the epistemic goal, we generate the ramification constraints ϕ **causes** L_ϕ and $\neg\phi$ **causes** $\neg L_\phi$. Then we apply the compilation we described above. Soundness and completeness now follows from the theorems above together with soundness of the compilation of ramifications into effect axioms.

6 Computing Diagnostic Plans

The purpose of this paper was largely to define the theoretical underpinnings that support the exploitation of state-of-the-art AI planning systems for diagnostic problem solving. As such, our translation can be exploited by any planning system capable of handling conditional effects and sensing actions; in particular it can be used along with conditional planners such as Contingent-FF (Hoffmann and Brafman 2005), POND (Bryce, Kambhampati, and Smith 2006), and the CNF- and DNF-based conditional planners by To, Pontelli, and Son (2011).

Our translation could also be used with the latest contingent online planning systems CLG (Albore, Palacios, and Geffner 2009), CLG+ (Albore and Geffner 2009), and the SDR planner by (Brafman and Shani 2012), even though some of these systems may not return a complete conditional plan. However, for our experiments we wished to generate offline conditional plans and we opted to use Contingent-FF.

We developed 8 diagnostic planning problem scenarios in the following domains: an extension of the light-switch-battery domain given in the example presented in Section 3, an agent moving between rooms fixing light bulbs to complete a circuit, and embedded computer chips. We varied the complexity of the problems and ran them with Contingent-FF using a PC with an Intel Xeon 2.66 GHz processor with 4GB RAM running Linux. The simple problems generated reasonable plans, requiring from under 0.01 seconds to 0.03 seconds to complete. The more complex problems resulted in poor quality plans that favoured conformant rather than contingent solutions. We attribute much of this poor quality to the general effectiveness of the planner and how it's underlying heuristics interact with our approach to handling ramification constraints. We also experimented with encoding ramifications as additional actions rather than compiling them into effects. In future work, we will explore different representations for our ramification constraints across different planners.

An interesting result came from the problems created for the embedded computer chips domain, which consists of a collection of computer chips which themselves contain chips, and so forth, where all chips must be working normally for the output to be displayed. When allowing the planner to sense the status of and replace any chip, the resulting plan was always to replace the top level chips. This supports the notion of taking a purposeful view of diagnosis – it can be much faster to simply repair the issue than to determine the unique diagnosis. More generally, selecting the best course of purposeful actions can be informed by many factor including the cost of actions (sensing and world altering), time-criticality of a response, and issues of specificity or generality with respect to how a grouping of related faults should be addressed (e.g., fix them individually vs. doing a more general fix). The tradeoff between reasoning and acting, and the value of information has been addressed by a variety of researchers, notably Horvitz and Seiver (1997).

7 Related Work and Concluding Remarks

In addition to the literature on model-based diagnosis cited in Section 3, there is a body of previous work that relates diagnosis to theories of action in some guise. The relationship between actions and diagnoses was observed sometime ago by (e.g., Cordier and Thiébaux 1994; McIlraith 1994), while Sampath et al. (1995) were the first to present comprehensive results diagnosing discrete event systems via finite state automata. Thielscher (1997), McIlraith (1998), and subsequently Iwan (2001) and Baral, McIlraith, and Son (2000) cast the diagnosis problems in terms of an AI theory of action and change. More recently Grastien et al. (2007), Sohrabi, Baier, and McIlraith (2010), Lamperti and Zanella (2011) and Yu, Wen, and Liu (2013) have all addressed aspects of dynamical diagnosis.

Specifically in the area of diagnostic and repair planning, the most notable related work is that of Baral, McIlraith, and Son (2000) who introduced the notion of diagnostic and repair plans as conditional plans, and who have a treatment of causality and sensing. That work shares a number of intuitions with the work presented here, but without the focus on planning for epistemic goals, and the correspondence to conformant and contingent planning. Also of note is the work of Kuhn et al. (2008) who introduce the notion of *pervasive diagnosis* which produces diagnostic production plans that achieve production goals while coincidentally uncovering additional information about system health. The notion of combining diagnosis with repair has been addressed in varying fashion by Sun and Weld (1993) and by Friedrich, Gottlob, and Nejdl (1992) among others. Thiébaux et al. (1996), in this and later work, discuss the challenges of diagnosis and repair in the context of a power supply restoration problem, identifying the task as problem of planning with uncertainty. These works share intuitions with the approach advocated here, but do not reflect the advances in our collective understanding of the representational and computational issues associated with planning and sensing. Finally, outside the area of diagnostic problem solving there has been a variety of work looking at planning with some form of sensing. Of particular note is the work of Brenner and Nebel (2009) on MAPL, a continual planning system that interleaves planning with acting and sensing. This paradigm of planning and sensing is also one that is very amenable to diagnostic problem solving.

In this paper we have argued for and explored a purposeful view of diagnostic problem solving, examining the problem through the lens of AI automated planning. We have

characterized diagnostic planning with both ontic and epistemic goals, and established properties of these diagnostic planning tasks, including both complexity results and an understanding of their relationship to classical, conformant, and conditional planning systems. Of particular note was the characterization of diagnostic epistemic goals such as Discriminate and KnowWhether and their translation into planning problems with ontic goals. The correspondence with existing planning paradigms enables diagnostic planning to leverage ongoing advances in the development of non-classical planners. We discuss the exploitation of such planners, outlining our experience addressing diagnostic problem solving with Contingent-FF. Results to date are guardedly encouraging but expose the need for further investigation of the nuances of these planners as a complement to the results of this paper.

Beyond diagnostic problem solving, the work presented is relevant to a diversity of problems that involve generating hypotheses to conjecture system state, and sensing and acting in the world to discriminate those hypotheses or to purposefully effect change in response to observed behaviour. Some such problems include active vision applications, activity recognition, and goal recognition.

Satisfiability of Alternating-Time Temporal Epistemic Logic Through Tableaux

Francesco Belardinelli
Laboratoire IBISC – Université d'Evry

Abstract

In this paper we present a tableau-based method to decide the satisfiability of formulas in ATEL, an extension of the alternating-time temporal logic ATL including epistemic modalities for individual knowledge. Specifically, we analyse satisfiability of ATEL formulas under a number of conditions. We evaluate the assumptions of synchronicity and of a unique initial state, which have been proposed in the context of Interpreted Systems. Also, we consider satisfiability at an initial state as opposed to any state in the system. We introduce a tableau-based decision procedure for each of these combinations. Moreover, we adopt an agent-based approach to satisfiability, namely, the decision procedure returns a set of agents inducing a concurrent game structure that satisfies the relevant specification.

1 Introduction

Formal languages for knowledge reasoning and representation find increasingly application to the analysis of concurrent and reactive systems (van Harmelen, Lifschitz, and Porter 2007). In particular, multi-modal epistemic logics (Fagin et al. 1995; Meyer and Hoek 1995) have proved to be an invaluable tool for the specification and verification of systems of autonomous agents, especially in combination with temporal operators (Gammie and van der Meyden 2004; Lomuscio, Qu, and Raimondi 2009; Kacprzak et al. 2008). Among these multi-agent logics, the alternating-time temporal epistemic logic ATEL has been proposed as a formal language to represent and reason about individual and group strategies, as well as the knowledge thereof (van der Hoek and Wooldridge 2003; Jamroga and van der Hoek 2004). The theoretical properties of ATEL have been thoroughly investigated, also w.r.t. the assumptions of imperfect information and commitment in strategies, thus producing a wealth of results (Agotnes, Goranko, and Jamroga 2007; Bulling, Dix, and Jamroga 2010).

This paper aims to make a novel contribution to the formal analysis of logics of knowledge and strategies by introducing a tableau-based decision procedure for ATEL formulas. Tableaux are a well-established technique to decide satisfiability, actively researched both in the realm of logic and in theoretical computer science (D'Agostino et al. 1999). Recently, a stream of papers has appeared on tableau methods for various flavours of temporal logics as well as multi-agent epistemic logics (Goranko and Shkatov 2009a; 2009b; 2009c; Ajspur, Goranko, and Shkatov 2013). While we explicitly acknowledge the influence of these works and make use of part of their formal machinery, we substantially extend the object of investigation. Specifically, our work differs from the contributions above in three ways. Firstly, we adopt an agent-based perspective and consider agents as the basic components of our epistemic concurrent game models. This means that the decision procedure returns not just a model satisfying the formula if successful, instead a system of agents is provided. Secondly, we follow the paradigm of Interpreted Systems (Fagin et al. 1995) and consider forms of interaction between the temporal and epistemic dimensions. In particular, we introduce epistemic concurrent game models which are synchronous or have a unique initial state. Thirdly, we analyse two different notions of satisfiability, namely satisfiability in some initial state, as opposed to satisfiability in any state. We maintain that the former notion is typical in the modelling and verification of concurrent systems (Baier and Katoen 2008), while the latter has traditionally been studied in mathematical logic (Blackburn, de Rijke, and Venema 2001). We will see that all these choices do have an impact on tableaux construction.

The motivation for the present work comes also from the fact that, besides the theoretical interest of algorithmic decision techniques, tableaux for ATEL can in principle be used to synthesize agent systems capable of enforcing behaviours specified as ATEL formulas. Thus, the investigations carried out hereafter can be seen as a preliminary contribution to bridge the gap between knowledge representation and model synthesis.

Related Work. This contribution builds on a series of papers on tableaux for multi-agent modal logics. Specifically, (Goranko and Shkatov 2009a) puts forward incremental tableaux for (non-epistemic) ATL; while in (Ajspur, Goranko, and Shkatov 2013) an epistemic logic with group knowledge is considered. In (Goranko and Shkatov 2009b; 2009c) the linear- and branching-time temporal epistemic logics LTLK and CTLK are given tableau-based decision procedures. However, we extend the object of investigation as detailed above. In (Walther 2005) tableaux for ATEL are

Copyright © 2014, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

presented, but their construction is top-down, while we follow the references above and provide incremental tableaux. This point is crucial because, even though in the worst case the computational complexity remains the same, the incremental procedure needs not to build all formula types. Hence, for the purpose of implementation its performance is, on average, better. On a related subject, we remark that in (Goranko and Jamroga 2004) a translation from ATEL to ATL is provided, but at the cost of an exponential blow-up.

Scheme of the paper. In Section 2 we present the epistemic concurrent game models and the logic ATEL; while Section 3 introduces the Hintikka structures for ATEL. In Section 4 we define the tableaux for satisfiability in any state of the model; while Section 5 is dedicated to satisfiability at initial states. We conclude in Section 6 and point to future work. For reasons of space we provide sketches of proofs only in selected cases. An extended version with some more details is available for the reader's perusal (Belardinelli 2014).

2 Epistemic Concurrent Game Models

In this section we present the formal machinery that will be used in the rest of the paper. We first introduce the epistemic concurrent game models, inspired to (van der Hoek and Wooldridge 2003; Jamroga and van der Hoek 2004), by adopting an agent-based perspective. Then, we consider the alternating-time epistemic logic ATEL. We start with the notion of *agent*.

Definition 1 (Agent) *An* agent *is a tuple* $i = \langle L_i, Act_i, Pr_i \rangle$ *where*

- L_i *is a set of* local states $l_i, l_i', \ldots$;
- Act_i *is the finite set of* actions $\sigma_i, \sigma_i', \ldots$;
- $Pr_i : L_i \mapsto 2^{Act_i}$ *is the* protocol function.

Intuitively, at each moment the agent i is situated in some local state $l_i \in L_i$ representing all the information she has. In this respect we follow the typical approach to Multi-agent Systems (Fagin et al. 1995; Wooldridge 2000). Also, we assume that agents perform the actions in Act_i according to the protocol function Pr_i.

As we are interested in agent interactions, we introduce their composition. Given a set $Ag = \{i_0, \ldots, i_n\}$ of agents, we define the set L of *global states* $s, s', \ldots$ (resp. the set Act of *joint actions* $\sigma, \sigma', \ldots$) as the cartesian product $L_0 \times \ldots \times L_n$ (resp. $Act_0 \times \ldots \times Act_n$). In the rest of the paper we fix a set AP of atomic propositions and represent the j-th element of a tuple $t = \langle t_1, \ldots, t_n \rangle$ as t_j or $t(j)$.

Definition 2 (ECGM) *Given a set* $Ag = \{i_0, \ldots, i_n\}$ *of agents* $i = \langle L_i, Act_i, Pr_i \rangle$*, an* epistemic concurrent game model *is a tuple* $\mathcal{P} = \langle Ag, I, \tau, \pi \rangle$ *where*

- $I \subseteq L$ *is the set of* initial global states;
- $\tau : L \times Act \mapsto L$ *is the* global transition function*, where* $\tau(s, \sigma)$ *is defined iff* $\sigma_i \in Pr_i(l_i)$ *for every* $i \in Ag$;
- $\pi : AP \to 2^L$ *is an* interpretation *of atomic propositions.*

Intuitively, an ECGM evolves from an initial state in I as specified by the global transition function τ, which returns a successor state for each enabled joint action σ. In line with the tradition of Interpreted Systems (Fagin et al. 1995), the agent i_0 will be reserved to model the environment the agents act in. That is, i_0 will encode all the relevant information about the system that does not appear in the private local state of any agent. In this capacity we denote i_0 as Env. Further, we observe that standard notions of concurrent game models can be defined in the present framework. Specifically, given a global state $s = \langle l_0, \ldots, l_n \rangle$ and an agent i, we introduce the functions $D_i(s) = Pr_i(l_i)$ for the set of enabled actions, $d_i(s) = |Pr_i(l_i)|$ for the number of enabled actions, and $D(s) = \{\sigma \in Act \mid \text{for every } i \in Ag, \sigma_i \in Pr_i(l_i)\} = D_0(s) \times \ldots \times D_n(s)$ for the set of joint enabled actions (Alur, Henzinger, and Kupferman 2002; Goranko and Shkatov 2009a).

We now fix some more notation. The *transition relation* $\to$ on global states is defined so that $s \to s'$ if there exists $\sigma \in Act$ and $s \xrightarrow{\sigma} s'$, i.e., $\tau(s, \sigma) = s'$. We will also consider the transitive closure $\to^*$. A *run* λ from a state s, or s-run, is an infinite sequence $s^0, s^1, \ldots$ s.t. $s_i \to s_{i+1}$ and $s^0 = s$. For $n, m \in \mathbb{N}$, with $n \leq m$, we define $\lambda(n) = s^n$ and $\lambda[n, m] = s^n, s^{n+1}, \ldots, s^m$. A state s' is *reachable from* s iff $s \to^* s'$. Now, $\mathcal{R}$ is the set of all s_0-runs, for some initial state $s_0 \in I$, and $S = \{\lambda(n) \mid \lambda \in \mathcal{R}, n \in \mathbb{N}\}$ is the set of states reachable from any initial state. Further, let $\sharp$ be a placeholder for arbitrary actions. Given a group $A \subseteq Ag$ of agents, an *A-action* σ_A is an $|Ag|$-tuple s.t. *(i)* $\sigma_A(i) \in Act_i$ for $i \in A$, and *(ii)* $\sigma_A(j) = \sharp$ for $j \notin A$. We denote by Act_A the set of all such A-actions and $D_A(s) = \{\sigma_A \in Act_A \mid \text{for every } i \in A, \sigma_A(i) \in Pr_i(l_i)\}$. A joint action σ *extends* an A-action σ_A, or $\sigma_A \sqsubseteq \sigma$, iff $\sigma_A(i) = \sigma(i)$ for all $i \in A$. The *outcome of an A-action σ_A at a state s*, denoted by $out(s, \sigma^A)$, is the set of all states s' for which there exists a joint action $\sigma \in Act$ s.t. $\sigma_A \sqsubseteq \sigma$ and $\tau(s, \sigma) = s'$. As for the epistemic component of ECGM, two global states $s = \langle l_0, \ldots, l_n \rangle$ and $s' = \langle l_0', \ldots, l_n' \rangle$ are *indistinguishable* for agent i, written $s \sim_i s'$, iff $l_i = l_i'$ (Fagin et al. 1995).

In this paper we consider two conditions on ECGM.

Definition 3 *An ECGM* $\mathcal{P}$

- *is* synchronous *iff for every* $\lambda, \lambda' \in \mathcal{R}$*,* $i \in Ag$*,* $n \in \mathbb{N}$*, if* $\lambda(n) \sim_i \lambda'(n')$ *then* $n = n'$;
- *has a* unique initial state *iff* $|I| = 1$.

Synchronicity and uniqueness of initial state are typically considered in the context of Interpreted Systems, where their impact on axiomatisations and the satisfiability problem has been thoroughly assessed (Halpern and Vardi 1986; 1989; Halpern, van der Meyden, and Vardi 2004). The meaning of a unique initial state is intuitively clear; while in synchronous ECGM the agents are assumed to have access to a global clock. Hereafter, we denote the class of all ECGM satisfying either uniqueness of initial state or synchronicity with the superscripts uis and $sync$. Hence, for instance, $ECGM^{uis,sync}$ is the class of all synchronous ECGM with a unique initial state.

We now present the alternating-time epistemic logic ATEL as a specification language for ECGM.

Definition 4 (ATEL) *The ATEL formulas* φ *are defined in BNF as follows:*

$\varphi ::= p \mid \neg\varphi \mid \varphi \to \varphi \mid \langle\langle A\rangle\rangle X\varphi \mid \langle\langle A\rangle\rangle G\varphi \mid \langle\langle A\rangle\rangle \varphi U \varphi \mid K_i\varphi$

where $A \subseteq Ag$, $i \neq Env$, *and* $Env \notin A$.

The language ATEL is an extension of the alternating-time logic ATL enriched with an epistemic operator K_i for each agent different from the environment (van der Hoek and Wooldridge 2003). Also, the environment Env does not appear in coalition modalities. This is once more in line with the semantics of Interpreted Systems, where the environment is seen as adversarial w.r.t. the other agents (Fagin et al. 1995). The ATEL formulas *(i)* $\langle\langle A\rangle\rangle X\varphi$, *(ii)* $\langle\langle A\rangle\rangle G\varphi$ and *(iii)* $\langle\langle A\rangle\rangle \varphi U \varphi'$ are read as "the agents in A have a strategy to..." *(i)* "...enforce φ at the next state", *(ii)* "...always enforce φ", and *(iii)* "...enforce φ until φ'"; while $\langle\langle A\rangle\rangle F\varphi$ is defined as $\langle\langle A\rangle\rangle \top U \varphi$. The epistemic formula $K_i\varphi$ intuitively means that "agent i knows φ". For ease of presentation we do not consider operators for group knowledge, even if we envisage such an extension. In what follows we define $(\langle\langle A\rangle\rangle X)^k\phi$ by induction on k as *(i)* $(\langle\langle A\rangle\rangle X)^0\phi = \phi$, and *(ii)* $(\langle\langle A\rangle\rangle X)^{k+1}\phi = (\langle\langle A\rangle X)^k\langle\langle A\rangle\rangle X\phi$. Also, the positive (resp. negative) X-formulas have the form $\langle\langle A\rangle\rangle X\phi$ (resp. $\neg\langle\langle A\rangle\rangle X\phi$).

To intepret ATEL formulas on ECGM we need to introduce the notion of a *strategy* for a set A of agents. Let γ be an ordinal with $1 \leq \gamma \leq \omega$, a *$\gamma$-recall A-strategy* is a mapping $F_A[\gamma] : \bigcup_{1\leq n<1+\gamma} S^n \mapsto \bigcup_{s\in S} D_A(s)$ s.t. $F_A[\gamma](\kappa) \in D_A(lst(\kappa))$ for every $\kappa \in \bigcup_{1\leq n<1+\gamma} S^n$, where $lst(\kappa)$ is the last element of κ and $1 + \gamma = \gamma$ for $\gamma = \omega$. Intuitively, a strategy returns an enabled A-action for every finite sequence of states. We remark that, according to standard terminology in concurrent game models (Bulling, Dix, and Jamroga 2010), the agents in ECGM have *perfect information*, that is, their strategies are determined by all information available at each global state. Further, the *outcome* of strategy $F_A[\gamma]$ at state s, or $out(s, F_A[\gamma])$, is the set of all s-runs λ s.t. $\lambda(i+1) \in out(\lambda(i), F_A[\gamma](\lambda[j,i]))$ for all $i \geq 0$ and $j = max(i - \gamma + 1, 0)$. Depending on γ, we can define positional strategies, perfect-recall strategies, etc. Since these distinctions are not relevant for the present discussion, as they all generate the same class of models, hereafter we assume that γ is fixed and omit it.

Definition 5 (Semantics of ATEL) *We define whether an ECGM $\mathcal{P}$* satisfies *a formula φ at state s, or $(\mathcal{P}, s) \models \varphi$, as follows:*

$(\mathcal{P}, s) \models p$ *iff* $s \in \pi(p)$
$(\mathcal{P}, s) \models \neg\varphi$ *iff* $(\mathcal{P}, s) \not\models \varphi$
$(\mathcal{P}, s) \models \varphi \to \varphi'$ *iff* $(\mathcal{P}, s) \not\models \varphi$ *or* $(\mathcal{P}, s) \models \varphi'$
$(\mathcal{P}, s) \models \langle\langle A\rangle\rangle X\varphi$ *iff there is an A-strategy F_A s.t. for all $\lambda \in out(s, F_A)$, $(\mathcal{P}, \lambda(1)) \models \varphi$*
$(\mathcal{P}, s) \models \langle\langle A\rangle\rangle G\varphi$ *iff there is an A-strategy F_A s.t. for all $\lambda \in out(s, F_A)$, $i \geq 0$, $(\mathcal{P}, \lambda(i)) \models \varphi$*
$(\mathcal{P}, s) \models \langle\langle A\rangle\rangle \varphi U \varphi'$ *iff there is an A-strategy F_A s.t. for all $\lambda \in out(s, F_A)$ there is $k \geq 0$ s.t. $(\mathcal{P}, \lambda(k)) \models \varphi'$, and for all j, $0 \leq j < k$ implies $(\mathcal{P}, \lambda(j)) \models \varphi$*
$(\mathcal{P}, s) \models K_i\varphi$ *iff for all $s' \in S$, $s \sim_i s'$ implies $(\mathcal{P}, s') \models \varphi$*

As to the notion of satisfaction, multiple choices are possible. In mathematical logic satisfaction typically takes into account all the states in a system (Blackburn, de Rijke, and Venema 2001); while in the modelling of concurrent systems satisfaction w.r.t. initial states only is also considered (Baier and Katoen 2008). This remark motivates the following definition.

Definition 6 (Satisfaction) *An ATEL-formula θ is* S-satisfied *(resp.* I-satisfied*) in a ECGM $\mathcal{P}$ iff there exists $s \in S$ (resp. $s \in I$) s.t. $(\mathcal{P}, s) \models \theta$.*

While for the class of all ECGM the two notions are equivalent, under the assumptions of a unique initial state or synchronicity this is not longer the case. For instance, the ATEL-formula $\langle\langle\emptyset\rangle\rangle G\phi \wedge \langle\langle A\rangle\rangle F\neg K_i\phi$ is not I-satisfiable in $ECGM^{uis}$, but it is S-satisfiable in the same class. Similarly, the ATEL-formula $(\langle\langle\emptyset\rangle\rangle X)^k\phi \wedge (\langle\langle A\rangle\rangle X)^k\neg K_i\phi$ is not I-satisfiable in $ECGM^{uis,sync}$, but it is S-satisfiable. Indeed, for ECGM with a unique initial state, the operator $\langle\langle\emptyset\rangle\rangle G$ acts as a universal modality, traversing the whole state space. We maintain that both notions of satisfaction are of interest and will analyse both. In the following lemma we report the equivalences between classes of formulas, where, for instance, $ATEL_I^{uis}$ is the set of ATEL-formulas I-satisfiable in the class $ECGM^{uis}$.

Lemma 1 *The classes of ATEL formulas in different boxes are different.*

$ATEL_S = ATEL_S^{uis} = ATEL_S^{sync} = ATEL_S^{sync,uis}$ $= ATEL_I = ATEL_I^{sync}$
$ATEL_I^{uis}$
$ATEL_I^{sync,uis}$

By Lemma 1 we have to consider three distinct cases: $ATEL_S$, $ATEL_I^{uis}$, and $ATEL_I^{sync,uis}$, which will be the main focus of the paper. Hereafter we simply refer to *satisfaction* to indicate any of the two notions above. Moreover, satisfiability can be also considered w.r.t. different sets of agents (Walther et al. 2006). Let Ag_θ be the set of agents mentioned in an ATEL-formula θ, while $Ag_\theta^+ = Ag_\theta \cup \{Env\}$ (remember that Env does appear in θ.)

Definition 7 *An ATEL-formula θ is*

1. Ag-satisfiable*, for some $Ag \supseteq Ag_\theta^+$, iff θ is satisfiable in an ECGM $\mathcal{P} = \langle Ag, I, \tau, \pi\rangle$;*
2. generally satisfiable *iff θ is satisfiable in an ECGM $\mathcal{P} = \langle Ag, I, \tau, \pi\rangle$ for some $Ag \supseteq Ag_\theta^+$.*

By "absorbing" the agents in $Ag \setminus Ag_\theta$ in the environment and by adding dummy agents, we can now prove the following result that extends Corollary 2.25 in (Goranko and Shkatov 2009a) to ATEL.

Theorem 2 *Every ATEL-formula θ is generally satisfiable iff it is Ag_θ^+-satisfiable.*

As a result, it is sufficient to consider Ag_θ^+-satisfiability when checking for models of ATEL formulas.

3 Hintikka Structures for ECGM

Tableau-based methods do not provide directly the formula in question with a relevant model (ECGM in the present case), but they first go through the construction of *Hintikka*

α	α_1	α_2
$\neg\neg\phi$	ϕ	ϕ
$\neg(\phi \to \psi)$	ϕ	$\neg\psi$
$\langle\langle A\rangle\rangle G\phi$	ϕ	$\langle\langle A\rangle\rangle X\langle\langle A\rangle\rangle G\phi$
$K_i\phi$	ϕ	$K_i\phi$

β	β_1	β_2
$\phi \to \psi$	$\neg\phi$	ψ
$\langle\langle A\rangle\rangle(\phi U\psi)$	ψ	$\phi \wedge \langle\langle A\rangle\rangle X\langle\langle A\rangle\rangle(\phi U\psi)$
$\neg\langle\langle A\rangle\rangle(\phi U\psi)$	$\neg\phi \wedge \neg\psi$	$\neg\psi \wedge \neg\langle\langle A\rangle\rangle X\langle\langle A\rangle\rangle(\phi U\psi)$
$\neg\langle\langle A\rangle\rangle G\phi$	$\neg\phi$	$\neg\langle\langle A\rangle\rangle X\langle\langle A\rangle\rangle G\phi$

Figure 1: α- and β-formulas in ATEL.

structures. The main difference between ECGM and Hintikka structures is that, while the former define truth conditions for every ATEL formula on the set AP of atomic propositions, the latter is only concerned with formulas 'related' to the satisfaction of the formula to be checked. To specify this relation between ATEL formulas, we introduce the distinction between α- and β-formulas of ATEL in Fig. 1. Intuitively, the states in a Hintikka structures are sets of formulas that contain α_1 *and* α_2 (resp. β_1 *or* β_2) whenever they contain α (resp. β), according to the semantics of the main logical symbol. This idea is made precise by the following definition.

Definition 8 *A set Δ of ATEL formulas is*

- consistent *if it does not contain both ψ and $\neg\psi$.*
- downward saturated *if*
  1. *$\alpha \in \Delta$ implies $\alpha_1 \in \Delta$ and $\alpha_2 \in \Delta$;*
  2. *$\beta \in \Delta$ implies $\beta_1 \in \Delta$ or $\beta_2 \in \Delta$.*

The states of a Hintikka structure will be consistent and downward saturated sets of ATEL formulas. To introduce the epistemic concurrent game Hintikka structures, we need to present the notions of *co-action* and *co-strategy* from (Goranko and van Drimmelen 2006). First, a *co-A-move* at state s is a function $\sigma^c_A : D_A(s) \to D(s)$ s.t. $\sigma_A \sqsubseteq \sigma^c_A(\sigma_A)$; $D^c_A(s)$ denotes the set of all co-A-moves at s. Further, $out(s, \sigma^c_A) = \{\tau(s, \sigma^c_A(\sigma_A)) \mid \sigma_A \in D_A(s)\}$ is the *outcome* of σ^c_A at s. Then, a *γ-recall co-A-strategy* is a mapping $F^c_A[\gamma] : \bigcup_{1\le n<1+\gamma} S^n \mapsto \bigcup_{s\in S} D^c_A(s)$ s.t. $F^c_A[\gamma](\kappa) \in D^c_A(lst(\kappa))$ for every $\kappa \in \bigcup_{1\le n<1+\gamma} S^n$. Finally, the *outcome* of $F^c_A[\gamma]$ at s is the set $out(s, F^c_A[\gamma])$ of all s-runs λ s.t. $\lambda(i+1) \in out(\lambda(i), F^c_A[\gamma](\lambda[j,i]))$ for all $i \ge 0$ and $j = max(i - \gamma + 1, 0)$. Co-strategies are used to define the labelling function of Hintikka structures in the cases of ATEL-formulas $\neg\langle\langle A\rangle\rangle X\varphi$ and $\neg\langle\langle A\rangle\rangle G\varphi$. In what follows we assume γ fixed and omit it.

Definition 9 (ECGHS) *Let $\mathcal{A}$ be a finite set of agent indexes $i_0, \ldots, i_n$. An epistemic concurrent game Hintikka structure, or ECGHS, is a tuple $\mathcal{H} = \langle \S, I, \{Act_i\}_{i\in\mathcal{A}}, \{\sim_i\}_{i\in\mathcal{A}\setminus\{Env\}}, \tau, H\rangle$ where*

- *$\S$ is a set of states;*
- *$I \subseteq \S$ is a set of initial states;*
- *for each $i \in \mathcal{A}$, Act_i is a finite set of actions;*
- *$\tau : \S \times Act \to \S$ is the transitions function;*
- *for each $i \in \mathcal{A} \setminus \{Env\}$, $\sim_i$ is a symmetric, reflexive and transitive relation on $\S$;*
- *H is a labelling function from $\S$ to sets of ATEL formulas s.t.*

H1 if $\neg\phi \in H(s)$ then $\phi \notin H(s)$;

H2 every $H(s)$ is downward saturated;

H3 if $\langle\langle A\rangle\rangle X\varphi \in H(s)$ then there is an A-strategy F_A s.t. for all $\lambda \in out(s, F_A)$, $\varphi \in H(\lambda(1))$;

H4 if $\neg\langle\langle A\rangle\rangle X\varphi \in H(s)$ then there is a co-A-strategy F^c_A s.t. for all $\lambda \in out(s, F^c_A)$, $\neg\varphi \in H(\lambda(1))$;

H5 if $\neg\langle\langle A\rangle\rangle G\varphi \in H(s)$ there is a co-A-strategy F^c_A s.t. for all $\lambda \in out(s, F^c_A)$ there is $i \ge 0$ s.t. $\neg\varphi \in H(\lambda(i))$;

H6 if $\langle\langle A\rangle\rangle\varphi U\varphi' \in H(s)$ there is an A-strategy F_A s.t. for all $\lambda \in out(s, F_A)$ there is $k \ge 0$ s.t. $\varphi' \in H(\lambda(k))$, and for all j, $0 \le j < k$ implies $\varphi \in H(\lambda(j))$;

H7 if $s \sim_i s'$ then $K_i\varphi \in H(s)$ iff $K_i\varphi \in H(s')$;

H8 if $\neg K_i\varphi \in H(s)$ then there is $s' \in \S$ s.t. $s \sim_i s'$ and $\neg\varphi \in H(s')$.

Notice that conditions H3-8 mimic the satisfaction clauses for ATEL formulas in Def. 5. Also, ECGHS are syntactic structures, where each state is labelled by a finite set of ATEL formulas. In addition, the main difference w.r.t. ECGM consists in that global states are primitive. This implies that the indistinguishability relations $\sim_i$ are also primitive. Further, as for ECGM, we can define a notion of run, as well as the set $\mathcal{R}$ of all runs. Hence, we can introduce the following classes of ECGHS.

Definition 10 *An ECGHS $\mathcal{H}$*

- *is* synchronous *iff for every $\lambda, \lambda' \in \mathcal{R}$, $i \in \mathcal{A}$, if $\lambda(n) \sim_i \lambda'(n')$ then $n = n'$;*
- *has a* unique initial state *iff $|I| = 1$.*

Further, similarly to the case for ECGM, we introduce two notions of satisfaction.

Definition 11 (Satisfaction) *An ECGHS $\mathcal{H}$ $\S$-satisfies (resp. I-satisfies) an ATEL-formula θ iff $\theta \in H(s)$ for some $s \in \S$ (resp. $s \in I$).*

The tableau procedure that we present in the following sections ultimately generates a Hintikka structure. From this ECGHS we are always able to extract an ECGM, as stated in the following result.

Theorem 3 *Given a finite set $\mathcal{A}$ of agent indexes and an ECGHS $\mathcal{H}$ on $\mathcal{A}$ that $\S$-satisfies (resp. I-satisfies) an ATEL-formula θ, we can derive a finite set $\mathcal{A}$ of agents and an ECGM $\mathcal{P}$ on $\mathcal{A}$ that also S-satisfies (resp. I-satisfies) θ. Further, this can be done so as to preserve synchronicity and uniqueness of initial state.*

As a consequence of Theorem 3, satisfiability w.r.t. Hintikka structures suffices to obtain satisfiability w.r.t. ECGM. Also, we underline that Theorem 3 is constructive as it provides a set $\mathcal{A}$ of agents generating the ECGM $\mathcal{P}$. In this respect our approach is agent-based. In the following sections we present the tableau-based procedures for deciding satisfiability of ATEL formulas.

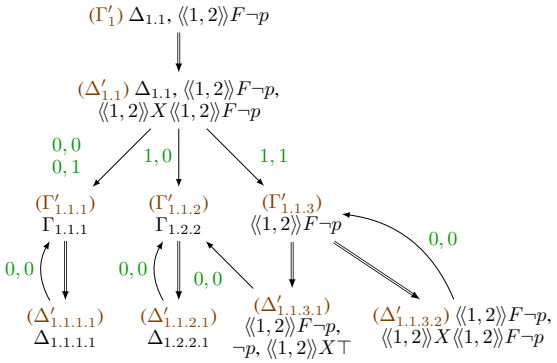

Figure 2: fragment of the pre-tableau for $\Gamma'_1 = \{\theta_1, \langle\langle 1,2\rangle\rangle F(\neg p \wedge \neg K_2 p)\}$.

4 Tableaux for S-Satisfiability

In this section we introduce a tableau-based decision procedure for S-satisfiability of ATEL formulas. Specifically, we build on the methods developed for (non-epistemic) ATL and multi-agent epistemic CMAEL(CD) in (Goranko and Shkatov 2009a; Ajspur, Goranko, and Shkatov 2013). As stated in Lemma 1, for S-satisfiability the assumptions of a unique initial state or synchronicity do not affect satisfiability of ATEL formulas. Nonetheless, we deem the tableaux for S-satisfiability interesting in themselves, as well as useful for a comparison with the case of I-satisfiability. Indeed in this section we introduce notions and present results that will be used also in Section 5.

Similarly to (Goranko and Shkatov 2009a; Ajspur, Goranko, and Shkatov 2013), the tableau procedure for ATEL consists of two phases: a *construction phase*, where a *pre-tableau* is populated with states and prestates (i.e., sets of formulas), and an *elimination phase*, where the pre-tableau is pruned into a proper *tableau* by removing pre-states together with "unsatisfiable" states. The aim of the whole construction is to obtain a tableau from which it is possible to extract a Hintikka structure iff the relevant formula is satisfiable. We start with the construction phase.

4.1 Construction Phase

The construction of the pre-tableau pre-$\mathcal{T}^\theta$ for an ATEL-formula θ proceeds in stages. At each stage rules are applied to create either states from pre-states or pre-states from states. The process starts with the pre-state $\Gamma = \{\theta\}$ containing the ATEL formula to be checked. Then at each stage we apply one of the rules $\mathbf{SR}_S$, $\mathbf{K}_S$ and $\mathbf{Next}_S$ that adapt the corresponding rules in (Goranko and Shkatov 2009a; 2009c). In what follows we say that a set Δ of formulas is a *minimal downward saturated* extension of a set Γ if *(i)* Δ is downward saturated, *(ii)* $\Gamma \subseteq \Delta$, and *(iii)* there is no downward saturated Δ' s.t. $\Gamma \subseteq \Delta' \subset \Delta$. The first rule we present allows us to build states from pre-states.

Definition 12 (Saturation Rule $\mathbf{SR}_S$) *Given a pre-state Γ s.t. $\boldsymbol{SR}_S$ has not been applied to Γ, for every consistent and minimal downward saturated extension Δ of Γ,*

- *if the pre-tableau contains a state Δ' that coincides with Δ, set $\Gamma \Rightarrow \Delta'$;*
- *else,*
  - *add Δ as a new state to the pre-tableau;*
  - *if Δ contains no positive nor negative X-formula, then add $\langle\langle Ag_\theta\rangle\rangle X\top$ to Δ;*
  - *set $\Gamma \Rightarrow \Delta$.*

The (finite) set of states $\{\Delta \mid \Gamma \Rightarrow \Delta\}$ is denoted by **states**(Γ). To introduce the next rule we need some more notation. Hereafter, $\Delta_{|K_i}$ denotes the set $\{K_i\psi \mid K_i\psi \in \Delta\}$. Also, we do not distinguish between a finite set of formulas and their conjunction, the context will disambiguate. The next rule is designed to ensure the satisfaction of epistemic possibilities of the form $\neg K_i\phi$.

Definition 13 (Rule $\mathbf{K}_S$) *Given a state Δ s.t. $\boldsymbol{K}_S$ has not been applied to Δ, for every $\neg K_i\phi \in \Delta$ and consistent $\Gamma = \{\neg\phi\} \cup \Delta_{|K_i}$,*

- *if the pre-tableau contains a pre-state $\Gamma' = \Gamma$, set $\Delta \xrightarrow{\neg K_i\phi} \Gamma'$;*
- *else, add Γ as a new pre-state and set $\Delta \xrightarrow{\neg K_i\phi} \Gamma$.*

Finally, we consider the rule $\mathbf{Next}_S$, which builds the next level of pre-states.

Definition 14 (Rule $\mathbf{Next}_S$) *Given a state Δ s.t. $\boldsymbol{Next}_S$ has not been applied to Δ,*

1. *order linearly all positive X-formulas of Δ followed by all negative ones:*

$$L = \langle\langle A_0\rangle\rangle X\phi_0, \ldots, \langle\langle A_{m-1}\rangle\rangle X\phi_{m-1}, \neg\langle\langle B_0\rangle\rangle X\psi_0, \ldots, \neg\langle\langle B_{l-1}\rangle\rangle X\psi_{l-1}$$

(because of $\boldsymbol{SR}_S$, L is always non-empty.) Let $r_\Delta = m+l$ and $D(\Delta) = \{0, \ldots, r_\Delta - 1\}^{|Ag^+_\theta|}$. Further, for every $\sigma \in D(\Delta)$, we set $N(\sigma) = \{i \mid \sigma_i \geq m\}$ and $neg(\sigma) = \sum_{i \in N(\sigma)}(\sigma_i - m) \mod l$.

2. *For each $\sigma \in D(\Delta)$ consider every consistent*

$$\Gamma_\sigma = \{\neg\psi_q \mid \neg\langle\langle B_q\rangle\rangle X\psi_q \in \Delta, neg(\sigma) = q, Ag^+_\theta \setminus B_q \subseteq N(\sigma)\} \cup \{\phi_p \mid \langle\langle A_p\rangle\rangle X\phi_p \in \Delta \text{ and } \sigma_i = p \text{ for all } i \in A_p\} \quad (1)$$

where $\Gamma_\sigma = \{\top\}$ if the set on the RHS of (1) is empty.

- *If the pre-tableau contains a pre-state $\Gamma' = \Gamma_\sigma$, set $\Delta \xrightarrow{\sigma} \Gamma'$;*
- *else, add Γ_σ as a new pre-state and set $\Delta \xrightarrow{\sigma} \Gamma_\sigma$.*

We remark that by definition of $\mathbf{SR}_S$, $\mathbf{K}_S$ and $\mathbf{Next}_S$, no state nor pre-state in pre-$\mathcal{T}^\theta$ is inconsistent, i.e., it does not contain both ϕ and $\neg\phi$. Also, we denote the (finite) set of pre-states $\{\Gamma \mid \Delta \xrightarrow{\sigma} \Gamma \text{ for some } \sigma\}$ as **pre-states**(Δ). We now briefly describe the construction of the pre-tableau for an ATEL-formula θ. We begin at stage $k = 0$ by creating a pre-state $\Gamma = \{\theta\}$ for the input formula θ. Then, at each stage $k > 0$, we alternatingly apply the rule $\mathbf{SR}_S$ to obtain the states in **states**(Γ), followed by $\mathbf{Next}_S$ and $\mathbf{K}_S$ to create the next level of pre-states and the epistemically related pre-states. The construction phase terminates, after a finite number of stages, when $\mathbf{K}_S$ and $\mathbf{Next}_S$ do not produce any new pre-state, nor $\mathbf{SR}_S$ new states. We conclude this section with an example.

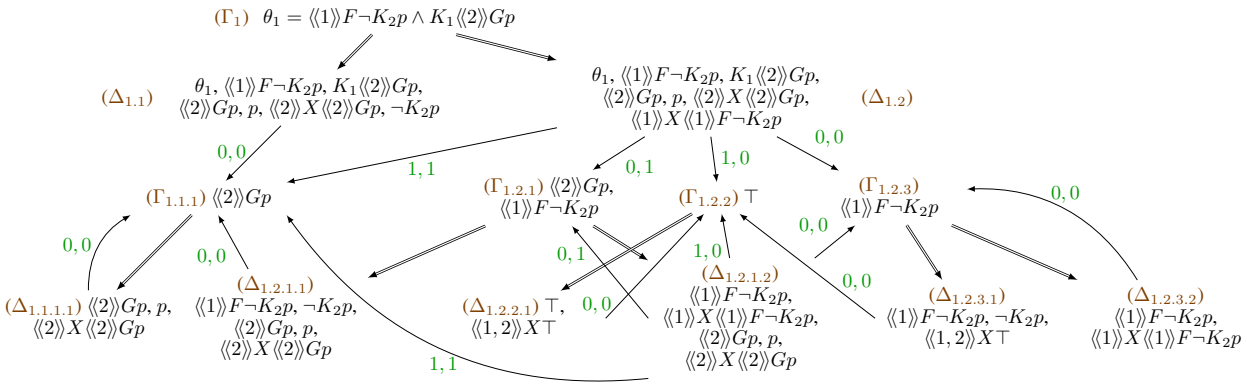

Figure 3: fragment of the pre-tableau for $\theta_1 = \langle\langle 1\rangle\rangle F\neg K_2 p \wedge K_1\langle\langle 2\rangle\rangle Gp$ obtained by applying $\mathbf{SR}_S$ and $\mathbf{Next}_S$ only.

Example 1 Fig. 3 shows a fragment of the pre-tableau for the ATEL-formula $\theta_1 = \langle\langle 1\rangle\rangle F\neg K_2 p \wedge K_1\langle\langle 2\rangle\rangle Gp$ obtained by applying rules $\mathbf{SR}_S$ and $\mathbf{Next}_S$ only. We present this restricted structure as it will be used later on. Also, the environment's actions are omitted. Indeed, since no negative X-formula appears in the pre-tableau, it suffices to consider each action σ_1, σ_2 in Fig. 3 as a shorthand for the set $\{\sigma_{Env}, \sigma_1, \sigma_2 \mid 0 \leq \sigma_{Env} < r_\Delta\}$. ■

4.2 Elimination phase

After completion of the pre-tableau pre-$\mathcal{T}^\theta$ we step into the elimination phase, where we prune pre-$\mathcal{T}^\theta$ first by removing all pre-states, and then by deleting "unsatisfiable" states. We have already noticed that by construction no state in the pre-tableau is inconsistent. Moreover, if a state either *(i)* has no successor for an enabled joint action, or *(ii)* it does not fulfil an epistemic possibility, or *(iii)* it does not fulfil a temporal eventuality, then it is removed. We make this intuition precise in the following elimination rules, adapted from (Goranko and Shkatov 2009a).

Definition 15 (Rule PR) *For every state Δ and pre-state Γ in pre-$\mathcal{T}^\theta$, and $\Delta' \in$ **states**(Γ),*

- *if $\Delta \xrightarrow{C} \Gamma$ then $\Delta \xrightarrow{C} \Delta'$, where C can be either an action σ or an epistemic possibility $\neg K_i\phi$;*
- *remove Γ from pre-$\mathcal{T}^\theta$.*

We now describe the process of state elimination also in stages. We start with the tableau $\mathcal{T}^\theta_0$, obtained by applying **PR** to pre-$\mathcal{T}^\theta$. At each stage n we apply one of the rules **E1**-**3** below to obtain the tableau $\mathcal{T}^\theta_{n+1}$.

E1 If for some $\sigma \in D(\Delta)$ there is no $\Delta' \in \mathcal{T}^\theta_n$ s.t. $\Delta \xrightarrow{\sigma} \Delta'$, then $\mathcal{T}^\theta_{n+1} = \mathcal{T}^\theta_n \setminus \{\Delta\}$.

E2$_S$ If for some $\neg K_i\phi \in \Delta$ there is no $\Delta' \in \mathcal{T}^\theta_n$ s.t. $\Delta \xrightarrow{\neg K_i\phi} \Delta'$, then $\mathcal{T}^\theta_{n+1} = \mathcal{T}^\theta_n \setminus \{\Delta\}$.

Rule **E1** removes states with no successor for an enabled action; while **E2**$_S$ deletes states with unrealized epistemic possibilities. Rule **E3** to be introduced deals with the realisation of temporal eventualities, namely the satisfaction of formulas of the form $\langle\langle A\rangle\rangle\phi U\psi$ and $\neg\langle\langle A\rangle\rangle G\phi$. To present **E3** we consider the following notation. Let Δ be a state in $\mathcal{T}^\theta_0$ and $\langle\langle A\rangle\rangle X\phi$ (resp. $\neg\langle\langle B\rangle\rangle X\psi$) the p-th (resp. q-th) formula in the linear ordering L of X-formulas of Δ in the application of $\mathbf{Next}_S$. Then,

$$D(\Delta, \langle\langle A\rangle\rangle X\phi) = \{\sigma \in D(\Delta) \mid \sigma_i = p \text{ for every } i \in A\}$$
$$D(\Delta, \neg\langle\langle B\rangle\rangle X\psi) = \{\sigma \in D(\Delta) \mid neg(\sigma) = q \text{ and } Ag^+_\theta \setminus B \subseteq N(\sigma)\}$$

We can now define when a temporal eventuality is realized.

Definition 16 (Realization of temporal eventualities) *A temporal eventuality $\beta = \langle\langle A\rangle\rangle\phi U\psi$ (resp. $\neg\langle\langle A\rangle\rangle G\phi$) in $\Delta \in \mathcal{T}^\theta_n$ is* realized *at Δ iff*

1. *$\beta_1 \in \Delta$, or*
2. *$\beta_2 \in \Delta$ and for every $\sigma \in D(\Delta, \langle\langle A\rangle\rangle X\langle\langle A\rangle\rangle\phi U\psi)$ (resp. $D(\Delta, \neg\langle\langle A\rangle\rangle X\langle\langle A\rangle\rangle G\phi)$) there exists $\Delta' \in \mathcal{T}^\theta_n$ s.t.* (i) *$\Delta \xrightarrow{\sigma} \Delta'$; and* (ii) *$\beta$ is realized at $\Delta' \in \mathcal{T}^\theta_n$.*

We can now state the final elimination rule.

E3 If $\Delta \in \mathcal{T}^\theta_n$ contains an unrealized temporal eventuality, then $\mathcal{T}^\theta_{n+1} = \mathcal{T}^\theta_n \setminus \{\Delta\}$.

The elimination phase terminates when none of the rules **E1**-**3** is any longer applicable (obviously, this happens after a finite number of stages.) The tableau thus obtained is denoted as $\mathcal{T}^\theta$. In particular, we say that $\mathcal{T}_\theta$ is *open* if $\theta \in \Delta$ for some $\Delta \in \mathcal{T}_\theta$; otherwise, it is *closed*. In the next sections we show the soundness and completeness of the tableau procedure, that is, the tableau $\mathcal{T}^\theta$ is open iff θ is S-satisfiable.

4.3 Soundness and Completeness

We first outline the soundness proof for the tableau procedure presented above, which amounts to the following result:

Theorem 4 (Soundness) *If θ is S-satisfiable, then $\mathcal{T}^\theta$ is open.*

The proof of Theorem 4 consists of two parts. First, we use the following lemma to show that if θ is S-satisfiable, then at least one of the states in **states**$(\{\theta\})$ is S-satisfiable.

Lemma 5 *Let Γ be an S-satisfiable pre-state in pre-$\mathcal{T}^\theta$ Then, at least one $\Delta \in$ **states**(Γ) is S-satisfiable.*

Then, we show that no satisfiable state is removed during the elimination phase. The soundness result then follows, as θ belongs to $\Delta \in \mathcal{T}^\theta$, for some $\Delta \in$ **states**$(\{\theta\})$. To show that no S-satisfiable state is removed, we prove by induction on the number n of stages that, for every $\Delta \in \mathcal{T}_0^\theta$, if Δ is S-satisfiable, then Δ is not removed at stage n. The base case for $n = 0$ is trivial as no elimination rule has been applied. As regards the inductive step, we consider the following lemma:

Lemma 6 *If $\Delta \in \mathcal{T}_n^\theta$ is S-satisfiable, then*

1. *for every $\sigma \in D(\Delta)$ there is $\Delta' \in \mathcal{T}_n^\theta$ s.t. $\Delta \xrightarrow{\sigma} \Delta'$;*
2. *for every $\neg K_i\phi \in \Delta$ there is $\Delta' \in \mathcal{T}_n^\theta$ s.t. $\Delta \xrightarrow{\neg K_i\phi} \Delta'$;*
3. *every temporal eventuality is realized at Δ.*

We conclude that if Δ is S-satisfiable, then it will not be eliminated by **E1**-**3**. Hence, some $\Delta \supseteq \{\theta\}$ belongs to $\mathcal{T}^\theta$, i.e., $\mathcal{T}^\theta$ is open.

The completeness proof consists in showing that if the tableau $\mathcal{T}^\theta$ is open, then the ATEL-formula θ is S-satisfiable.

Theorem 7 (Completeness) *If $\mathcal{T}^\theta$ is open, then θ is S-satisfiable.*

The proof amounts to building an ECGHS $\mathcal{H}_\theta$ starting from the open tableau $\mathcal{T}^\theta$. By Theorem 3 the desired result immediately follows. Specifically, when building the Hintikka structure for θ we take care of satisfying conditions H5, H6 and H8 for temporal eventualities and epistemic possibilities. In this task the key concept is that of a *temporal component* $F(\xi, \Delta)$ for an eventuality ξ and state Δ (Goranko and Shkatov 2009a; 2009c). If $\xi \in \Delta$ then $F(\xi, \Delta)$ is a tree rooted at Δ that realizes ξ. If $\xi \notin \Delta$ then $F(\xi, \Delta)$ is a tree with all the successor of Δ. We now outline the construction of the ECGHS $\mathcal{H}_\theta$ satisfying an ATEL-formula θ.

The construction proceeds in stages. First, we list all states in $\mathcal{T}^\theta$ as $\Delta_0, \ldots, \Delta_{n-1}$ and all temporal eventualities as $\xi_0, \ldots, \xi_{m-1}$. Further, we assume that the temporal components are arranged in an $m \times n$ matrix, whose rows (resp. columns) are marked with the corresponding temporal eventualities (resp. states). Hence, $F_{p,q} = F(\xi_p, \Delta_q)$. Now, if θ is the temporal eventuality ξ_p, for $p < m$, we set $\mathfrak{S}_0^0 = F_{p,q}$ for some q s.t. $\theta \in \Delta_q$. Otherwise, we set $\mathfrak{S}_0^0 = F_{0,q}$, where q is as above. For the induction step, suppose that we have defined $\mathfrak{S}_k^i$. Then, we construct $\mathfrak{S}_k^{i+1}$ by realizing all temporal eventualities $\xi \in \mathfrak{S}_k^i$. That is, we keep track of the last realized eventuality, say ξ_i, and replace every deadlocked state w such that $l(w) = \Delta_j$ with the temporal component $F_{(i+1) \mod m,j}$. We repeat the procedure until all temporal eventualities have been realized. Further, given $\mathfrak{S}_k^i$ we construct $\mathfrak{S}_{k+1}^i$ by adding for every $\Delta \in \mathfrak{S}_k^i$ and every epistemic possibility $\neg K_i\phi \in \Delta$ a state $\Delta' \in \mathcal{T}^\theta$ s.t. $\neg\phi \in \Delta'$. Notice that such Δ' always exists as $\Delta \in \mathcal{T}^\theta$. We proceed in this way to realize all epistemic possibilities contained in $\mathfrak{S}_k^i$. To guarantee that the ECGHS we are building remains finite, whenever the component we are about to add, say $F_{p,q}$, is already contained in $\mathfrak{S}_k^i$, instead of replacing the state w (s.t. $l(w) = \Delta_q$) with $F_{p,q}$, we connect every "predecessor" v of w to the root of $F_{p,q}$. The procedure is repeated until no more components are added, thus obtaining an ECGHS $\mathcal{H}_\theta$.

Lemma 8 *If $\mathcal{T}^\theta$ is open, then there exists an ECGHS $\mathcal{H}_\theta$ that $\S$-satisfies θ.*

Complexity. We conclude this section with a discussion of the complexity of the decisione procedure outlined above. It can be shown that the construction and elimination phases can be performed in time exponential in the size of the formula. Hence, the procedure here provided meets the lower-bound of the satisfiability problem for ATEL (Walther 2005). In this respect, it is optimal. Further, as discussed in (Goranko and Shkatov 2009a), since the tableau construction is incremental, in many cases it allows to decide satisfaction in less time than top-down tableaux, which need to build all formula types.

5 Tableaux for I-Satisfiability

In this section we introduce the tableau-based decision procedure for I-satisfiability. Specifically, in Lemma 1 we remarked that the notions of I- and S-satisfiability coincide over the class of all (resp., synchronous) ECGM. On the other hand, for ECGM with a unique initial state we need to consider a different construction for I-satisfiability.

5.1 Construction Phase

We start with the rules to build the pre-tableau pre-$\mathcal{T}^\theta$, but first we need to introduce some new terminology. In what follows we index each state and pre-state with a finite set $\{\vec{k}\}$ of time-stamps (we assume the set is enumerated). Intuitively, these represent the times at which a state (resp. pre-state) occurs in a fragment of a run. Operations on a time-stamp $\{\vec{k}\}$ (such as addition) are defined on each member of $\{\vec{k}\}$. Further, in the construction phase we define a sequence $\Gamma_0^{\{0\}}, \ldots, \Gamma_n^{\{0\}}$ of "initial" pre-states, starting from $\Gamma_0^{\{0\}} = \{\theta\}$. Also, we introduce a mark mk that intuitively keeps track of the initial state a state (resp. pre-state) stems from. We set $mk(\Gamma_0^{\{0\}}) = undef$ at the beginning. Finally, let $\mapsto$ be the transitive closure of $\Rightarrow \cup \rightarrow$. We now provide the saturation rule $\mathbf{SR}_I^{uis,sync}$ for I-satisfiability w.r.t. synchronous ECGM with a unique initial state.

Definition 17 (Saturation Rule $\mathbf{SR}_I^{uis,sync}$) *Given a pre-state $\Gamma^{\{\vec{k}\}}$ s.t. $\boldsymbol{SR}_I^{uis,sync}$ has not been applied to $\Gamma^{\{\vec{k}\}}$, consider every consistent and minimal downward saturated extensions $\Delta^{\{\vec{k}\}}$ of $\Gamma^{\{\vec{k}\}}$,*

- *if the pre-tableau contains a state $\Delta'^{\{\vec{m}\}} = \Delta^{\{\vec{k}\}}$ and $mk(\Delta'^{\{m\}}) = mk(\Gamma^{\{\vec{k}\}})$, then*
  - *rename $\Delta'^{\{\vec{m}\}}$ and all pre-states and states $\Theta_i^{\{\vec{m}+i\}}$ s.t. $\Delta'^{\{\vec{m}\}} \mapsto \Theta_i^{\{\vec{m}+i\}}$ as $\Delta'^{\{\vec{m}\}\cup\{\vec{k}\}}$ and $\Theta_i^{\{\vec{m}+i\}\cup\{\vec{k}+i\}}$. Then, set $\Gamma^{\{\vec{k}\}} \Rightarrow \Delta'^{\{\vec{m}\}\cup\{\vec{k}\}}$.*
- *else,*
  - *add $\Delta^{\{\vec{k}\}}$ as a new state to the pre-tableau;*

– *if* $\Delta^{\{\vec{k}\}}$ *contains no positive nor negative X-formulas, then add* $\langle\langle Ag_\theta\rangle\rangle X\top$ *to* $\Delta^{\{\vec{k}\}}$*;*

– *set* $\Gamma^{\{\vec{k}\}} \Rightarrow \Delta^{\{\vec{k}\}}$ *and* $mk(\Delta^{\{\vec{k}\}}) = mk(\Gamma^{\{\vec{k}\}})$ *unless* $\{\vec{k}\} = \{0\}$ *and* $mk(\Gamma^{\{0\}}) = undef$*. In this case, set* $mk(\Delta^{\{0\}}) = \Delta^{\{0\}}$*.*

Hence, $\mathbf{SR}_I^{uis,sync}$ modifies $\mathbf{SR}_S$ by keeping track of time-stamps as well as of mark mk: the former are needed for synchronicity, while the latter registers the initial state. In particular, for all $\Delta, \Delta' \in$ **states**(Γ), $mk(\Delta) = mk(\Delta')$, and for every state Δ', $\Delta^{\{0\}} \mapsto \Delta'$ iff $mk(\Delta') = \Delta^{[0]}$. The rule $\mathbf{SR}_I^{uis}$ for I-satisfiability w.r.t. $ECGM^{uis}$ can be obtained from $\mathbf{SR}_I^{uis,sync}$ by omitting time-stamps. Further, we need to modify the rule $\mathbf{Next}_S$ as follows.

Definition 18 (Rule $\mathbf{Next}_I^{uis,sync}$) *Given a state* $\Delta^{\{\vec{k}\}}$ *s.t.* $\boldsymbol{Next}_I^{uis,sync}$ *has not been applied to* $\Delta^{\{\vec{k}\}}$*,*

1. *(as in rule* $\boldsymbol{Next}_S$*)*
2. *For each* $\sigma \in D(\Delta^{\{\vec{k}\}})$ *consider every consistent*

$$\Gamma_\sigma^{\{\vec{k}+1\}} = \{\phi_p \mid \langle\langle A_p\rangle\rangle X\phi_p \in \Delta^{\{\vec{k}\}}, \sigma_i = p \text{ for all } i \in A_p\} \cup \{\neg\psi_q \mid \neg\langle\langle B_q\rangle\rangle X\psi_q \in \Delta^{\{\vec{k}\}}, neg(\sigma) = q, Ag_\theta^+ \setminus B_q \subseteq N(\sigma)\} \quad (2)$$

where $\Gamma_\sigma^{\{\vec{k}+1\}} = \{\top\}$ *if the set on the RHS of (2) is empty.*

- *If the pre-tableau contains a pre-state* $\Gamma'^{\{\vec{m}\}} = \Gamma_\sigma^{\{\vec{k}+1\}}$ *s.t.* $mk(\Gamma'^{\{\vec{m}\}}) = mk(\Gamma_\sigma^{\{\vec{k}+1\}})$*, then*
  – *rename* $\Gamma'^{\{\vec{m}\}}$ *and all pre-states and states* $\Theta_i^{\{\vec{m}+i\}}$ *s.t.* $\Gamma'^{\{\vec{m}\}} \mapsto \Theta_i^{\{\vec{m}+i\}}$ *as* $\Gamma'^{\{\vec{m}\}\cup\{\vec{k}+1\}}$ *and* $\Theta_i^{\{\vec{m}+i\}\cup\{\vec{k}+i+1\}}$*. Then, set* $\Delta^{\{\vec{k}\}} \xrightarrow{\sigma} \Gamma'^{\{\vec{m}\}\cup\{\vec{k}+1\}}$*;*
- *else,*
  – *add* $\Gamma_\sigma^{\{\vec{k}+1\}}$ *as a new pre-state to the pre-tableau;*
  – *set* $\Delta^{\{\vec{k}\}} \xrightarrow{\sigma} \Gamma_\sigma^{\{\vec{k}+1\}}$ *and* $mk(\Gamma_\sigma^{\{\vec{k}+1\}}) = mk(\Delta^{\{\vec{k}\}})$*.*

Also in this case, the rule $\mathbf{Next}_I^{uis}$ is obtained by omitting indexes from states and pre-states in $\mathbf{Next}_I^{uis,sync}$. Now we consider the epistemic operator. Similarly to the above, we have to introduce a distinct case for each of $ECGM^{uis}$ and $ECGM^{uis,sync}$. Moreover, for each case we have to introduce two rules that apply at different stages of the construction phase.

Definition 19 (Rule $\mathbf{K}_1^{uis}$) *Given a state* Δ *s.t.* $\boldsymbol{K}_1^{uis}$ *has not been applied to* Δ*, for every* $\neg K_i\phi \in \Delta$*,*

- *if* $\langle\langle Ag_\theta\rangle\rangle F(\neg\phi \wedge \Delta|_{K_i}) \notin mk(\Delta)$*, then add* $\Gamma_{i+1} = mk(\Delta) \cup \{\langle\langle Ag_\theta\rangle\rangle F(\neg\phi \wedge \Delta|_{K_i})\}$ *if it is consistent, where* i *is the greatest index s.t.* Γ_i *appears in the pre-tableau;*
- *set* $mk(\Gamma_{i+1}) = undef$*.*

Intuitively, when Δ contains an epistemic possibility $\neg K_i\phi$ and the root of Δ does not anticipate to fulfil this possibility (i.e., $\langle\langle Ag_\theta\rangle\rangle F(\neg\phi \wedge \Delta|_{K_i}) \notin mk(\Delta)$), then by $\mathbf{K}_1^{uis}$ we attempt to construct a branch of the pre-tableau that satisfies $\neg K_i\phi$ by adding a pre-state Γ_{i+1} as above. To define the corresponding rule for $ECGM^{uis,sync}$ we introduce the notion of a *loop* on a state Δ, that is, a sequence $\Delta_0, \Gamma_1, \Delta_1 \ldots, \Gamma_n, \Delta_n$ s.t. *(i)* $\Delta = \Delta_0 = \Delta_n$; *(ii)* $\Gamma_{i+1} \in$ **pre-states**(Δ_i); *(iii)* $\Delta_i \in$ **states**(Γ_i); and *(iv)* $\Delta_i \neq \Delta$ for $0 < i < n$. Let n be the *length* of the loop. We denote the set of lengths of all loops for a state Δ as $loop(\Delta)$. Also, for $\neg K_i\phi \in \Delta^{\{\vec{k}\}}$, we use ζ as a shorthand for $\neg\phi \wedge \Delta^{\{\vec{k}\}}|_{K_i}$.

Definition 20 (Rule $\mathbf{K}_1^{uis,sync}$) *Given a state* $\Delta^{\{\vec{k}\}}$ *s.t.* $\boldsymbol{K}_1^{uis,sync}$ *has not been applied to* $\Delta^{[\vec{k}]}$*, for every* $\neg K_i\phi \in \Delta^{\{\vec{k}\}}$*,* $Y \subseteq \{\vec{k}\}$*, and* $W \subseteq loop(\Delta^{\{\vec{k}\}})$*,*

- *if* $\eta = \bigwedge_{y\in Y}(\langle\langle Ag_\theta\rangle\rangle X)^y(\zeta \wedge \langle\langle\emptyset\rangle\rangle G(\zeta \rightarrow \bigwedge_{w\in W}(\langle\langle Ag_\theta\rangle\rangle X)^w\zeta)) \notin \Delta^{\{\vec{k}\}}$*, then add* $\Gamma_{i+1}^{\{0\}} = mk(\Delta^{\{\vec{k}\}}) \cup \{\eta\}$ *if it is consistent, where* i *is the smallest index s.t.* $\Gamma_i^{\{0\}}$ *appears in the pre-tableau;*
- *set* $mk(\Gamma_{i+1}^{\{0\}}) = undef$*.*

The *rationale* for $\mathbf{K}_1^{uis,sync}$ comes from the fact that satisfiability w.r.t. $ECGM^{sync,uis}$ needs stronger conditions. Indeed, we have to ensure that for every $\neg K_i\phi$ in $\Delta^{\{\vec{k}\}}$ there exists a $\Delta'^{\{\vec{k}\}}$ s.t. $\neg\phi \in \Delta^{\{\vec{k}\}}$. In particular, $\Delta^{\{\vec{k}\}}$ and $\Delta'^{\{\vec{k}\}}$ have to share the same time-stamp $\{\vec{k}\}$.

The construction phase for satisfiability w.r.t. $ECGM^{uis}$ (resp. $ECGM^{uis,sync}$) goes then as follows. As customary, we start with the initial pre-state $\Gamma_0^{\{0\}} = \{\theta\}$, which contains only the input formula. Then, we alternatingly apply $\mathbf{SR}_I$ and $\mathbf{Next}_I$ (we omit superscripts to refer to both cases) until these rules are no longer applicable. This procedure builds a purely temporal pre-tableau, i.e., a pre-tableau whose $\rightarrow$-edges are marked by joint actions only. At this point, we apply $\mathbf{K}_1^{uis}$ (resp. $\mathbf{K}_1^{uis,sync}$). If a new initial pre-states $\Gamma_i^{\{0\}}$ is created, then we repeat the procedure above. We proceed in this way until none of the rules is any longer applicable. Finally, we apply the rules $\mathbf{K}_2^{uis}$ (resp. $\mathbf{K}_2^{uis,sync}$).

Definition 21 (Rule $\mathbf{K}_2^{uis,sync}$) *Given a state* $\Delta^{\{\vec{k}\}}$ *s.t.* $\boldsymbol{K}_2^{uis,sync}$ *has not been applied to* $\Delta^{[\vec{k}]}$*, for every* $\neg K_i\phi \in \Delta^{\{\vec{k}\}}$ *and state* $\Delta'^{[\vec{k}]}$*,*

- *if* $mk(\Delta'^{\{\vec{k}\}}) = mk(\Delta^{\{\vec{k}\}})$ *and* $\{\neg\phi\} \cup \Delta^{\{\vec{k}\}}|_{K_i} \subseteq \Delta'^{\{\vec{k}\}}$*, then set* $\Delta^{\{\vec{k}\}} \xrightarrow{\neg K_i\phi} \Delta'^{\{\vec{k}\}}$*.*

The rule $\mathbf{K}_2^{uis}$ is obtained from $\mathbf{K}_2^{uis,sync}$ by omitting time-stamps, so we can relate states with different time-stamps. Notice that neither $\mathbf{K}_2^{uis}$ nor $\mathbf{K}_2^{uis,sync}$ creates new pre-states. Instead, they link a state containing an epistemic possiblity with a state that fulfils that possibility. Also in the present case we can prove that the construction phase terminates after a finite number of steps. We conclude this section with an example.

Example 2 In Fig. 3 we reported a fragment of the pre-tableau for the ATEL-formula $\theta_1 = \langle\langle 1\rangle\rangle F\neg K_2 p \wedge K_1\langle\langle 2\rangle\rangle Gp$. We now observe that it also corresponds to the fragment of the pre-tableau obtainable by applying rules $\mathbf{SR}_I^{uis}$ and $\mathbf{Next}_I^{uis}$ only, modulo the mark mk. Since state

$\Delta_{1.1}$ in Fig. 3 contains an epistemic possibility, we apply rule $\mathbf{K}_1^{uis}$ and create a new initial pre-state $\Gamma'_1 = \{\theta_1, \langle\langle 1,2\rangle\rangle F(\neg p \wedge \neg K_2 p)\}$. The fragment of the pre-tableau for Γ'_1 is shown in Fig. 2. ■

5.2 Elimination Phase

For I-satisfiability the elimination phase makes use of most of the rules for S-satisfiability, with some exceptions. First, by **PR** we remove all pre-states and re-direct incoming and outcoming $\rightarrow$-edges. Further, we proceed in stages and at each stage we apply one of the elimination rules **E1**, **E3**, and the following new rule:

E2$_I^{uis,sync}$ If for some $\neg K_i\phi \in \Delta^{\vec{k}}$ there is no $\Delta'^{\vec{k}} \in \mathcal{T}_n^\theta$ s.t. $mk(\Delta'^{\vec{k}}) = mk(\Delta^{\vec{k}})$, $mk(\Delta'^{\vec{k}}) \Rightarrow^* \Delta'^{\vec{k}}$, and $\Delta^{\vec{k}} \xrightarrow{\neg K_i\phi} \Delta'^{\vec{k}}$, then $\mathcal{T}_{n+1}^\theta = \mathcal{T}_n^\theta \setminus \{\Delta^{\vec{k}}\}$.

This means that epistemic possibilities have to be satisfied by states that have the same time-stamp and are reachable from an initial state. The corresponding rule **E2**$_I^{uis}$ can be obtained by omitting time-stamps. Finally, for synchronous ECGM only, we have also to consider the following rule to manipulate time-stamps:

Ets$_I$ If $\mathcal{T}_{n+1}^\theta = \mathcal{T}_n^\theta \setminus \{\Delta^{\vec{k}}\}$ and in $\mathcal{T}_n^\theta$ it was the case that $\Delta^{\vec{k}} \Rightarrow^* \Delta'^{\vec{m}}$, then in $\mathcal{T}_{n+1}^\theta$ rename $\Delta'^{\vec{m}}$ as $\Delta'^{\vec{m}\setminus\vec{k}}$ (remove $\Delta'^{\vec{m}}$ if $\vec{m} \setminus \vec{k} = \emptyset$.)

The elimination phase terminates when it is no longer possible to apply any of the elimination rules above. As in the case of S-satisfiability, the structure obtained at the end of the elimination phase is the tableau $\mathcal{T}^\theta$, which is said to be open if $\theta \in \Delta$, for some $\Delta \in \mathcal{T}^\theta$ s.t. $\Delta \in$ **states**(Γ_i), for some initial Γ_i. Hereafter we outline the soundess and completeness proof of the tableau procedure for I-satisfiability.

5.3 Soundness and Completeness

The soundness proof for the tableau-based decision procedure amounts to the following result, analogous to Theorem 4.

Theorem 9 *If θ is I-satisfiable, then $\mathcal{T}^\theta$ is open.*

The structure of the proof is similar to Theorem 4, i.e., we show that the elimination rules do not remove satisfiable state. However, we need to consider different elimination rules. Hereafter we briefly consider the case of **E2**$_I^{uis}$. Suppose that $\Delta' \in \mathcal{T}_n^\theta$ is S-satisfiable and reachable from Δ, also $\neg K_i\phi \in \Delta'$, and there exists a sequence $\Theta_0 \rightarrow \ldots \rightarrow \Theta_n$ of states s.t. $\Theta_0 = \Delta$, $\Theta_n = \Delta'$, and each Θ_i is S-satisfiable (the existence of such a sequence follows from Lemma 5.2 in (Goranko and Shkatov 2009a)). In particular, we can deduce that there exists an ECGM $\mathcal{P}$ with a unique initial state, and $s_0 \in \mathcal{P}$ s.t. $(\mathcal{P}, s_0) \models \Theta_0 = \Delta$, $s_i \rightarrow s_{i+1}$ and $(\mathcal{P}, s_i) \models \Theta_i$. Since $\neg K_i\phi \in \Delta' = \Theta_n$, there exists $s' \in \mathcal{P}$ s.t. $s' \sim_i s$ and $(\mathcal{P}, s') \models \neg\phi \wedge \Delta|_{K_i}$. By the uniqueness of the initial state, we have that s' is reachable from s_0. Hence $(\mathcal{P}, s_0) \models \langle\langle Ag_\theta\rangle\rangle F(\neg\phi \wedge \Delta|_{K_i})$. As a result we obtain that $\Gamma_{i+1} = \Delta \cup \{\langle\langle Ag_\theta\rangle\rangle F(\neg\phi \wedge \Delta|_{K_i})\}$ is also I-satisfiable, and by Lemma 5 some Δ_{i+1} saturating Γ_{i+1} is also I-satisfiable. Now, we remark that if Θ is satisfiable and $\Delta \rightarrow^* \Theta$ then $\Delta_{i+1} \rightarrow^* \Theta$. In particular, Δ' is reachable from Δ_{i+1}. Moreover, since $\langle\langle Ag_\theta\rangle\rangle F(\neg\phi \wedge \Delta|_{K_i})\} \in \Delta_{i+1}$ and Δ_{i+1} is I-satisfiable, the eventuality $\langle\langle Ag_\theta\rangle\rangle F(\neg\phi \wedge \Delta|_{K_i})$ is realized in some Δ'' reachable from Δ_{i+1}. As a consequence, when we apply rule $\mathbf{K}_2^{uis}$ we obtain that $\Delta' \xrightarrow{\neg K_i\phi} \Delta''$ and Δ' cannot be eliminated by an application of **E2**$_I^{uis}$. As a final result, we have that the I-satisfiable set Δ containing θ is never removed from $\mathcal{T}^\theta$, thus it remains open.

To prove the completeness of the tableaux for I-satisfiability, we have to prove the following result, corresponding to Theorem 7.

Theorem 10 (Completeness) *If $\mathcal{T}^\theta$ is open, then θ is I-satisfiable.*

Also in this case, the proof amounts to build an ECGHS $\mathcal{H}_\theta$ starting from the open tableau $\mathcal{T}^\theta$. Moreover, $\mathcal{H}_\theta$ has to have an unique initial state, or being synchronous. The key remark here is that we can restrict the construction of temporal components to states having the same mark mk. Thus, we state the following result, from which Theorem 10 immediately follows.

Lemma 11 *If $\mathcal{T}^\theta$ is open, then there exists an ECGHS $\mathcal{H}_\theta$ that I-satisfies θ.*

Complexity. We briefly discuss the complexity of the procedure above and notice that it is non-elementary, as in the worst case we have to reinitiate the tableau construction for each epistemic possibility to be fulfilled. We are not aware of any contribution to the complexity of I-satisfiability for ATEL formulas in either $ECGM^{sync}$ or $ECGM^{uis,sync}$. So, we here provide an upper bound for this problem.

6 Conclusions

In this paper we presented a tableau-based method for deciding the satisfiability of ATEL formulas in a number of settings. We considered satisfiability in some initial state as opposed to any state of the model. We argued that the former problem is of interest for verification purposes, while the latter notion is typical of logical investigations. Further, we considered the assumptions of synchronicity and of a unique initial state. These are standard conditions in the literature on Interpreted Systems and their impact on the satisfiability problem has been assessed in relation with various temporal epistemic logics, based on both linear and branching time (Halpern and Vardi 1986; 1989). This paper aimed at extending this type of investigations to alternating time epistemic logic.

There is a number of possible extensions for the present results. In one direction, other assumptions from Interpreted Systems, such as perfect knowldge and no learning, can be imposed on ECGM and corresponding decision procedures developed. It is well-known that the decision problem under these conditions becomes particularly hard (Halpern and Vardi 1986; 1989). So, incremental tableau techniques can contribute to alleviate the decision task for such cases, at least on average, since we do not have to build all formula types as in top-down tableaux. On another direction, notions such as imperfect information and commitment in strategies

have been considered in relation to ATL. It would be of interest to check their impact also w.r.t. satisfiability of ATEL formulas. In yet another direction, modalities for group knowledge can be added to ATEL. This extension has not been considered here, so as not to make the formal language too cumbersome. We leave all these issues for future research.

Reasoning about Equilibria in Game-Like Concurrent Systems

Julian Gutierrez and **Paul Harrenstein** and **Michael Wooldridge**
Department of Computer Science
University of Oxford

Abstract

Our aim is to develop techniques for reasoning about game-like concurrent systems, where the components of the system act rationally and strategically in pursuit of logically-specified goals. We first present a computational model for such systems, and investigate its properties. We then define and investigate a branching-time logic for reasoning about the equilibrium properties of such systems. The key operator in this logic is a path quantifier $[\mathbf{NE}]\varphi$, which asserts that φ holds on all Nash equilibrium computations of the system.

1 Introduction

Our goal is to develop a theory and techniques for reasoning about *game-like concurrent systems*: concurrent systems in which system components (agents) act strategically in pursuit of their own interests. Game theory is the mathematical theory of strategic interaction, and as such is an obvious candidate to provide the analytical tools for this purpose (Osborne and Rubinstein 1994). However, since the systems we are interested in modelling and reasoning about are interacting computer programs, it seems appropriate to consider how existing techniques for the analysis of computer systems might be combined with game theoretic concepts. Temporal logics (Emerson 1990) and model checking (Clarke, Grumberg, and Peled 2000) form the most important class of techniques for reasoning about computer programs, and in this paper we are concerned with extending such formalisms and techniques to the strategic analysis of systems.

The AI/computer science literature is of course replete with logics intended for reasoning about game-like systems: Parikh's Game Logic was an early example (Parikh 1985), and more recently ATL (Alur, Henzinger, and Kupferman 2002) and Strategy Logic (Chatterjee, Henzinger, and Piterman 2010) have received much attention. However, these formalisms are primarily intended for reasoning about the strategies/choices of players and their effects, rather than the preferences of players and the strategic choices they will make arising from them. It is, of course, possible to use a temporal logic like ATL or Strategy Logic (or indeed LTL, CTL, ...) to define the goals of agents, and hence their preferences; but such languages don't provide any direct mechanism for reasoning about the behaviour of such agents under the assumption that they act rationally and strategically in pursuit of their goals. In this paper, we present a branching time logic that is explicitly intended for this purpose. Specifically, we provide a logic for reasoning about the *equilibrium* properties of game-like concurrent systems.

Equilibrium concepts are the best-known and most widely applied analytical tools in the game theory literature, and of these Nash equilibrium is the best-known (Osborne and Rubinstein 1994). A Nash equilibrium is an outcome that obtains because no player has a rational incentive to deviate from it. If we consider Nash equilibrium in the context of game-like concurrent systems, then it is natural to ask *which computations (runs, histories, ...) will be generated in equilibrium*? In (Gutierrez, Harrenstein, and Wooldridge 2013), this question was investigated using the Iterated Boolean Games (iBG) model. In this model, each player is assumed to control a set of Boolean variables, and the game is played over an infinite sequence of rounds, where at each round every player chooses values for its variables. Each player has a goal, expressed as an LTL formula, and acts strategically in pursuit of this goal. Given this, some computations of a game can be identified as being the result of Nash equilibrium strategies, and (Gutierrez, Harrenstein, and Wooldridge 2013) suggested that the key questions in the strategic analysis of the system are whether a given LTL formula holds in some or all equilibrium computations.

While the iBG model of (Gutierrez, Harrenstein, and Wooldridge 2013) is useful for the purposes of exposition, it is not a realistic model of concurrent programs. Moreover, (Gutierrez, Harrenstein, and Wooldridge 2013) provides no language for reasoning *about* the equilibria of systems: such reasoning must be carried out at the meta-level. This paper fills those gaps. First, we present a computational model that is more appropriate for modelling concurrent systems than the iBG model. In this model, the goals (and thus preferences) of players are given as temporal logic formulae that the respective player aspires to satisfy. After exploring some properties of this model, we introduce *Equilibrium Logic* (EL) as a formalism for reasoning about the equilibria of such systems. EL is a branching time logic that provides a new path quantifier $[\mathbf{NE}]\varphi$, which asserts that φ holds *on all Nash equilibrium computations of the system*. Thus, EL supports reasoning about equilibria directly in the object language. We then investigate some properties of this logic.

In particular in this paper we show that via a logical characterisation of equilibria one can check useful properties of strategy profiles. We consider four logics for players' goals: LTL (Pnueli 1977), CTL (Clarke and Emerson 1981), the linear-time μ-calculus (Vardi 1988), and the branching-time μ-calculus (Kozen 1983). Based on our logical characterisation of equilibria in infinite games, three problems are studied: STRATEGY-CHECKING, NE-CHECKING, and EQUIVALENCE-CHECKING, all of which are shown to be in PSPACE or in EXPTIME depending on the particular problem and temporal logic at hand. We also study the computational complexity of checking equilibrium properties, which can be expressed in EL. We show that the problem is 2EXPTIME-hard, even for LTL or CTL goals. This result shows, in turn, that checking equilibrium properties is equally hard in the linear-time and in the branching-time spectra. A summary of key results is given at the end of the paper. Note that most proofs are omitted due to lack of space.

2 Models

Before giving formal definitions, let us start by describing a situation that can naturally be modelled as a game-like concurrent and multi-agent system.

Example 1. Consider a situation in which two agents can request a resource from a dispatch centre infinitely often; assume both agents will always eventually need the resource. The centre's behaviour is as follows:

1. if only one of the agents requests the resource, it gets it;
2. if both agents request the resource, neither agent gets it;
3. if one agent requested the resource twice in a row while the other agent did not do so, the latter agent gets the resource for ever after (thus, punishing greedy behaviour).

Because of 2 and 3 it may be the case that an agent (or both) fails to achieve its goal of being granted the resource infinitely often. But, of course, we can see a simple solution: if both agents request the resource alternately, then both agents get their goals achieved. Indeed, a game-theoretic analysis reveals that *in all equilibria of this system both agents get the resource infinitely often*.

In order to model this kind of situation, we will define a model for concurrent strategic interactions. Using this model, in Section 5 we present a formal model of the above example, and we then formally analyse its equilibrium properties (Example 14).

The basic formal model for capturing strategic interactions is a graph-based structure that is used for various distinct purposes. It will be used for both the *model* of game-like concurrent systems we are interested in modelling and the *strategies* of players in these systems. Depending on how we use and instantiate our model to each of the above applications they may acquire a particular name and have a refined structure. As will be clear from their definition (below), our basic model generalises both Kripke frames and transition systems, among others, thus allowing them to be used in very many different contexts. More importantly, compositions of these models naturally represent the behaviour of synchronous, multi-agent, and concurrent systems with interleaving semantics as well as of asynchronous systems (Nielsen and Winskel 1995). Formally, let

$$M = (V, E, v^0, \Omega, \Lambda, \omega, \lambda)$$

be a Λ-labelled Ω-model M, where V is the set of vertices[1] of M, $v^0 \in V$ is the initial vertex, $E \in V \times V$ is the set of edges[2], and $\omega : V \to 2^\Omega$ and $\lambda : E \to 2^\Lambda$ are two functions, the former indicating the set of 'properties' of a vertex and the latter the ways to go/move from one vertex to another. Based on M, some sets can be defined. The set of *transitions*:

$$T_M = \{(v, a, v') \in V \times \Lambda \times V \mid (v, v') \in E \wedge a \in \lambda(v, v')\};$$

and the sets of sequences[3] of adjacent vertices and transitions starting at v^0, which we denote by V^*_M and T^*_M.

A model is total if for every $v \in V$ there is $v' \in V$ and $a \in \Lambda$ such that $(v, a, v') \in T_M$; it is, moreover, Λ-total if for every $v \in V$ and every $a \in \Lambda$ there is $v' \in V$ such that $(v, a, v') \in T_M$. Observe that if M is total the set T^*_M contains only infinite sequences. The sets T^*_M and V^*_M induce two additional sets of sequences, one over the elements in Λ (the *action* names labelling the transitions) and another one over the elements in 2^Ω (the *properties* that hold, or can be observed, in the vertices of the model); namely the sets

$$\mathcal{A}^*_M = \{a, a', \ldots \mid (v^0, a, v'), (v', a', v'') \ldots \in T^*_M\}, \text{and}$$

$$\mathcal{P}^*_M = \{\omega(v^0), \omega(v'), \omega(v''), \ldots \mid v^0, v', v'', \ldots \in V^*_M\}.$$

Hereafter, for all sets and in all cases, we may omit their subscripts whenever clear from the context. Given a sequence ρ (of any kind), we write $\rho[0], \rho[1], \ldots$ for the first, second, ... element in the sequence; if ρ is finite, we write $last(\rho)$ to refer to its last element. We also write $|\rho|$ for the size of a sequence. The empty sequence is denoted by $\rho[\,] = \epsilon$ and has size 0. Restrictions to parts of a sequence and operations on them are useful. Given $k, k' \in \mathbb{N}$, with $k \leq k'$, we write $\rho[0 \ldots k]$ for the sequence $\rho[0], \rho[1], \ldots, \rho[k]$ (an initial segment of ρ), $\rho[k \ldots k']$ for the sequence $\rho[k], \ldots, \rho[k']$, and $\rho[k \ldots \infty]$ for the infinite sequence $\rho[k], \rho[k+1], \ldots$. We also write, *e.g.*, $\rho[k \ldots k')$ if the element $\rho[k']$ of the sequence is not included. Given a finite sequence ϱ, we write $\varrho \in \rho$ if $\varrho[k] = \rho[k]$ for all $0 \leq k \leq |\varrho|$. We also write $\varrho; \rho$ for the binary operation on sequences/words—and resulting run—of concatenating a finite run ϱ with a run ρ. When working with sequences, we assume the standard laws on them, in particular, w.r.t. concatenation ";" with the empty sequence ϵ we have $\epsilon; \rho = \rho$, for any ρ, and $\rho; \epsilon = \rho$, for any finite ρ.

We find it useful to associate *input and output languages* with models. The input language $\mathcal{L}_i(M)$ of M is defined to be $\mathcal{A}^*_M$ and the output language $\mathcal{L}_o(M)$ of M is defined to be $\mathcal{P}^*_M$. Given a set of models $\vec{M} = \{M_1, \ldots, M_n\}$, the input language of $\vec{M}$ is defined to be

$$\mathcal{L}_i(\vec{M}) = \bigcap_{1 \leq j \leq n} \mathcal{L}_i(M_j).$$

[1] We may write 'nodes' or 'states' when talking about vertices.
[2] We also call them 'events' or 'actions'.
[3] We also say 'words' or 'strings' when talking about sequences.

The set $\mathcal{L}_i(\vec{M})$ determines synchronised runs $V^*_{\vec{M}}$ for $\vec{M}$, *i.e.*, sequences $(v^0_1,\ldots,v^0_n),(v'_1,\ldots,v'_n),\ldots \in (V_1\times\ldots\times V_n)^*$ such that

$$\bigwedge_{1\leq j\leq n}(v^0_j,a,v'_j),(v'_j,a',v''_j),\ldots \in T^*_{M_j},$$

for some $a,a',\ldots\in\mathcal{L}_i(\vec{M})$. The set $V^*_{\vec{M}}$, in turn, determines the output language $\mathcal{L}_o(\vec{M})$ of $\vec{M}$, defined to be all sequences

$$\bigcup_{1\leq j\leq n}\omega_j(\rho[0]),\ \bigcup_{1\leq j\leq n}\omega_j(\rho[1]),\ldots\in(2^{\Omega_1\cup\cdots\cup\Omega_n})^*$$

where $\rho\in V^*_{\vec{M}}$ and $\omega_j(\rho[k])$, with $0\leq k<|\rho|$, is the application of the ω_j of M_j to the jth component of each $\rho[k]$.

Let $\mathcal{L}$ function equally for an input or output language of a model M or compound system $\vec{M}$; moreover, let $\mathcal{L}[\varrho]$ be the (sub)language of (sub)words $\{\rho[|\varrho|\ldots\infty]\mid \varrho\in\rho\in\mathcal{L}\}$.

There is an induced tree language $\mathit{TreeL}(\mathcal{L})$ for every (word) language $\mathcal{L}$, defined as:

$$\mathit{TreeL}(\mathcal{L})=\{\mathcal{T}\text{ is a tree}\mid \rho\in\mathcal{L},\text{ for each path }\rho\text{ in }\mathcal{T}\},$$

that is, the *tree language* of a *word language* $\mathcal{L}$ is the set of all trees all of whose paths are in $\mathcal{L}$.

Remark 2. Note that any non-empty word language induces a tree language comprising infinitely many trees, if such trees are allowed to be non-deterministic. For instance, the (singleton) word language $\mathcal{L}=\{a\}$ induces the tree language $\mathit{TreeL}(\mathcal{L})$ containing the following trees: the empty tree, the tree with one a-labelled branch, the tree with two a-labelled branches, ..., and the infinite tree with infinitely many a-labelled branches. However, if non-determinism is not allowed (or at least restricted in some way) some finite word languages may always induce finite tree languages. For the sake of *generality* we impose no restrictions at this point.

Our models support two useful operations: *restriction* and *projection*. The former selects a subset of the output language; a restriction with respect to a subset of the input language. We denote by $\mathcal{L}_o(M)|_{\mathcal{L}}$, where $\mathcal{L}\subseteq\mathcal{L}_i(M)$, such a subset of the output language. Projection, on the other hand, takes the sequences in the output language and forgets the elements in some subset of Ω. We write $\mathcal{L}_o(M)|_{\Omega'}$ for such an operation and resulting set, which is formally given by:

$$\{\rho[0]\cap\Omega',\rho[1]\cap\Omega',\ldots\in(2^{\Omega'})^*\mid\rho\in\mathcal{L}_o(M)\}.$$

3 Games and Strategies

Games. Using the model given in Section 2, we will define reactive games, a class of multi-player nonzero-sum games. In a reactive game a finite set of players interact with each other by assigning values to variables they have control over. The game has a designated initial state and the values given to the variables at each round determine the next state of the game. The game is played for infinitely many rounds. Players in a reactive game have goals they wish to satisfy. Such goals are expressed as temporal logic formulae. Formally, a reactive game is defined as follows. A *reactive* game (sometimes just called a "game") is a structure:

$$G=(N,C,(C_i)_{i\in N},(\gamma_i)_{i\in N},X,A)$$

where $N=\{1,\ldots,n\}$ is a set of *agents* (the players of the game), $C=\{p,q,r,\ldots\}$ is a set of *controlled variables*, $C_i\subseteq C$ is the set of variables under the *unique control* of player i, and γ_i is a formula (of some logical system[4]) over a set $X=\{x,y,\ldots\}$ of propositions; formula γ_i describes the *goal* that player i wants to achieve. There is a requirement on C: the sets of variables $C_1,\ldots,C_n$ form a partition of C, that is, $C_i\cap C_j=\emptyset$ for all $i\neq j\in N$, and $C=C_1\cup\cdots\cup C_n$. A *choice* c_i for agent $i\in N$ is an assignment of values for the variables under its control. Let Ch_i be the set of choices for agent i. A *choice vector* $\vec{c}=(c_1,\ldots,c_n)$ is a collection of choices, one for each player. Let Ch be the set of all choice vectors. And A—the *"arena" or "board"* where the game is played—is a Λ-total Ω-model such that $\Lambda=\mathit{Ch}$ and $\Omega=X$.

Note that Λ-totality ensures in a simple manner that a reactive game is played for an infinite number of rounds without imposing further consistency or validity conditions on strategies. Moreover, it does not limit our modelling power.

Remark 3. Reactive games can be considered as a metamodel of *infinite* games of *control* since their definition does not specify the logic each γ_i belongs to, the kinds of strategies used in the game, the types of variables the players have control over, what the outcome of a game would be given a set of players' strategies, or when the outcome of a game makes a player's goal satisfied. As we will see, different kinds of games and results will arise from different choices with respect to these properties. All we know for now is that (1) the games are played for *infinitely* many rounds, (2) the players have *unique control* over some given set of variables, and that (3) they have goals given in a *logical form*.

Strategies. Since in a reactive game a play is infinite, it is natural to think of a strategy for a player i as a function $f_i:E^*\to\mathit{Ch}_i$ or as $f'_i:V^*\to\mathit{Ch}_i$, that is, as a function from what has been played so far (or at least what a player *knows so far*) to a choice c_i for player i. To formalise this, we use a strategy model that is *finite*, *simple*, and *expressive* enough for most computational purposes. Our definition of strategies is based on the model in Section 2. Similar representations have been used to study, *e.g.*, 'repeated games' in game theory (Osborne and Rubinstein 1994, pp. 140-143).

Formally, we define a *strategy* σ_i for player i in a reactive game $G=(N,C,(C_i)_{i\in N},(\gamma_i)_{i\in N},X,A)$ to be a structure

$$\sigma_i=(Q_i,q^0_i,\delta_i,\tau_i)$$

modelled as a structure $M_i=(V,E,v^0,\Omega,\Lambda,\omega,\lambda)$ in which $Q_i=V$ is a finite and non-empty set of *states*, $q^0_i=v^0$ is the *initial* state, $\delta_i:Q_i\times\Lambda\to 2^{Q_i}$, with $\Lambda=2^{X_A}$, is the *transition function* given by T_{M_i}, and $\tau_i=\omega:Q_i\to\mathit{Ch}_i$ is a *choice function*. As one requires that a strategy for player i is able to *react* to any possible valid behaviour/strategy of the others, we only consider as *valid* the strategies that are based on structures M_i where δ_i is total.

[4] We will consider several logical temporal languages for γ_i, *e.g.*, LTL (Pnueli 1977), CTL (Clarke and Emerson 1981), or fixpoint linear-time and branching-time modal logics (Vardi 1988; Kozen 1983). At this point all definitions can be made leaving this choice open, which will make our framework more general.

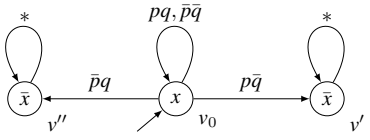

Figure 1: An arena, where $* = \{pq, \bar{p}q, p\bar{q}, \bar{p}\bar{q}\}$.

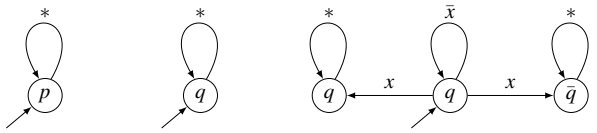

Figure 2: Strategy σ_1 for player 1 (left) and the strategies σ_2 (middle) and σ_2' (right) for player 2. Here $* = \{x, \bar{x}\}$.

Henceforth, given a game G with n players in N and a set of strategies $\vec{\sigma} = (\sigma_1, \ldots, \sigma_n)$, we call $\vec{\sigma}$ or any subset of it a strategy profile. We write $\vec{\sigma}_{-S}$, with $S \subseteq N$, for $\vec{\sigma}$ without the strategies σ_i such that $i \in S$; we omit brackets if S is a singleton set. Also, we write $(\vec{\sigma}_{-i}, \sigma_i')$, with $1 \leq i \leq n$, for the strategy profile $\vec{\sigma}$ where σ_i is replaced with σ_i'.

Example 4. Consider a game with $N = \{1, 2\}$, $C_1 = \{p\}$, and $C_2 = \{q\}$ and arena as in Figure 1. There, we have $\omega_A(v^0) = x$, $\omega_A(v') = \omega_A(v'') = \bar{x}$. Moreover, the symbol $\bar{p}$ means $p := \bot$, p means $p := \top$ (and likewise for q and x). A possible strategy for player 1 would be to always play p and is depicted in Figure 2 (left). The exact outcome(s) of the game—to be defined next—can be determined only once the strategy for player 2 is given.

Our strategy model is simple but powerful; in particular, it can generate any word or tree ω-regular language. Formally:

Lemma 5. *Let $\mathcal{T}$ be an ω-regular tree—i.e., the unfolding of a finite, total graph. There is σ such that $\mathcal{T} \in TreeL(\mathcal{L}_o(\sigma))$.*

It is important to point out that the strategy σ may be non-deterministic. However, with respect to word languages, only deterministic strategies are needed. Specifically, because ω-regular words are ω-regular trees that do not branch, the following is an easy corollary of Lemma 5.

Corollary 6. *Let w be an ω-regular word. There is σ such that $w = \mathcal{L}_o(\sigma)$.*

Lemma 5 and Corollary 6 will be used to ensure the existence of strategies in a reactive game with ω-regular goals.

Outcomes and composition of strategies. Given a set of strategies $(\sigma_i)_{i \in N}$, which hereafter we will denote by $\vec{\sigma}$ whenever the set N is clear from the context, the *histories* (of choices) when playing such a set of strategies in a game $G = (N, C, (C_i)_{i \in N}, (\gamma_i)_{i \in N}, X, A)$ are the sequences in the input language of A, denoted by $\mathcal{L}_i^{\vec{\sigma}}(A)$, given by

$$\mathcal{L}_i^{\vec{\sigma}}(A) = \mathcal{L}_o(\vec{\sigma})|_{\mathcal{L}_i(\vec{\sigma}) \cap \mathcal{L}_o(A)[\vec{q}^0]},$$

where $\vec{q}^0 = (\tau_1(q_1^0), \ldots, \tau_n(q_n^0))$.

Informally, since $\mathcal{L}_o(\vec{\sigma})$, and hence $\mathcal{L}_i^{\vec{\sigma}}(A)$, is restricted to $\mathcal{L}_i(\vec{\sigma}) \cap \mathcal{L}_o(A)[\vec{q}^0]$, we know that when playing a strategy profile there is an alternation in the interaction between strategies and the arena, with the strategies making transitions only after a transition in the arena has been made.

The histories of a game with respect to a strategy profile $\vec{\sigma}$ record the choices that the players make based on such a given strategy profile $\vec{\sigma}$. These choices, in turn, determine the *outcomes* of the game, denoted by $\mathcal{L}_o^{\vec{\sigma}}(A)$ and defined as

$$\mathcal{L}_o^{\vec{\sigma}}(A) = \mathcal{L}_o(A)|_{\mathcal{L}_i^{\vec{\sigma}}(A)}.$$

Then, whereas *histories* are sequences in the *input* language of A, *outcomes* are sequences in its *output* language.

As defined, the outcomes of a game form a set of words or infinite sequences over $(2^{\Omega_A})^*$. However, they naturally define a set of trees with respect to the tree-unfolding of A. We write $unf(A, v)$ for the usual tree-unfolding of A—when A is seen as a graph—with respect to a given vertex $v \in V$; we simply write $unf(A)$ whenever $v = v^0$. Define the set

$$Tree(A) = \{T \mid T \text{ is a subtree of } unf(A)\}.$$

Thus, given a strategy profile $\vec{\sigma}$ in a reactive game G, the tree/branching outcomes of G are the trees in the set

$$TreeL(\mathcal{L}_o^{\vec{\sigma}}(A)) \cap Tree(A).$$

Regardless of whether we are talking about word outcomes or tree outcomes, we will uniformly denote by $Out(G, \vec{\sigma})$ the outcomes of a game G when playing the set of strategies $\vec{\sigma}$. Similarly we will denote by Out_G the set of all outcomes of the game G, that is, with respect to all valid sets of strategies, and omit the subscript G whenever which game G we are referring to is either clear or irrelevant. It is worth noting that Out is $\mathcal{L}_o(A)$ in case of word outcomes and, therefore, is $TreeL(\mathcal{L}_o(A)) \cap Tree(A)$ in case of tree outcomes. Also, note that because we allow *non-determinism*, the set $Out(G, \vec{\sigma})$ is not necessarily a singleton, as illustrated next.

Example 7. Consider again the game in Example 4 and the two strategies for player 2 depicted in Figure 2. The strategy profile $\vec{\sigma} = (\sigma_1, \sigma_2)$ induces the unique (word) outcome $x^\omega = x, x, \ldots$ in Out; the strategy profile $\vec{\sigma}' = (\sigma_1, \sigma_2')$, on the other hand, induces infinitely many outcomes, namely those sequences given by the ω-regular expression $x^\omega \cup x.\bar{x}^\omega$. The reason why $\vec{\sigma}'$ induces more than one outcome is because σ_2' is non-deterministic; thus, multiple outcomes are possible even when A is deterministic.

Also, given a set of *deterministic strategies* one can have a reactive game where multiple outcomes are possible if A is a *non-deterministic arena*, since the same players' choice can lead to different successor vertices in A. In this case the next state of the game is selected non-deterministically in A, *i.e.*, it is not under the control of any of the players.

Remark 8. Observe that the reactive games model strictly generalises the iBG model (Gutierrez, Harrenstein, and Wooldridge 2013), which can be represented as a reactive game where the arena is an *implicitly* defined clique whose nodes are the valuations of the variables the players control, goals are LTL formulae, and strategies are deterministic.

4 Equilibria in Logical Form

Because players have goals, which they wish to satisfy, and their satisfaction depends on the outcomes—whether word or tree outcomes—of the game, the players may prefer some sets of outcomes over others. To formalise this situation we define, for each player i, a *preference* relation $\leq_i$ over 2^{Out}. Even though $\leq_i$ can be any binary relation over 2^{Out}, it is natural to assume that it is a preorder, that is, a reflexive and transitive relation. We write $<_i$ whenever $\leq_i$ is strict—or asymmetric, *i.e.*, $X \leq_i X'$ implies that $X' \leq_i X$ does not hold. Because strategy profiles induce sets of outcomes, we abuse notation by writing $\vec{\sigma} \leq_i \vec{\sigma}'$ to mean $Out(G,\vec{\sigma}) \leq_i Out(G,\vec{\sigma}')$, that is, that player i does not prefer the set of outcomes $Out(G,\vec{\sigma})$ over the set of outcomes $Out(G,\vec{\sigma}')$.

Based on players' preferences, a notion of *equilibrium* can be defined. We provide the definition of the, arguably, main concept of equilibrium—sometimes called solution concept—in game theory, namely, *Nash equilibrium*. However, many solution concepts can be found in the literature, *e.g.*, dominant strategy, subgame perfect Nash, correlated, amongst others. We say that a strategy profile $\vec{\sigma}$ is a Nash equilibrium if for every player i and strategy σ_i' we have

$$(\vec{\sigma}_{-i}, \sigma_i') \leq_i \vec{\sigma}.$$

Intuitively, a Nash equilibrium formalises the idea that no player can be better off (have a beneficial deviation) provided that all other players do not change their strategies. Let $NE(G)$ be the set of Nash equilibria of the game G.

Remark 9. Note that since strategies or arenas can be non-deterministic—hence multiple outcomes can be induced, our definition of Nash equilibrium is phrased in terms of *sets* of outcomes, rather than in terms of single outcomes only. Even though the definition of equilibrium is given w.r.t. preferences over sets of outcomes, we can think of such a definition as based on a *preference relation* over strategy profiles instead, since strategy profiles induce sets of outcomes. Thus a preference relation allows one to define equilibria in a general way, not only for binary goals as in this paper.

We can think of equilibria with respect to the goals the players of the game wish to satisfy. To make this statement precise, we need to know which logic the goals of the players belong to and when a set of outcomes satisfy such goals, that is, we need to define a semantics of players' goals w.r.t. 2^{Out}—*i.e.*, with respect to the outcomes of a game.

We can then abstractly think of the existence of a *satisfaction* relation "$\models$" between sets of outcomes and logical formulae, that is, a binary relation indicating whether a given goal γ_i for player i is satisfied or not by a set of outcomes $Out(G,\vec{\sigma})$ in a game G played with a strategy profile $\vec{\sigma}$. Assuming the existence of a denotation function $[\![\cdot]\!]$ from goals to sets of outcomes, we can then write

$$Out(G,\vec{\sigma}) \models \gamma_i \qquad \text{if and only if} \qquad Out(G,\vec{\sigma}) \subseteq [\![\gamma_i]\!].$$

Again, as strategy profiles induce sets of outcomes, we abuse notation and write $\vec{\sigma} \models \gamma_i$ if $Out(G,\vec{\sigma}) \models \gamma_i$. And, in order to simplify notations used in the paper, we will also write $[\![\vec{\sigma}]\!]$ for either the set of outcomes or the associated set of infinite sequences of vertices in V_A^* induced by $\vec{\sigma}$; which one we are referring to will always be clear from the context.

Based on the definitions above one can now formally state with respect to the goals $(\gamma_i)_{i\in N}$ of the game, when $\vec{\sigma}$ is a Nash equilibrium. We say that $\vec{\sigma}$ is a Nash equilibrium if, for every player i and for every strategy σ_i', we have that

$$(\vec{\sigma}_{-i}, \sigma_i') \models \gamma_i \Longrightarrow \vec{\sigma} \models \gamma_i.$$

Remark 10. Since our model generalises Kripke structures and Labelled Transition Systems (among other structures), it can be used to give the standard semantics of all usual linear-time and branching-time temporal logics. In this paper, we will assume that players have *ω-regular goals*. In particular, in case of linear-time goals we will let each γ_i be either a linear-time μ-calculus or an LTL formula, strategies be deterministic, and outcomes be word outcomes; in case of branching-time goals, we will assume that the goals are either CTL or μ-calculus formulae, that the strategies can be non-deterministic, and that the outcomes are tree outcomes.

The details of the semantics of these logics need not be given to obtain the results in this paper. All one needs to know is the complexities of their satisfiability and model checking problems, which are as follows: for satisfiability CTL and the μ-calculus are EXPTIME, whereas LTL and the linear-time μ-calculus are PSPACE; for model checking w.r.t. a product of transition systems, the logics LTL, CTL, and linear-time μ-calculus are PSPACE, while the μ-calculus is EXPTIME. The next question becomes relevant:

Given: Game G, strategy profile $\vec{\sigma}$, goal γ.
STRATEGY-CHECKING: Is it the case that $\vec{\sigma} \models \gamma$?

Clearly, the answer to this question depends on the logic to which the formula γ belongs. The following lemma answers this question for various temporal logics.

Lemma 11. *The* STRATEGY-CHECKING *problem for LTL, CTL, and linear-time μ-calculus goals is PSPACE-complete. For modal μ-calculus goals the problem is in EXPTIME.*

Using STRATEGY-CHECKING we can, moreover, show that the following problem, namely, membership of a strategy profile in the set of Nash equilibria of a reactive game, may be harder only in the branching-time case.

Given: Game G, strategy profile $\vec{\sigma}$.
NE-CHECKING: Is it the case that $\vec{\sigma} \in NE(G)$?

Formally, we have

Lemma 12. *The* NE-CHECKING *problem for LTL and linear-time μ-calculus goals is PSPACE-complete. For CTL and μ-calculus goals the problem is EXPTIME-complete.*

Equivalences of equilibria. The characterisation of equilibrium with respect to the goals of the game given above provides a natural way of comparing strategy profiles, and hence of comparing equilibria, in a logical way. But first, we provide a notion of equivalence of strategy profiles purely based on the outcomes they induce and later on a weaker definition with a more logical flavour. Given a game G, we say that two strategy profiles $\vec{\sigma}$ and $\vec{\sigma}'$ are equivalent, and

write $\vec{\sigma} \sim \vec{\sigma}'$ in such a case, if and only if they induce the same set of outcomes, that is, iff $[\![\vec{\sigma}]\!] = [\![\vec{\sigma}']\!]$.

Even though the definition of $\sim$ immediately provides a definition for equivalence between equilibrium strategy profiles, such a definition is rather strong. Instead, one would like a definition where only the satisfaction of goals was taken into account. Having this in mind, we propose a weaker, logically based definition of equivalence between strategy profiles. Formally, given a game G, we say that two strategy profiles $\vec{\sigma}$ and $\vec{\sigma}'$ are logically equivalent, and write $\vec{\sigma} \sim_\gamma \vec{\sigma}'$ in such a case, if and only if, they induce sets of outcomes that satisfy the same set of goals of the game, that is, iff for every goal in $(\gamma_i)_{i\in N}$ of G we have that

$$\vec{\sigma} \models \gamma_i \Longleftrightarrow \vec{\sigma}' \models \gamma_i.$$

Formally, the decision problem one wants to solve is:

Given: Game G, strategy profiles $\vec{\sigma}, \vec{\sigma}'$.
EQUIVALENCE-CHECKING: Does $\vec{\sigma} \sim_\gamma \vec{\sigma}'$ hold?

An immediate consequence of Lemma 11 is:

Corollary 13. *The* EQUIVALENCE-CHECKING *problem for LTL, CTL, and linear-time μ-calculus goals is PSPACE-complete. For μ-calculus goals the problem is in EXPTIME.*

5 Equilibrium logics

We now introduce two logics for expressing equilibrium properties of (reactive) games: these two logics are closely related to the branching time logics CTL and CTL* (see, *e.g.*, (Emerson and Halpern 1986)). We refer to our basic logical framework as *Equilibrium Logic*, (EL), and will refer to the two versions of this logic as EL (roughly corresponding to CTL) and EL* (roughly corresponding to CTL*). Since EL* will be defined as an extension of CTL*, the logic LTL will also appear as a syntactic fragment.

The basic idea of Equilibrium Logic is to extend the logic CTL* by the addition of two modal quantifiers, which we will write as "$[\mathbf{NE}]$" and "$\langle\mathbf{NE}\rangle$". In Equilibrium Logic, the modalities $[\mathbf{NE}]$ and $\langle\mathbf{NE}\rangle$ quantify over *paths that could arise as the consequence of processes (agents/players) selecting strategies in equilibrium*. For example, if we are dealing with Nash equilibrium, then an EL formula $[\mathbf{NE}]\mathbf{F}p$ (where $\mathbf{F}$ is the "eventually" LTL modality) means that on all Nash equilibrium computations—*i.e.*, on all computations (paths or trees) that correspond to runs or plays where a set of agents/players use a strategy profile in equilibrium—eventually p will hold. In this way, we can use Equilibrium Logic to directly reason about the equilibrium properties of game-like concurrent systems. Equilibrium Logic is parameterised by a solution concept, which determines the outcomes over which the "equilibrium modalities" quantify. For now, we consider Nash equilibrium as our by-default solution concept, but of course others can be considered too.

Syntax. The syntax of Equilibrium Logic is defined w.r.t. a set X of propositions, by the following grammars:

Path Formulae: $\varphi ::= \psi \mid \theta \mid \neg\varphi \mid \varphi \vee \varphi \mid \mathbf{X}\varphi \mid \varphi\,\mathbf{U}\,\varphi$
State Formulae: $\psi ::= x \mid \mathbf{A}\varphi$
Nash Formulae: $\theta ::= [\mathbf{NE}]\varphi$

where $x \in X$. Thus, as in CTL*, path formulae φ express properties of paths (*cf.* LTL), while state formulae ψ express properties of states. In addition, Nash equilibrium formulae also express properties of paths, but only if such paths are induced by strategy profiles in equilibrium. We take the universal modalities $\mathbf{A}$ and $[\mathbf{NE}]$ as primitives, and define the existential modalities $\mathbf{E}$ and $\langle\mathbf{NE}\rangle$ as their duals as usual:[5] $\mathbf{E}\varphi \equiv \neg\mathbf{A}\neg\varphi$ and $\langle\mathbf{NE}\rangle\varphi \equiv \neg[\mathbf{NE}]\neg\varphi$.

Semantics. The semantics of EL formulae is given here w.r.t. a reactive game $G = (N, C, (C_i)_{i\in N}, (\gamma_i)_{i\in N}, X, A)$, where $A = (V_A, E_A, v_A^0, \Omega_A = X, \Lambda_A = Ch, \omega_A, \lambda_A)$. The semantics of path formulae ("$\models_{\mathcal{P}}$") is essentially the same for LTL, and so given with respect to paths π in A, with two additional rules for state and equilibrium formulae, respectively. The semantics of state formulae ("$\models_{\mathcal{S}}$") is given with respect to states/vertices $v \in V$ of A. The semantics of equilibrium formulae ("$\models_{\mathcal{E}}$") is given with respect to the set of Nash equilibria of G. Let ϱ be a run of A, *i.e.*, an infinite sequence of states over V_A^* starting at v_A^0, and $t \in \mathbb{N}$. Define

$(G, \varrho, t) \models_{\mathcal{P}} \psi$	iff	$(G, \varrho, t) \models_{\mathcal{S}} \psi$ for state formulae ψ.
$(G, \varrho, t) \models_{\mathcal{P}} \theta$	iff	$(G, \varrho, t) \models_{\mathcal{E}} \theta$ for equilibrium formulae θ.
$(G, \varrho, t) \models_{\mathcal{P}} \neg\varphi$	iff	$(G, \varrho, t) \models_{\mathcal{P}} \varphi$ does not hold.
$(G, \varrho, t) \models_{\mathcal{P}} \varphi \vee \varphi'$	iff	$(G, \varrho, t) \models_{\mathcal{P}} \varphi$ or $(G, \varrho, t) \models_{\mathcal{P}} \varphi'$
$(G, \varrho, t) \models_{\mathcal{P}} \mathbf{X}\varphi$	iff	$(G, \varrho, t+1) \models_{\mathcal{P}} \varphi$
$(G, \varrho, t) \models_{\mathcal{P}} \varphi\,\mathbf{U}\,\varphi'$	iff	$(G, \varrho, t') \models_{\mathcal{P}} \varphi'$ for some $t' \geq t$ and $(G, \varrho, k) \models_{\mathcal{P}} \varphi$ for all $t \leq k < t'$.

The satisfaction relation "$\models_{\mathcal{S}}$" for state formulae is defined as follows:

$(G, \varrho, t) \models_{\mathcal{S}} x$	iff	$x \in \omega_A(\varrho[t])$
$(G, \varrho, t) \models_{\mathcal{S}} \mathbf{A}\varphi$	iff	$(G, \varrho', t) \models_{\mathcal{P}} \varphi$ for all ϱ' such that $\varrho[0 \ldots t) \in \varrho'$.

And the satisfaction relation "$\models_{\mathcal{E}}$" for equilibrium formulae is defined as follows:

$(G, \varrho, t) \models_{\mathcal{E}} [\mathbf{NE}]\varphi$	iff	$(G, \varrho', t) \models_{\mathcal{P}} \varphi$ for all $\varrho' \in [\![\vec{\sigma}]\!]$ with both $\vec{\sigma} \in NE(G)$ and $\varrho[0 \ldots t) \in \varrho'$

We say that G is a model of φ (in symbols $G \models \varphi$) if and only if $(G, \varrho, 0) \models_{\mathcal{P}} \varphi$ for all ϱ of G, that is, for all paths or sequences of states of A starting at v_A^0—sequences in V_A^*.

Example 14. The situation of Example 1 is modelled by the game $G = (N, C, C_1, C_2, \gamma_1, \gamma_2, X, A)$, where $X = \{x, y\}$, $C_1 = \{p\}$, $C_2 = \{q\}$ and A is the arena as in Figure 3. Intuitively, x and y signify player 1 and player 2 get the resource, respectively. Setting p to true corresponds to player 1 requesting the resource, while setting p to false means refraining from doing so. Similarly, for q and player 2. The goals

[5] All usual abbreviations for the Boolean operators not explicitly given in the grammars above are also assumed to be defined.

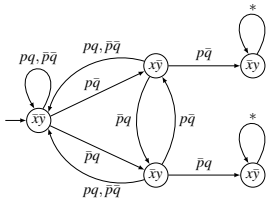

Figure 3: Formal model of the system in Example 1

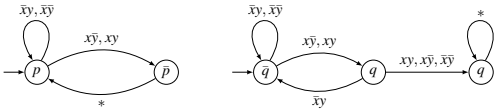

Figure 4: Strategies σ_1 (left) and σ_2 (right).

of the players are the LTL goals $\gamma_1 = \mathbf{GF}x$ and $\gamma_2 = \mathbf{GF}y$. The structures in Figure 4 are two strategies σ_1 and σ_2 for player 1 and 2, respectively. Strategy σ_1 requests the resource by playing p until it gets it, and then refrains from doing so by playing $\bar{p}$ once. Strategy σ_2 toggles but between $\bar{q}$ and q, beginning with the former, and additionally threatens to set q to true for ever if p is true (at least) twice in a row, which can be deduced from x being set to true or $\bar{y}$ while having set q to true previously. The strategy profile $\vec{\sigma} = (\sigma_1, \sigma_2)$ yields $\mathcal{L}_i^{\vec{\sigma}}(A) = \{(p\bar{q};\bar{p}q)^\omega\}$ and $\mathcal{L}_o^{\vec{\sigma}}(A) = \{\bar{x}\bar{y};(x\bar{y};\bar{x}y)^\omega\}$. The run $\rho = \bar{x}\bar{y}, x\bar{y}, \bar{x}y, x\bar{y}, \bar{x}y, \ldots$ in $\mathcal{L}_o^{\vec{\sigma}}(A)$ satisfies both players' goals and as such $\vec{\sigma}$ is a Nash equilibrium. Thus, we have $G \models \langle\mathbf{NE}\rangle(\gamma_1 \wedge \gamma_2)$. This is no coincidence, as we have for this game that $G \models [\mathbf{NE}](\gamma_1 \wedge \gamma_2)$: in all Nash equilibria both players' goals are satisfied. This contrasts sharply with $\mathbf{A}(\gamma_1 \wedge \gamma_2)$, which does not hold in the game G.

This example shows that even in small concurrent systems it is not obvious that a Nash equilibrium exists—let alone that a temporal property holds in some or all equilibrium computations of the system. The example also shows an important feature of game-like concurrent systems: that even though a desirable property may not hold in general (*cf.*, $\mathbf{A}(\gamma_1 \wedge \gamma_2)$), it may well be the case that one can design or automatically synthesise a communication protocol or a synchronisation mechanism—directly from a logical specification—so that the desirable property holds when restricted to agents acting rationally (*cf.*, $[\mathbf{NE}](\gamma_1 \wedge \gamma_2)$).

Indeed, Equilibrium logics are specifically designed to *reason about what can be achieved in equilibrium and what cannot*, while abstracting away from the particular strategies that the agents/players of the system/game may use.

Expressivity. Observe that apart from $[\mathbf{NE}]$ all other operators are intended to have the same meaning as in CTL*. However, note that the semantics of $\mathbf{A}\varphi$ is not quite the same as its counter-part in CTL* because of the additional condition "such that $\varrho[0\ldots t) \in \varrho'$." In the standard semantics of CTL* it should be "for all ϱ' starting at $\varrho[t]$" instead. In other words, in CTL* the path used to reach the state $\varrho[t]$ is forgotten. This information is actually needed only for the semantics of the equilibrium modality $[\mathbf{NE}]$, but must be remembered throughout. Formally, we have

Proposition 15. *Let G be a game and φ be a $[\mathbf{NE}]$-free EL* formula. Then, for all runs ϱ and $t \in \mathbb{N}$, we have that*

$$(G, \varrho, t) \models \mathbf{A}\varphi \text{ iff } (G, \varrho', 0) \models \varphi,$$

for all ϱ' starting at $\varrho[t]$.

Thus, because of Proposition 15, we know that the semantics of EL* conservatively extends that of CTL*. To be more precise, the fact that we must "remember" how we got to a particular state when evaluating an equilibrium formula in that state means that, technically, EL is a *memoryfull* extension of CTL*; see, *e.g.*, (Kupferman and Vardi 2006).

More interesting is the question as to whether EL* can be translated into a logic for strategic reasoning already in the literature. This is largely an open question. However, a few observations can be made at this point. Firstly it is known that neither ATL* (Alur, Henzinger, and Kupferman 2002) nor Strategy logic (Chatterjee, Henzinger, and Piterman 2010) can express the existence of a Nash equilibrium in a multi-player game with deterministic strategies and LTL players' goals. This property is simply stated as $\langle\mathbf{NE}\rangle\top$ in EL, where we restrict ourselves to reactive games with deterministic strategies and arenas and only LTL players' goals. Thus, we can conclude that both *Strategy logic and ATL* are not as expressive as Equilibrium logics*.

On the other hand, the existence of Nash equilibria in multi-player games and w.r.t. deterministic strategies and LTL goals can be expressed in the Strategy logic developed in (Mogavero, Murano, and Vardi 2010a). Using their logical specification of the existence of a Nash equilibrium, we can encode the $\langle\mathbf{NE}\rangle$ operator (and hence any $\langle\mathbf{NE}\rangle\psi$, with LTL ψ), again when restricted to LTL goals and deterministic games and strategies. This gives a 2EXPTIME upper bound for the model checking problem of this fragment of our logic. Note that the fragment is not only syntactic since the underlying reactive games model is also being restricted.

Letting EL*[LTL] be the fragment of EL* given above, we can show (w.r.t. deterministic arenas and strategies):

Proposition 16. *The model checking problem for EL*[LTL] formulae is in 2EXPTIME.*

Together with the hardness result that we will give in the next section, we obtain that model checking EL*[LTL] formulae is an 2EXPTIME-complete problem.

6 Complexity

In this section we show that the model checking problem for Equilibrium logics is 2EXPTIME-hard, even for LTL or CTL players' goals. More precisely, the model checking problem for Equilibrium logics is stated as follows:

Given: Game G, EL* formula φ.
EL* MODEL-CHECKING: Does $G \models \varphi$ hold?

In fact, we will show a very strong claim: that the EL* MODEL-CHECKING problem is 2EXPTIME-hard, even for the EL* formula $\varphi = \langle\mathbf{NE}\rangle\top$ (the simplest equilibrium logic formula one can write) and for either LTL or CTL goals (two of the simplest temporal logics in the literature).

Hardness in the linear-time framework. In order to show 2EXPTIME-hardness of checking equilibrium properties given that the players of the game have linear-time goals, we provide a reduction from the LTL games in (Alur, La Torre, and Madhusudan 2003). Formally, we have

Lemma 17. *The* EL* MODEL-CHECKING *problem where players' goals are LTL formulae is 2EXPTIME-hard.*

Proof. (Sketch) We reduce the LTL games studied in (Alur, La Torre, and Madhusudan 2003), which are 2EXPTIME-complete, to EL* model checking $\varphi = \langle \mathbf{NE} \rangle \top$.

LTL games. An LTL game (Alur, La Torre, and Madhusudan 2003) is a two-player zero-sum game given by (G, ψ, u), where ψ is an LTL formula over a set of properties Σ, and

$$G = (V_G, V_0, V_1, \gamma : V \to 2^V, \mu : V \to \Sigma)$$

is a graph with vertices in V_G which are partitioned in player 0 vertices V_0 and player 1 vertices V_1. The transitions of the graph are given by γ; if $v' \in \gamma(v)$, for some $v, v' \in V_G$, then there is a transition from v to v', which we may assume is labelled by v'. Each vertex v has a set of properties p associated with it, which are given by μ; thus $p \in \Sigma$ holds in vertex v if $p = \mu(v)$. The graph G is assumed to be total, that is, for every $v \in V_G$, we have $\gamma(v) \neq \emptyset$.

The game is played for infinitely many rounds by each player choosing a successor vertex whenever it is their turn: player 0 plays in vertices in V_0 and player 1 plays in vertices in V_1. The game starts in the initial vertex $u \in V_G$. Playing the game defines an infinite word/sequence of adjacent vertices $w = v_0, v_1, v_2, \ldots$, such that $v_0 = u$ and for each v_k, with $k \in \mathbb{N}$, we have $v_{k+1} \in \gamma(v_k)$. An LTL game is won by player 0 if $w \models \psi$; otherwise player 1 wins. LTL games are determined, that is, there is always a winning strategy either for player 0 or for player 1. Checking whether player 0 has a winning strategy in an LTL game is a 2EXPTIME-complete problem (Alur, La Torre, and Madhusudan 2003).

We reduce the LTL game (G, ψ, u) to model checking the EL* formula $\varphi = \langle \mathbf{NE} \rangle \top$ in two stages. We first construct a reactive game G_1 that simulates the behaviour exhibited in the LTL game (G, ψ, u), and then transform G_1 into another reactive game G_2 with the property that player 0 has a winning strategy in (G, ψ, u) if and only if there is a Nash equilibrium in G_2, that is, if and only if $G_2 \models \varphi$.

Reactive games. The first construction (the one for G_1) comprises two players, 0 and 1, who control variables t_0 and t_1, respectively, whose domain is the set of vertices in the LTL with two additional actions, δ_0 and δ_1, to delay/skip when it is not their turn to play in the corresponding LTL game. Notice that in a reactive game they always must play, at each round, concurrently and synchronously. Their goals are $\gamma_0 = (\psi \wedge \mathbf{G}\neg l_0) \vee \mathbf{F} l_1$ and $\gamma_1 = (\neg\psi \wedge \mathbf{G}\neg l_1) \vee \mathbf{F} l_0$, respectively, where l_0 and l_1 are two fresh atomic propositions which hold only on two new states where, intuitively, player 0 loses the LTL game (state l_0) and player 1 loses the LTL game (state l_1). This translation from (G, ψ, u) to G_1 is polynomial. There are $|V_G| + 2$ vertices and $|\mu| + \mathcal{O}(|V_G|^3)$ transitions in the arena where G_1 is played. This first translation, from (G, ψ, u) to G_1, transforms a sequential zero-sum LTL game into a non-zero sum reactive game (where players make choices concurrently and synchronously) that is able to simulate the original LTL game. Players in G_1 are not forced to play consistently with plays in (G, ψ, u), but these players can be punished if they do not do so.

Then, we transform G_1 into G_2 in order to ensure that all (and only the) Nash equilibria of the reactive game G_2 correspond to plays where player 0 wins. The game G_2 comprises four players. The two new players, 3 and 4, control two Boolean variables t_2 and t_3, and have goals $\gamma_2 = \psi \vee (\mathbf{X} e)$ and $\gamma_3 = \psi \vee (\mathbf{X}\neg e)$, where e is a new atomic proposition. The arena of G_2 is linear in the size of the arena of G_1. It contains a copy of the vertices in game G_1 where the proposition $\neg e$ holds. In all other vertices—*i.e.,* those in G_1—the proposition e holds. The choice of where the game proceeds after the first round, namely, to the vertices already in G_1 or their copies, is ultimately controlled by the choices of players 2 and 3. In particular, in the former case, we have $t_2 = t_3$ (and move to a vertex where e holds) whereas, in the latter, we have $t_2 \neq t_3$ (and move to a vertex where $\neg e$ holds). This power allows these two players to deviate whenever ψ is not satisfied. As a consequence, all Nash equilibria of G_2 must satisfy formula ψ and hence the goals of players 2 and 3. Using this fact and Corollary 6, we build a winning strategy in the LTL game iff there is a Nash equilibrium in G_2. □

Hardness in the branching-time framework. Now, in order for us to show the 2EXPTIME-hardness of checking equilibrium properties given that the players of the game have *branching-time goals*, we use a reduction from the control-synthesis problem with respect to reactive environments (Kupferman et al. 2000). The control-synthesis problem for reactive environments is similar to the LTL game. However, in such a game player 1 may challenge player 0 with sets of successor vertices rather than with singletons, as in the LTL game. As a consequence, a play of the game can produce a tree instead of a word of vertices. In this game, player 0 wins if such a tree satisfies formula ψ; otherwise, player 1 wins. This game is also 2EXPTIME-complete and can be reduced to a reactive game in a way similar to that for LTL games. In particular, in this case, we can use Lemma 5 instead of Corollary 6 to ensure that strategies in these games always exist. Formally, we have

Lemma 18. *The* EL* MODEL-CHECKING *problem where players' goals are CTL formulae is 2EXPTIME-hard.*

Since LTL and CTL are syntactic fragments of, respectively, the linear-time μ-calculus and the modal μ-calculus, the hardness results can be transferred, to obtain:

Corollary 19. *The* EL* MODEL-CHECKING *problem, with players' goals given by linear-time μ-calculus or by modal μ-calculus formulae, is 2EXPTIME-hard.*

Notice that model checking the equilibrium operators of EL* formulae may require the solution of a number of "internal" synthesis problems for $(\gamma_i)_{i \in N}$ so that $\vec{\sigma} \in NE(G)$ can be checked and a run $\varrho \in [\![\vec{\sigma}]\!]$ can be determined before an EL* formula can be checked. This problem, known as reactive synthesis, is 2EXPTIME-complete for both LTL and CTL specifications, and seems to be the main source of the high complexity of checking equilibrium properties.

7 Concluding Remarks and Related Work

Complexity. We have shown that checking the equilibrium properties of a concurrent and multi-agent system is a computationally very hard problem as any interesting property is at least in PSPACE. On the positive side, we have also shown that in most cases the difficulty of checking equilibrium properties is independent of whether the goals of the players are given by linear-time or branching time temporal formulae. A summary of our complexity results is in Table 1.

	ST–CHECK	NE–CHECK	EQ–CHECK	EL*–MC
LTL	PSPACE	PSPACE	PSPACE	2EXPT$-$h
CTL	PSPACE	EXPT	PSPACE	2EXPT$-$h
TL$_\mu$	PSPACE	PSPACE	PSPACE	2EXPT$-$h
L$_\mu$	iEXPT	EXPT	iEXPT	2EXPT$-$h

Table 1: Overview of computational complexity results. In this table TL$_\mu$ stands for the linear-time μ-calculus, L$_\mu$ for the modal μ-calculus, ST–CHECK for STRATEGY-CHECKING, NE–CHECK for NE-CHECKING, EQ–CHECK for EQUIVALENCE-CHECKING, EL*–MC for EL* MODEL CHECKING, and iEXPT for in EXPTIME.

Logic.
Our work relates to logics either that are to reason about the behaviour of game-like systems or that are memoryfull. In (Kupferman and Vardi 2006) a memoryfull branching-time logic, called mCTL*, that extends CTL* was introduced. This logic has a special atomic proposition ("present") that allows one to reason about computations starting in the present or computations starting somewhere in the past (in CTL* all formulae are interpreted w.r.t. computations that start in the present). This logic is not more powerful than CTL*, but can be exponentially more succinct. No equilibrium issues are addressed there. In the linear-time framework, memoryfull logics have also been studied. In (Laroussinie, Markey, and Schnoebelen 2002) and extension of LTL with past is extended with an operator ("Now") that allows one to "forget the past" when interpreting logical formulae. This logic is exponentially more succinct than LTL with past, which in turn is exponentially more succinct than LTL; all such logics are nevertheless equally expressive. Thus, it seems that adding memory to temporal logics, either in the linear-time or in the branching-time framework, can make them more succinct but not any more powerful. Another shared feature of memoryfull temporal logics is that their verification problem is at least EXPSPACE. It follows from our 2EXPTIME-hardness results that checking equilibrium properties, which requires the use of a memoryfull logic, is even a harder problem. Another memoryfull logic, this time one designed to reason about game-like scenarios, is Strategy logic (Chatterjee, Henzinger, and Piterman 2010). Strategy logic has strategies as first-class objects in the language and based on this feature one can indirectly reason about equilibrium computations of a system. In Equilibrium logic reasoning is done the other way around: we can directly refer to equilibrium computations of a system, and based on them reason about the strategic power of the players in a game. Verification is extremely hard in Strategy logic too: it is $(d+1)$EXPTIME-complete, where d is the alternation between universal and existential strategy quantifiers in the logic, which has LTL as base language—a logic in the linear-time framework. Strategy logic as defined in (Chatterjee, Henzinger, and Piterman 2010) is a logic with a two-player semantic game. This logic was later on extended to the multi-player setting in (Mogavero, Murano, and Vardi 2010a). Recent works, for instance (Mogavero et al. 2012; Mogavero, Murano, and Sauro 2013), have focused on the discovery of syntactic fragments of Strategy logic which are expressive enough, *e.g.*, to express the existence of equilibria, and yet with decidable satisfiability and model checking problems. As with Equilibrium logics, the exact complexity upper bound of model checking a syntactic fragment that is able to express Nash equilibria is, presently, an open problem. Finally, in (Mogavero, Murano, and Vardi 2010b) a memoryfull extension of ATL, called mATL*, is studied. Again, this logic identifies the need for memoryfull power when reasoning about strategic interactions. Since mATL* extends ATL, it is an alternating-time temporal logic (Alur, Henzinger, and Kupferman 2002). This logic, as mCTL*, extends ATL* with a "present" proposition to differentiate between (and reason about) computations that start in the present state of play and computations that start far in the past—in a state previously visited. The verification problem for this logic, as it is for ATL*, is in 2EXPTIME.

Future work.
It would be interesting to discover *"easy" classes of reactive games* for which the decision problems studied in the paper are computationally simpler. Because of the nature of the problems at hand, all relevant questions about equilibria are expected to be at least NP-hard. Another avenue for further work is the study of solution concepts specifically designed for the analysis of dynamic systems, in particular, we would like to investigate the well-known concept of *subgame-perfect Nash equilibrium*. We also leave for future work the study of richer preference relations as well as quantitative and imperfect information. Certain decision problems slightly discussed in this paper should also be studied in more detail. In this paper, we have investigated the complexity of some questions about reactive games and equilibrium computations in multi-agent and concurrent systems, and would like to understand better the *expressivity of equililibrium logics*. They certainly offer a different paradigm for reasoning about equilibria in infinite games, but whether they can be translated into one of the logics already in the literature (or the other way around) is an open and interesting question. Finally, our results naturally lead to further algorithmic solutions and a tool implementation, for instance, as done using logics such as ATL and probabilistic variants of CTL* in model checkers such as PRISM (Chen et al. 2013), MCMAS (Lomuscio, Qu, and Raimondi 2009), or MOCHA (Alur et al. 1998).

A Temporal Logic of Strategic Knowledge

Xiaowei Huang and **Ron van der Meyden**
The University of New South Wales

Abstract

The paper presents an extension of temporal epistemic logic that adds "strategic" agents in a way that allows standard epistemic operators to capture what agents could deduce from knowledge of the strategies of some subset of the set of agents. A number of examples are presented to demonstrate the broad applicability of the framework, including reasoning about implementations of knowledge-based programs, game theoretic solution concepts and notions from computer security. It is shown that notions from several variants of alternating temporal epistemic logic can be expressed. The framework is shown to have a decidable model checking problem.

Introduction

The design and study of distributed and multi-agent systems typically has to deal with agents who have a choice of action to perform, and have individual and possibly conflicting goals. This leads agents to act strategically, attempting to select their actions over time so as to guarantee these goals even in the face of other agents' behaviour. The choice of actions generally needs to be done on the basis of *imperfect* information concerning the state of the system.

These concerns have motivated the development of a variety of modal logics that aim to capture the essential notions of such settings. One of the earliest, dating from the 1980's was multi-agent epistemic logic (Halpern and Moses 1990; Parikh and Ramanujam 1985), which introduces modal operators that deal with imperfect information by providing a way to state what agents *know*. Combining such constructs with temporal logic (Pnueli 1977) constructs gives temporal-epistemic logics, which support reasoning about how agents' knowledge changes over time. Temporal-epistemic logic is an area about which a significant amount is now understood (Fagin et al. 1995).

Logics dealing with reasoning about strategies, which started to be developed in the same period (Parikh 1983), had a slower initial start, but have in recent years become the focus of intense study (Pauly 2002; Horty. 2001; Alur, Henzinger, and Kupferman 2002). Many subtle issues that arise concerning what agents know in settings where multiple agents act strategically. In the process of understanding these issues, there has been a proliferation of modal logics. In particular, for dealing with epistemic reasoning in strategic settings, there are multiple proposals, with different semantic and syntactic bases, for how to capture reasoning about the availability to groups of agents of strategies for achieving particular goals (Jonker 2003; Schobbens 2004; van Otterloo and Jonker 2005; Jamroga 2003; Jamroga and Ågotnes 2007).

We argue in this paper that this proliferation is unnecessary, and that an appropriate application of temporal epistemic logic, with a minor innovation, already has the power to deal with many issues of concern when dealing with epistemic reasoning in strategic settings.

In particular, whereas logics in this area frequently leave strategies implicit in the semantic modelling, we propose to work in an instance of a standard semantic framework for temporal epistemic logic, but with strategies explicitly represented in the semantic model. In fact, we are not the first to have applied this instance of the standard temporal-epistemic model (Halpern and O'Neill 2008). Our main innovation is small but, we claim, powerful: we introduce new agent names that refer to the strategies being used by the main players, and allow these new agent names to be included in (otherwise standard) operators for group knowledge.

We argue that this gives a logical approach with broad applicability. In particular, it can express many of the subtly different notions that have been the subject of proposals for alternating temporal epistemic logics. We demonstrate this by results that show how such logics can be translated into our setting. We also present a number of other examples including reasoning about possible implementations of knowledge-based programs, game theoretic solution concepts, and issues of concern in computer security. Moreover, as we show, our approach retains from alternating temporal epistemic logic the desirable property that model checking is decidable, in the case of an imperfect recall semantics for knowledge. We show that it is in fact PSPACE-complete, no more than the complexity of model checking the temporal logic LTL, on which we build, although we have a much richer expressiveness.

The structure of the paper is as follows. We first recall some standard definitions from temporal epistemic logic. We then present a semantic model (also standard) for the environments in which agents choose their actions. Build-

ing on this model, we show how to construct a model for temporal epistemic logic that builds in information about strategic behaviour, but which introduces the new "strategy" agents. The following sections deal with applications of this model. We show successively that it can express reasoning about implementations of knowledge-based programs, many notions that have been proposed in the area of alternating temporal epistemic logic, game theoretic solution concepts, and problems from computer security. Next, we show that the framework has a decidable model checking problem. We conclude with a discussion of related literature.

Temporal Epistemic Logic

Suppose that we are working with a system in which there is a finite set Ags of agent names. Let $Prop$ be a set of atomic propositions. The language CTL*K($Ags, Prop$) has the syntax:

$$\phi \equiv p \mid \neg\phi \mid \phi_1 \vee \phi_2 \mid A\phi \mid \bigcirc\phi \mid \phi_1 U \phi_2 \mid D_G\phi \mid C_G\phi$$

where $p \in Prop$ and $G \subseteq Ags$. Intuitively, the formula $D_G\phi$ expresses that agents in G have distributed knowledge of ϕ, i.e., they could deduce ϕ if they pooled their information, and $C_G\phi$ says that ϕ is common knowledge to group G. The formulas $\bigcirc\phi$ and $\phi_1 U \phi_2$ express the linear time temporal logic notions "ϕ at the next moment of time" and "ϕ_1 until ϕ_2", respectively. The operator A refers to branching temporal structure: $A\phi$ says that the formula ϕ holds for all possible evolutions from the present situation. Other operators can be obtained in the usual way, e.g., $\phi_1 \wedge \phi_2 = \neg(\neg\phi_1 \vee \neg\phi_2)$, $\Diamond\phi = (trueU\phi)$, $\Box\phi = \neg\Diamond\neg\phi$, etc. For an agent $i \in Ags$ write $K_i\phi$ for $D_{\{i\}}\phi$, this expresses that agent i knows the fact ϕ. The notion of everyone in group G knowing ϕ can then be expressed as $E_G\phi = \bigwedge_{i\in G} K_i\phi$. Using this, common knowledge $C_G\phi$ can be understood as the conjunction of $E^k_G\phi$ for all $k \geq 0$.

Semantics of the language is given in *interpreted systems*, which are tuples $\mathcal{I} = \langle \mathcal{R}, \pi \rangle$, where $\mathcal{R}$ is a set, called the set of *runs*, and $\pi : \mathcal{R} \times \mathbb{N} \to \mathcal{P}(Prop)$ is a propositional interpretation. It is required that there exist for each $i \in Ags$, a nonempty set L_i of *local states of agent* i, such that $\mathcal{R}$ is a subset of the set of functions $r : \mathbb{N} \to \Pi_{i\in Ags} L_i$. Intuitively, this says that a run maps each moment of time to a *global state*, which gives a local state for each agent i. The usual presentation (Fagin et al. 1995), also includes a component in the global state for the state of the environment. We will handle this by including the special agent $e \in Ags$, representing the environment, when required. For $n \leq m$ write $r[n \dots m]$ for the sequence $r(n)r(n+1)\dots r(m)$. Elements of $\mathcal{R} \times \mathbb{N}$ are called the *points* of $\mathcal{I}$. For each agent $i \in Ags$, we write $r_i(m)$ for the i-component of $r(m)$, and define an equivalence relation on points by $(r, m) \sim_i (r', m')$ if $r_i(m) = r'_i(m')$. For $G \subseteq Ags$, we define the equivalence relation $\sim_G$ on points by $(r, m) \sim_G (r', m')$ if $(r, m) \sim_i (r', m')$ for all $i \in G$. Note that $\sim_\emptyset$ is then the universal relation on $\mathcal{R}\times\mathbb{N}$, intuitively representing an agent who knows nothing, and $\sim_{Ags}$ is an agent with complete information about the global state. In particular, it follows for runs $r, r' \in \mathcal{R}$ that if $(r, m) \sim_{Ags} (r', m)$ for all $m \in \mathbb{N}$, then $r = r'$.

The semantics of the language CTL*K is given by a relation $\mathcal{I}, (r, m) \models \phi$, representing that formula ϕ holds at point (r, m) of the interpreted system $\mathcal{I}$. This defined inductively on the structure of the formula ϕ, as follows:

- $\mathcal{I}, (r, m) \models p$ if $p \in \pi(r, m)$;
- $\mathcal{I}, (r, m) \models \neg\phi$ if not $\mathcal{I}, (r, m) \models \phi$;
- $\mathcal{I}, (r, m) \models \phi \wedge \psi$ if $\mathcal{I}, (r, m) \models \phi$ and $\mathcal{I}, (r, m) \models \psi$;
- $\mathcal{I}, (r, m) \models A\phi$ if $\mathcal{I}, (r', m) \models \phi$ for all $r' \in \mathcal{R}$ with $r[0 \dots m] = r'[0 \dots m]$;
- $\mathcal{I}, (r, m) \models \bigcirc\phi$ if $\mathcal{I}, (r, m+1) \models \phi$;
- $\mathcal{I}, (r, m) \models \phi U \psi$ if there exists $m' \geq m$ such that $\mathcal{I}, (r, m') \models \psi$ and $\mathcal{I}, (r, k) \models \phi$ for all k with $m \leq k < m'$.
- $\mathcal{I}, (r, m) \models D_G\phi$ if $\mathcal{I}, (r', m') \models \phi$ for all points (r', m') with $(r, m) \sim_G (r'm')$;
- $\mathcal{I}, (r, m) \models C_G\phi$ if $\mathcal{I}, (r', m') \models \phi$ for all points (r', m') with $(r, m) \sim^C_G (r'm')$, where $\sim^C_G = (\cup_{i\in G} \sim_i)^*$.

We write $\mathcal{I} \models \phi$ to mean that $\mathcal{I}, (r, 0) \models \phi$ for all runs of $\mathcal{I}$.

Strategic Environments

In order to deal with agents that operate in an environment by strategically choosing their actions, we introduce a type of transition system that models the available actions and their effects on the state. An *environment* for agents Ags is a tuple $E = \langle S, I, Acts, \to, \{O_i\}_{i\in Ags}, \pi \rangle$, where

1. S is a set of states,
2. I is a subset of S, representing the initial states,
3. $Acts = \Pi_{i\in Ags} Acts_i$ is a set of joint actions, where each $Acts_i$ is a nonempty set of actions that may be performed by agent i,
4. $\to \subseteq S \times Acts \times S$ is a transition relation, labelled by joint actions,
5. for each $i \in Ags$, component $O_i : S \to L_i$ is an observation function,
6. $\pi : S \to \mathcal{P}(Prop)$ is a propositional assignment.

Since later constructions add agent e, it is assumed here that $e \notin Ags$. An environment is said to be finite if all its components, i.e., $S, Ags, Acts_i, L_i$ and $Prop$ are finite. Intuitively, a joint action $a \in Acts$ represents a choice of action $a_i \in Acts_i$ for each agent $i \in Ags$, performed simultaneously, and the transition relation resolves this into an effect on the state. We assume that $\to$ is serial in the sense that for all $s \in S$ and $a \in Acts$ there exists $t \in S$ such that $(s, a, t) \in \to$.

A *strategy* for agent $i \in Ags$ in such an environment E is a function $\alpha : S \to \mathcal{P}(Acts_i) \setminus \{\emptyset\}$, selecting a set of actions of the agent at each state.[1] We call these the actions *enabled* at the state. A strategy is *deterministic* if $\alpha(s)$ is a singleton for all s.

A *strategy* for a group $G \subseteq Ags$ is a tuple $\alpha_G = \langle \alpha_i \rangle_{i\in G}$ such that α_i is a strategy for agent i, for each $i \in G$. A group

[1] More generally, one can take a strategy to be a function of the history. We focus in this paper on strategies that depend only on the final state.

strategy is *deterministic* if $\alpha_i(s)$ is a singleton for all states s and all $i \in G$. A strategy α_i for agent i is *uniform* if for all states s, t, if $O_i(s) = O_i(t)$, then $\alpha_i(s) = \alpha_i(t)$. A strategy $\alpha_G = \langle \alpha_i \rangle_{i \in G}$ for a group G is *locally uniform (deterministic)* if α_i is uniform (respectively, deterministic) for each agent $i \in G$.[2]

Given an environment E, we write $\Sigma(E)$ for the set of all joint strategies for the group Ags of all agents, $\Sigma^{det}(E)$ for the set of deterministic strategies, $\Sigma^{unif}(E)$ for the set of all locally uniform joint strategies, and $\Sigma^{unif,det}(E)$ for the set of all deterministic locally uniform joint strategies.

We now introduce a notation for referring to an agent's strategy, that enables us to treat the strategy as itself an agent. Given an agent i, we write $\sigma(i)$ for a new agent that represents agent i's strategy. For a set $G \subseteq Ags$ of agents, we define $\sigma(G) = \{\sigma(i) \mid i \in G\}$. We note that agent $\sigma(i)$ will typically not be associated with any actions, it is intended primarily for use in epistemic operators in the semantics of an interpreted system constructed to allow reference to what can be deduced were agents to reason using information about each other's strategies.

Given an environment $E = \langle S, I, Acts, \rightarrow, \{O_i\}_{i \in Ags}, \pi \rangle$ for agents Ags, where $O_i : S \rightarrow L_i$ for each $i \in Ags$, and a set $\Sigma \subseteq \Pi_{i \in Ags} \Sigma_i$ of joint strategies for the group Ags, we define the *strategy space* interpreted system $\mathcal{I}(E, \Sigma) = (\mathcal{R}, \pi')$ for agents $Ags \cup \sigma(Ags) \cup \{e\}$. The system $\mathcal{I}(E, \Sigma)$ has global states $\mathcal{G} = S \times \Pi_{i \in Ags} L_i \times \Pi_{i \in Ags} \Sigma_i$. Intuitively, each global state consists of a state of the environment E, a local state for each agent i in E, and a strategy for each agent i. We index the components of this cartesian product by e, the elements of Ags and the elements of $\sigma(Ags)$, respectively. We take the set of runs $\mathcal{R}$ of $\mathcal{I}(E, \Sigma)$ to be the set of all runs $r : \mathbb{N} \rightarrow \mathcal{G}$ satisfying the following constraints, for all $m \in \mathbb{N}$ and $i \in Ags$:

1. $r_e(0) \in I$ and $\langle r_{\sigma(i)}(0) \rangle_{i \in Ags} \in \Sigma$,
2. $r_i(m) = O_i(r_e(m))$,
3. $(r_e(m), a, r_e(m+1)) \in \rightarrow$ for some joint action $a \in Acts$ such that for all $j \in Ags$ we have $a_j \in \alpha_j(r_j(m))$, where $\alpha_j = r_{\sigma(j)}(m)$, and
4. $r_{\sigma(i)}(m+1) = r_{\sigma(i)}(m)$.

The first constraint, intuitively, says that runs start at an initial state of E, and the initial strategy profile at time 0 is one of the profiles in Σ. The second constraint states that the agent i's local state at time m is the observation that agent i makes of the state of the environment at time m. The third constraint says that evolution of the state of the environment is determined at each moment of time by agents choosing an action by applying their strategy at that time to their local state at that time. The joint action resulting from these individual choices is then resolved into a transition on the state of the environment using the transition relation from E. The fourth constraint says that agents' strategies are fixed during the course of a run. Intuitively, each agent picks a strategy, and then sticks to it. The interpretation π' of $\mathcal{I}(E, \Sigma)$ is determined from the interpretation π of E by taking $\pi'(r, m) = \pi(r_e(m))$ for all points (r, m).

Our epistemic strategy logic is now just an instantiation of the extended temporal epistemic logic in the strategy space generated by an environment. That is, we start with an environment E and an associated set of strategies Σ, and then work with the language $\mathrm{CTL}^*\mathrm{K}(Ags \cup \sigma(Ags) \cup \{e\}, Prop)$ in the interpreted system $\mathcal{I}(E, \Sigma)$. We call this instance of the language $\mathrm{CTL}^*\mathrm{K}(Ags, Prop)$, or just $\mathrm{CTL}^*\mathrm{K}$ when the parameters are implicit.

The key point is that the system $\mathcal{I}(E, \Sigma)$ represents the possible temporal evolutions under *all* possible choices of joint strategies from Σ by the agents, and provides a way to refer, using distributed knowledge operators D_G where G contains the new strategic agents $\sigma(i)$, to what agents would know, should they take into account not just their own observations, but also information about other agent's strategies. For example, the distributed knowledge operator $D_{\{i,\sigma(i)\}}$ captures the knowledge that agent i has, taking into account the strategy that it is running. $D_{\{i,\sigma(i),\sigma(j)\}}$ captures what agent i would know, taking into account its own strategy and the strategy being used by agent j. Various applications of the usefulness of this expressiveness are given in the following sections.

In general, we will be most interested in the case where $\Sigma = \Sigma^{unif}(E)$ is the set of all locally uniform strategies in E, so we use the abbreviation $\mathcal{I}^{unif}(E)$ for $\mathcal{I}(E, \Sigma^{unif}(E))$, and similarly for the other strategy sets that we defined above.

We remark that the agent e has perfect information about the state of the environment, including the agent's observation, so $D_{\{e\} \cup G}\phi$, for $G \subseteq Ags$ is equivalent to $D_{\{e\}}\phi$. Thus, the operator $D_{\{e\} \cup \sigma(G)}$ captures what can be deduced from knowledge of the state of the environment and the strategies of agents in G.

Reasoning about Knowledge-Based Programs

Knowledge-based programs (Fagin et al. 1997) are a form of specification of a multi-agent system in the form of a program structure that specifies how an agent's actions are related to its knowledge. They have been shown to be a useful abstraction for several areas of application, including the development of optimal protocols for distributed systems (Fagin et al. 1997), robot motion planning (Brafman et al. 1997), and game theoretic reasoning (Halpern and Moses 2007).

Knowledge-based programs cannot be directly executed, since there is a circularity in their semantics: which actions are performed depends on what the agents know, which in turn depends on which actions the agents perform. The circularity is not vicious, and can be resolved by means of a fixed point semantics, but it means that knowledge-based programs may have multiple distinct implementations (or none), and the problem of reasoning about these implementations is quite subtle. In this section, we show that our framework can capture reasoning about the set of possible knowledge-based program implementations.

[2] We prefer the term "locally uniform" to just "uniform" in the case of groups, since we could say a strategy α for group G is *globally uniform* if for all states s, t, if $O_i(s) = O_i(t)$ for all $i \in G$, then $\alpha_i(s) = \alpha_i(t)$ for all $i \in G$. While we do not pursue this in the present paper, this notion would be interesting in settings where agents share information to collude on their choice of move.

We consider joint knowledge-based programs P (as defined by (Fagin et al. 1997)) where for each agent i we have a knowledge-based program

$$P_i = \textbf{do } \phi^i_1 \rightarrow a^i_1 \ [] \ \ldots [] \ \phi^i_{n_i} \rightarrow a^i_{n_i} \textbf{ od}$$

where each ϕ^i_j is a formula of CTL*K($Ags, Prop$) of the form $K_i\psi$, and each a_i appears just once.[3] Intuitively, this program says to repeat forever the following operation: nondeterministically execute one of the actions a^i_j such that the corresponding guard ϕ^i_j is true.

We present a formulation of semantics for knowledge-based programs that refactors the definitions of (Fagin et al. 1997), following the approach of (van der Meyden 1996) which uses the notion of environment defined above rather than the original notion of *context*. A *potential implementation* of a knowledge-based program P in an environment E is a joint strategy α in E. Given a potential implementation α in E, we can construct the interpreted system $\mathcal{I}(E, \{\alpha\})$, which captures the possible runs of E when the agents choose their actions according to the single possible joint strategy α. Given this interpreted system, we can now interpret the epistemic guards in P. Say that a state s of E is α-reachable if there is a point (r, m) of $\mathcal{I}(E, \{\alpha\})$ with $r_e(m) = s$. We note that for a formula $K_i\phi$, and a point (r, m) of $\mathcal{I}(E, \{\alpha\})$, the statement $\mathcal{I}(E, \{\alpha\}), (r, m) \models K_i\phi$ depends only on the state $r_e(m)$ of the environment at (r, m). For an α-reachable state s of E, it therefore makes sense to define satisfaction of $K_i\phi$ at s rather than at a point, by $\mathcal{I}(E, \{\alpha\}), s \models K_i\phi$ if $\mathcal{I}(E, \{\alpha\}), (r, m) \models K_i\phi$ for all (r, m) with $r_e(m) = s$. We define α to be an *implementation* of P in E if for all α-reachable states s of E and agents i, we have

$$\alpha_i(s) = \{a^i_j \mid 1 \leq j \leq n_i, \ \ \mathcal{I}(E, \{\alpha\}), s \models K_i\phi^i_j\} \ .$$

Intuitively, the right hand side of this equation is the set of actions that are enabled at s by P_i when the tests for knowledge are interpreted using the system obtained by running the strategy α itself. The condition states that the strategy is an implementation if it enables precisely this set of actions at every reachable state.

We now show that our framework for strategic reasoning can express the same content as a knowledge-based program by means of a formula, and that this enables the framework to be used for reasoning about knowledge-based program implementations.

We need one constraint on the environment. Say that an environment E is *action-recording* if for each $a \in Acts_i$ there exists an atomic proposition $did_i(a)$ such that for $s \in I$ we have $did_i(a) \notin \pi(s)$ and for all states s, t and joint actions a such that $(s, a, t) \in \rightarrow$, we have $did_i(b) \in \pi(t)$ iff $b = a_i$, for all agents i. It is easily seen that any environment can be made action-recording, just by adding a component to the states that records the latest joint action.

We can now express knowledge-based program implementations as follows. For a formula ψ, write $\psi^\$$ for the result of substituting for each occurrence of an operator D_G in ψ the operator $D_{G\cup\sigma(Ags)}$. Intuitively, this substitution says that the operator D_G in ψ is to be interpreted as if it is known that the current joint strategy is being played. To understand the motivation for this, note that in $\mathcal{I}(E, \{\alpha\})$ it is common knowledge that the joint strategy α is being played. Let

$$\textbf{imp}(P) = D_{\sigma(Ags)}(\bigwedge_{i\in Ags, j=1\ldots n_i} ((\phi^i_j)^\$ \Leftrightarrow EXdid_i(a^i_j))).$$

Intuitively, this formula says that the current joint strategy gives an implementation of the knowledge-based program P. More precisely, we have the following:

Proposition 1 *Suppose that P is a knowledge-based program that does not make use of common knowledge operators. Let α be a locally uniform joint strategy in E and let r be a run of $\mathcal{I}^{unif}(E)$, in which the agents are running joint strategy α, i.e., where $r_{\sigma(i)}(0) = \alpha_i$ for all $i \in Ags$. Let $m \in \mathbb{N}$. Then the strategy α is an implementation of knowledge-based program P in E iff $\mathcal{I}^{unif}(E), (r, m) \models \textbf{imp}(P)$.*

Note that here we check $\textbf{imp}(P)$ in the system $\mathcal{I}^{unif}(E)$ that contains *all* joint strategies, not just a single strategy α, as in the definition of implementation for a knowledge-based program. The point of this is that *a priori*, we do not have an implementation at hand.

In particular, as a consequence of this result, it follows that several properties of knowledge-based programs (that do not make use of common knowledge operators) can be expressed in the system $\mathcal{I}^{unif}(E)$:

1. The statement that there exists an implementation of P in E can be expressed by
$$\mathcal{I}^{unif}(E) \models \neg D_\emptyset \neg \textbf{imp}(P)$$
2. The statement that all implementations of P in E guarantee that formula ϕ holds at all times can be expressed by
$$\mathcal{I}^{unif}(E) \models D_\emptyset(\textbf{imp}(P) \Rightarrow D_{\sigma(Ags)}\phi^\$))$$

We remark that as a consequence of these encodings and the fact that the model checking problem described below is in PSPACE, we obtain that testing for the existence of an implementation of a knowledge-based program is in PSPACE, as is the problem of determining whether all implementations satisfy some formula. For testing existence, this result was known (Fagin et al. 1997), but the result on verification has not previously been noted (though it could also have been shown using the techniques in (Fagin et al. 1997).)

We remark that the reason for excluding common knowledge $C_G\phi$ from the conditions in the knowledge-based program in Proposition 1 is that this would require us to express a greatest fixedpoint X of the equation $X \equiv \bigwedge_{i\in G} D_{\{i\}\cup\sigma(Ags)}(X \wedge \phi)$, which is not the same as $C_{G\cup\sigma(Ags)}\phi$. One appropriate way to handle this in our framework would be to work with a mu-calculus extension. We do not pursue this here.

[3] The guards in (Fagin et al. 1997) are allowed to be boolean combinations of formulas $K_i\psi$ and propositions p local to the agent: since for such propositions $p \Leftrightarrow K_ip$, and the operator K_i satisfies positive and negative introspection, our form for the guards is equally general. They do not require that a_i appears just once, but the program can always be put into this form by aggregating clauses for a_i into one and taking the disjunction of the guards.

Connections to variants of ATEL

Alternating temporal logic (ATL) (Alur, Henzinger, and Kupferman 2002) is a generalization of the branching time temporal logic CTL that can express the capability of agent strategies to bring about temporal effects. Essentially, each branching construct $A\phi$ is generalized to an *alternating* construct $\langle\!\langle G\rangle\!\rangle\phi$ for a group G of agents, where ϕ is a "prefix temporal" formula such as $X\phi'$, $F\phi'$, $G\phi'$ or $\phi_1 U \phi_2$, as would be used to construct a CTL operator. Intuitively, $\langle\!\langle G\rangle\!\rangle\phi$ says that the group G has a strategy for ensuring that ϕ holds, irrespective of what the other agents do.

Alternating temporal epistemic logic (ATEL), adds epistemic operators to ATL (van der Hoek and Wooldridge 2002). As a number of subtleties arise in the formulation of such logics, several variants of ATEL have since been developed. In this section, we consider a number of such variants and argue that our framework is able to express the main strategic concepts from these variants. We begin by recalling ATEL as defined in (van der Hoek and Wooldridge 2002). Various modellings of the environments in which agents operate have been used in the literature; we base our modelling on the notion of environment introduced above.

The syntax of ATEL is given as follows:

$$\phi \equiv p \mid \neg\phi \mid \phi_1 \vee \phi_2 \mid \langle\!\langle G\rangle\!\rangle \bigcirc \phi \mid \langle\!\langle G\rangle\!\rangle \Box \phi \mid \langle\!\langle G\rangle\!\rangle (\phi_1 U \phi_2) \mid K_i\phi \mid C_G\phi$$

where $p \in Prop$, $i \in Ags$ and $G \subseteq Ags$. The intuitive meaning of the constructs is as in CTL*K above, with additionally $\langle\!\langle G\rangle\!\rangle\phi$ having the intuitive reading that group G has a strategy for assuring that ϕ holds. The semantics is given by a relation $E, s \models^{\Sigma} \phi$, where $E = \langle S, I, Acts, \rightarrow, \{O_i\}_{i\in Ags}, \pi\rangle$ is an environment, $s \in S$ is a state of E, and ϕ is a formula. For reasons discussed below, we parameterize the definition on a set Σ of strategies for groups of agents in the environment E. For the definition, we need the notion of a path in E: this is a function $\rho : \mathbb{N} \rightarrow S$ such that for all $k \in \mathbb{N}$ there exists a joint action a with $(\rho(k), a, \rho(k+1)) \in \rightarrow$. A path ρ is *from* a state s if $\rho(0) = s$. A path ρ is *consistent* with a strategy α for a group G if for all $k \in \mathbb{N}$ there exists a joint action a such that $(\rho(k), a, \rho(k+1)) \in \rightarrow$ and $a_i \in \alpha_i(\rho(k))$ for all $i \in G$.

The relation $E, s \models^{\Sigma} \phi$ is defined inductively on the structure of the formula ϕ:

- $E, s \models^{\Sigma} p$ if $p \in \pi(s)$;
- $E, s \models^{\Sigma} \neg\phi$ if not $E, s \models^{\Sigma} \phi$;
- $E, s \models^{\Sigma} \phi \wedge \psi$ if $E, s \models^{\Sigma} \phi$ and $E, s \models^{\Sigma} \psi$;
- $E, s \models^{\Sigma} \langle\!\langle G\rangle\!\rangle \bigcirc \phi$ if there exists a strategy $\alpha_G \in \Sigma$ for group G such that for all paths ρ from s that are consistent with α_G, we have $E, \rho(1) \models^{\Sigma} \phi$;
- $E, s \models^{\Sigma} \langle\!\langle G\rangle\!\rangle \Box \phi$ if there exists a strategy $\alpha_G \in \Sigma$ for group G such that for all paths ρ from s that are consistent with α_G, we have $E, \rho(k) \models^{\Sigma} \phi$ for all $k \in \mathbb{N}$;
- $E, s \models^{\Sigma} \langle\!\langle G\rangle\!\rangle (\phi U \psi)$ if there exists a strategy $\alpha_G \in \Sigma$ for group G such that for all paths ρ from s that are consistent with α_G, there exists $m \geq 0$ such that $E, \rho(m) \models^{\Sigma} \psi$, and for all $k < m$, we have $E, \rho(k) \models^{\Sigma} \phi$.
- $E, s \models^{\Sigma} K_i\phi$ if $E, t \models^{\Sigma} \phi$ for for all $t \in S$ with $t \sim_i s$;
- $E, s \models^{\Sigma} C_G\phi$ if $E, t \models^{\Sigma} \phi$ for for all $t \in S$ with $(s, t) \in (\cup_{i\in G} \sim_i)^*$;

The specific version of ATEL defined in (van der Hoek and Wooldridge 2002) is obtained from the above definitions by taking $\Sigma = \Sigma^{det} = \{\sigma_G \mid G \subseteq Ags,\ \sigma_G$ a deterministic G-strategy in $E\}$. That is, following the definitions for ATL, this version works with arbitrary deterministic group strategies, in which an agent selects its action as if it has full information of the state. This aspect of the definition has been critiqued by Jonker (Jonker 2003) and (in the case of ATL without epistemic operators) by Schobbens (Schobbens 2004), who argue that this choice is not in the spirit of the epistemic extension, in which observations are intended precisely to represent that agents do not have full information of the state. They propose that the definition instead be based on the set $\Sigma^{\text{det},unif} = \{\sigma_G \mid G \subseteq Ags,\ \sigma_G$ a locally uniform deterministic G-strategy in $E\}$. This ensures that in choosing an action, agents are able to use only the information available in their observations.

We concur that the use of locally uniform strategies is the more appropriate choice, but in either event, we now argue that our approach using strategy space is able to express everything that can be expressed in ATEL. Consider the following translation from ATEL to CTL*K($Prop, Ags^+ \cup \sigma(Ags) \cup \{e\}$). For a formula ϕ, we write ϕ^* for the translation of ϕ, defined inductively on the construction of ϕ by the following rules

$$p^* = p \qquad (\neg\phi)^* = \neg\phi^* \qquad (\phi_1 \wedge \phi_2)^* = \phi_1^* \wedge \phi_2^*$$
$$(K_i\phi)^* = K_i\phi^* \qquad (C_G\phi)^* = C_G\phi^*$$
$$(\langle\!\langle G\rangle\!\rangle \bigcirc \phi)^* = \neg K_e \neg D_{\{e\}\cup\sigma(G)} \bigcirc \phi^*$$
$$(\langle\!\langle G\rangle\!\rangle \Box\phi)^* = \neg K_e \neg D_{\{e\}\cup\sigma(G)} \Box\phi^*$$
$$(\langle\!\langle G\rangle\!\rangle \phi_1 U \phi_2)^* = \neg K_e \neg D_{\{e\}\cup\sigma(G)} (\phi_1^* U \phi_2^*)$$

Given a strategy $\alpha = \langle\alpha_i\rangle_{i\in G}$ for a group of agents G in an environment E, define the *completion* of the strategy to be the joint strategy $comp(\alpha) = \langle\alpha'_i\rangle_{i\in G}$ with $\alpha'_i = \alpha_i$ for $i \in G$ and with $\alpha_i(s) = Acts_i$ for all $i \in Ags \setminus G$ and $s \in S$. Intuitively, this operation completes the group strategy to a joint strategy for all agents, by adding the random strategy for all agents not in G. Given a set of strategies Σ for groups of agents, we define $comp(\Sigma) = \{comp(\alpha) \mid \alpha \in \Sigma\}$. Say that a set Σ of group strategies is *restrictable* if for every $\alpha \in \Sigma$ for group of agents G and every group $G' \subseteq G$, the restriction $\alpha_{G'}$ of α to agents in G' is also in Σ. Say that Σ is *extendable* if for every strategy for a group $G' \subseteq G$, there exists a strategy $\alpha' \in \Sigma$ for group G whose restriction $\alpha'_{G'}$ to G' is equal to α. For example, the set of all group strategies, and the set of all locally uniform group strategies, are both restrictable and extendable.

For an environment E, write $E[S/I]$ for the environment obtained by making all states in E be initial, i.e., replacing the set of initial states I of E by the set of all states S of E. (This is a technical transformation that we require because E may have temporally unreachable states that would not occur in an interpreted system constructed from E, but that can be accessed via an equivalence relation $\sim_i$ in the semantics of ATEL.) We can then show the following.

Theorem 1 *For every environment E, nonempty set of group strategies Σ that is restrictable and extendable, for every state s of E and ATEL formula ϕ, we have $E, s \models^{\Sigma} \phi$ iff for all (equivalently, some) points (r, m) of $\mathcal{I}(E[S/I], comp(\Sigma))$ with $r_e(m) = s$ we have $\mathcal{I}(E[S/I], comp(\Sigma)), (r, m) \models \phi^*$.*

Similar translation results can be given for other alternating temporal epistemic logics from the literature. We sketch a few of these translations here.

Jamroga and van der Hoek (Jamroga and van der Hoek 2004) note that ATEL admits situations consisting of an environment E and a state s where $E, s \models K_i\langle\langle i\rangle\rangle\phi$, i.e., in every state consistent with agent i's knowledge, some strategy for agent i is guaranteed to satisfy ϕ, but still there is no strategy for agent i that agent i knows will work to achieve ϕ. They formulate a construct $\langle\langle G\rangle\rangle^{\bullet}_{\mathcal{K}(H)}\phi$ that says, effectively, that there is a strategy for a group G that another group H knows (for notion of group knowledge $\mathcal{K}$, which could be E for everyone knows, D for distributed knowledge, or C for common knowledge) to achieve goal ϕ. More precisely,

> $E, s \models \langle\langle G\rangle\rangle^{\bullet}_{\mathcal{K}(H)}\phi$ if there exists a uniform strategy α for group G such that for all states t with $s \sim^{\mathcal{K}}_{H} t$, we have that all paths ρ from t that are consistent with α satisfy ϕ.

Here $\sim^{\mathcal{K}}_{H}$ is the appropriate epistemic indistinguishability relation on states of E. The particular case $\langle\langle G\rangle\rangle^{\bullet}_{E(G)}\phi$ is also proposed as the semantics for the ATL construct $\langle\langle G\rangle\rangle\phi$ in (Schobbens 2004; Jonker 2003; Jamroga and Ågotnes 2007).

The construct $\langle\langle G\rangle\rangle^{\bullet}_{D(H)}\phi$ can be represented in our language as

$$\neg D_e \neg D_{H\cup\sigma(G)}\phi \ .$$

Intuitively, here the first modal operator $\neg D_e\neg$ switches the strategy of all the agents while maintaining the state s, thereby selecting a strategy α for group G in particular, and the next operator $D_{\{H,\sigma(G)\}}$ verifies that the group H knows that the strategy G being used by group G guarantees ϕ. Similarly, $\langle\langle G\rangle\rangle^{\bullet}_{E(H)}\phi$ can be represented as

$$\neg D_e \neg \bigwedge_{i\in H} D_{\{i\}\cup\sigma(G)}\phi \ .$$

This gives a reduction of these complex operators of (Jamroga and van der Hoek 2004) to a set of standard epistemic operators.[4] (An alternate approach to decomposing the operators $\langle\langle G\rangle\rangle^{\bullet}_{\mathcal{K}(H)}$ is proposed in (Jamroga and Ågotnes 2007). By comparison with our standard semantics, this proposal uses "constructive knowledge" operators which require a nonstandard semantics in which formulas are evaluated at sets of states rather than at individual states.)

(W. van der Hoek, Jamroga, and Wooldridge 2005) introduce constants that refer to strategies, and adds to ATL a new (counterfactual) modality $C_i(c, \phi)$, with the intended reading "if it were the case that agent i committed to the strategy denoted by c, then ϕ". The formula ϕ here is not permitted to contain further references to agent i strategies. To interpret the formula $C_i(c, \phi)$ in an environment E, the environment is first updated to a new environment E' by removing all transitions that are inconsistent with agent i running the strategy referred to by c, and then the formula ϕ is evaluated in E'. After introducing propositional constants $p_{i,c}$ that say that agent i is running the strategy referred to by c, the formula $C_i(c, \phi)$ could be expressed in our framework as $D_{\{e\}\cup\sigma(Ags\setminus\{i\})}(p_{i,c} \Rightarrow \phi^{+\sigma(i)})$ where in the translation $\phi^{+\sigma(i)}$ of ϕ we ensure that there is no further deviation from the strategy of agent i by adding $\sigma(i)$ to the group of every knowledge operator occurring later in the translation.

(W. van der Hoek, Jamroga, and Wooldridge 2005) do not include epistemic operators. Were they to be added in the obvious way, the effect would be to make the meaning of the knowledge operator (with respect to the agent's knowledge concerning the strategies in play) dependent on the context in the formula. In particular, in $(K_j\phi) \wedge C_i(c, K_j\psi)$, the first occurrence of K_j would refer to an agent j who does not know that i is playing c, whereas the second K_j would effectively refer to our $K_{\{j,\sigma(i)\}}$, i.e., j's knowledge taking into account that i is playing c. Our framework is more expressive in that we can continue to use the former meaning even in the second context.

Solution Concepts

It has been shown for a number of logics for strategic reasoning that they are expressive enough to state a variety of game theoretic solution concepts, e.g., (W. van der Hoek, Jamroga, and Wooldridge 2005; Chatterjee, Henzinger, and Piterman 2010) show that Nash Equilibrium is expressible. We now sketch the main ideas required to show that our framework also has this expressive power. We assume two players $Ags = \{0, 1\}$ in a normal form game, and assume that these agents play a deterministic strategy. The results in this section can be easily generalized to multiple players and extensive form games.

Given a game $\mathcal{G}$ we construct an environment $E_{\mathcal{G}}$ that represents the game. Each player has a set of actions that correspond to the moves that the player can make. We assume that $E_{\mathcal{G}}$ is constructed to model the game so that play happens in the first step from a unique initial state, and that subsequent transitions do not change the state.

Let u_i for $i \in \{0, 1\}$ be a variable denoting the utility gained by player i when play is finished. Let V_i be the set of possible values for u_i. We write $-i$ to denote the adversary of player i. We use formula

$$U_i(v) = \bigcirc(u_i = v)$$

to express that value v is player i's utility once play finishes.

Nash equilibrium (NE) is a solution concept that states no player can gain by unilaterally changing their strategy. We may write

$$BR_i(v) = U_i(v) \wedge K_{\sigma(-i)} \bigwedge_{v'\in V_i} (U_i(v') \Rightarrow v' \leq v)$$

to express that, given the current adversary strategy, the value v attained by player i's current strategy is the best possible utility attainable by player i, i.e., the present strategy of

[4] As with knowledge-based programs above, to handle common knowledge, it seems we require an extension to mu-calculus.

player i is a best response to the adversary. Thus

$$BR_i = \bigvee_{v \in V_i} BR_i(v)$$

says that player i is playing a best-response to the adversary's strategy. The following statement then expresses the existence of a Nash equilibrium for the game $\mathcal{G}$:

$$\mathcal{I}^{unif,det}(E_{\mathcal{G}}) \models \neg D_{\emptyset} \neg (BR_0 \wedge BR_1) \; .$$

That is, in a Nash equilibrium, each player is playing a best response to the other's strategy.

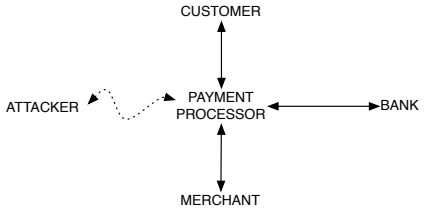
Perfect cooperative equilibrium (PCE) is a solution concept intended to overcome deficiencies of Nash equilibrium for explaining cooperative behaviour (Halpern and Rong 2010). It says that each player does at least as well as she would if the other player were best-responding. The following formula

$$BU_i(v) = D_{\emptyset}(\bigwedge_{v' \in V_i} ((BR_{-i} \wedge U_i(v')) \Rightarrow v' \leq v))$$

states that v is as good as any utility that i can obtain if the adversary always best-responds to whatever i plays. Thus,

$$BU_i = \bigvee_{v \in V_i} (U_i(v) \wedge BU_i(v))$$

says that i is currently getting a utility as good the best utility that i can obtain if the adversary is a best-responder. Now, the following formula expresses the existence of perfect cooperative equilibrium for the game $\mathcal{G}$:



$$\mathcal{I}^{unif,det}(E_{\mathcal{G}}) \models \neg D_{\emptyset} \neg (BU_0 \wedge BU_1)$$

That is, in a PCE, no player has an incentive to change their strategy, on the assumption that the adversary will best-respond to any change.

Computer Security Example: Erasure policies

Formal definitions of computer security frequently involve reference to the strategies available to the players, and to agent's reasoning based on these strategies. In this section we sketch an example that illustrates how our framework might be applied in this context.

Consider the scenario depicted in the following diagram:

A customer C can purchase items at a web merchant M. Payment is handled by a trusted payment processor P (this could be a service or device), which interacts with the customer, merchant, and a bank B to securely process the payment. (To keep the example simple, we suppose that the customer and merchant use the same bank). One of the guarantees provided by the payment processor is to protect the customer from attacks on the customer's credit card by the merchant: the specification for the protocol that runs the transaction requires that the merchant should not obtain the customer's credit card number. In fact, the specification for the payment processor is that after the transaction has been successfully completed, the payment processor should *erase* the credit card data, to ensure that even the payment processor's state does not contain information about the customer's credit card number. The purpose of this constraint is to protect the customer against subsequent attacks by an attacker A, who may be able to use vulnerabilities in the payment processor's software to obtain access to the payment processor's state.

We sketch how one might use our framework to express the specification. To capture reasoning about all possible behaviours of the agents, and what they can deduce from knowledge of those behaviours, we work in $\mathcal{I}^{unif}(E)$ for a suitably defined environment E. To simplify matters, we take $Ags = \{C, M, P, A\}$. We exclude the strategy of the bank from consideration: this amounts to assuming that the bank has no actions and is trusted to run a fixed protocol. We similarly assume that the payment processor P has no actions, but in order to talk about what information is encoded in the payment processor's local state, we do allow that this agent has observations. The customer C may have actions such as entering the credit card number in a web form, pressing a button to submit the form to the payment processor, and pressing a button to approve or cancel the transaction. The customer observes variable `cc`, which records the credit card number drawn from a set `CCN`, and boolean variable `done` which records whether the transaction is complete (which could mean either committed or aborted).

We assume that the attacker A has some set of exploit actions, as well as some innocuous actions (e.g., setting a local variable or performing *skip*). The effect of the exploit actions is to exploit a vulnerability in the payment processor's software and copy parts of the local state of the payment processor to variables that are observable by the attacker. We include in the environment state a boolean variable `exploited`, which records whether the attacker has executed an exploit action at some time in the past. The merchant M may have actions such as sending cost information to the payment processor and acknowledging a receipt certifying that payment has been approved by the bank (we suppose this receipt is transmitted from the bank to the merchant via the payment processor).

We may then capture the statement that the system is *potentially* vulnerable to an attack that exploits an erasure flaw in the implementation of the payment processor, by the following formula:

$$\neg D_{\emptyset} \neg (\mathtt{done} \wedge \bigvee_{x \in \mathtt{CCN}} K_P(\mathtt{cc} \neq x)))$$

This says that there exist behaviours of the agents, which can (at least on some points in some runs) leave the payment processor in a state where the customer has received confirmation that the transaction is done, but in which the payment

processor's local state somehow still encodes *some* information about the customer's credit card number. This encoding could be direct (e.g., by having a variable *customer_cc* that still stores the credit card number) or indirect (e.g. by the local state including both a symmetric encryption key K and an encrypted version of the credit card number, *enc_customer_cc*, with value $\texttt{Encrypt}_K(\texttt{cc})$ that was used for secure transmission to the bank). Note that for a breach of security, it is only required that the information suffices to *rule out* some credit card number (so that, e.g., knowing the first digit of the number would constitute a vulnerability)

The vulnerability captured by this formula is only potential, because it does not necessarily follow that the attacker is able to obtain the credit card information. Whether this is possible can be checked using the formula

$$\neg D_{\emptyset}\neg(\texttt{done} \wedge \neg\texttt{exploited} \wedge EF \bigvee_{x\in\texttt{CCN}} D_{\{A,\sigma(A)\}}(\texttt{cc} \neq x)))$$

which says that it is possible for the attacker to obtain information about the credit card number even after the transaction is done. (To focus on erasure flaws, we deliberately wish to exclude here the possibility that the attack occurs during the processing of the transaction.) Note that here we assume that the attacker knows their own strategy when making deductions from the information obtained in the attack. This is necessary, because the attacker can typically write its own local variables, so it needs to be able to distinguish between a value it wrote itself and a value it copied from the payment processor.

However, even this formula may not be sufficiently strong. Suppose that the payment processor implements erasure by writing a random value to its variable *customer_cc*. Then, even if the attacker obtains a copy of this value, and it happens to be equal to the customer's actual credit card number, the attacker would not have any knowledge about the credit card number, since, as far as the attacker knows, it could be looking at a randomly assigned number. However, there may still be vulnerabilities in the system. Suppose that the implementation of the payment processor operates so that the customer's credit card data is not erased by randomization until the merchant has acknowledged the receipt of payment from the bank, but to avoid annoying the customer with a hanging transaction, the customer is advised that the transaction is approved (setting done true) if the merchant does not respond within a certain time limit. It is still the case that on observing the copied value of *customer_cc*, the attacker would not be able to deduce that this is the customer's credit card number, since it might be the result of erasure in the case that the merchant responded promptly. However, if the attacker knows that the merchant has not acknowledged the receipt, the attacker can then deduce that the value is not due to erasure. One way in which the attacker might know that the merchant has not acknowledged receipt is that the attacker is in collusion with the merchant, who has agreed to omit sending the required acknowledgement messages.

This type of attack can be captured by replacing the term $D_{\{A,\sigma(A)\}}(\texttt{cc} \neq x)$ by $D_{\{A,\sigma(A),\sigma(M)\}}(\texttt{cc} \neq x)$, capturing that the attacker reasons using knowledge of both its own strategy as well as the strategy of the merchant, or even $D_{\{A,\sigma(A),\sigma(M),M\}}(\texttt{cc} \neq x)$ for a collusion in which the merchant shares information observed. Similarly, to focus on erasure flaws in the implementation of the payment gateway, independently of the attackers capability, we would replace the term $K_P(\texttt{cc} \neq x)$ above by $D_{\{P,\sigma(M)\}}(\texttt{cc} \neq x)$.

We remark that in the case of the attacker's knowledge, it would be appropriate to work with a perfect recall semantics of knowledge, but when using knowledge operators to express information in the payment gateway's state for purposes of reasoning about erasure policy, the more appropriate semantics of knowledge is imperfect recall.

This example illustrates some of the subtleties that arise in the setting of reasoning about security and the way that our framework helps to represent them. Erasure policies have previously been studied in the computer security literature, beginning with (Chong and Myers 2005), though generally without consideration of strategic behaviour by the adversary. However, many other notions in the security literature do involve reasoning about strategies and agent's knowledge based on strategies, including nondeducibility on strategies (Wittbold and Johnson 1990) and robust declassification (Zdancewic and Myers 2001). We leave the further exploration of such notions using our approach for future work.

Model Checking

We now consider the problem of model checking in strategy space. Recall that, given an interpreted system $\mathcal{I}$, we write $\mathcal{I} \models \phi$ when $\mathcal{I}, (r, 0) \models \phi$ for all runs r of $\mathcal{I}$. Since interpreted systems are infinite, we need a finite representation for a decision problem, for this we use a finite state environment E together with an associated set of strategies Σ, and consider the problem of determining whether $\mathcal{I}(\mathcal{E}(E, \Sigma)) \models \phi$. Typically, Σ would be a set such as the set $\Sigma^{unif}(E)$ of all uniform strategies for E.

For generality, we abstract Σ further, to a paramaterized class such that for each environment E, the set $\Sigma(E)$ is a set strategies for E. We say that the parameterized class $\Sigma(E)$ is *PTIME-presented*, if it is presented by means of an algorithm that runs in time polynomial in the size of E and verifies if a given strategy α is in $\Sigma(E)$. (We assume that strategies α are given as a list of tuples $(s, a) \in S \times Acts$ such that $a \in \alpha(s)$.) For example, the class $\Sigma(E)$ of all strategies for E can be PTIME-presented, as can $\Sigma^{unif}(E)$, $\Sigma^{det}(E)$ and $\Sigma^{unif,det}(E)$.

A naive model checking algorithm would construct an extended transition system over the state space $S \times \Sigma(E)$ and then apply standard model checking techniques for temporal epistemic logic. Note that a joint strategy for an environment E can be represented in space $|S| \times |Acts|$, where S is the set of states of E and $Acts$ the set of joint actions. Thus, such an extended transition system generally has exponentially many states as a function of the size of E. This means that the naive procedure would require not less than exponential time. In fact it, is possible to do better than this (assuming that PSPACE is better than EXPTIME). We show the following:

Theorem 2 *Let $\Sigma(E)$ be a PTIME presented class of strate-*

*gies for environments E. The complexity of deciding, given an environment E, and a CTL*K formula ϕ for agents $\{e\} \cup Ags(E) \cup \sigma(Ags(E))$, whether $\mathcal{I}(E, \Sigma(E)) \models \phi$, is PSPACE-complete.*

It is interesting to note that, although we have significantly more expressive power than the temporal logic LTL on which we build, we achieve this without an increase in complexity: model checking LTL is already PSPACE-complete (Sistla and Clarke 1985). We note that this result also strongly suggests that we do have a strictly stronger expressive power than ATEL, since the complexity of model checking ATEL, assuming uniform strategies, is P^{NP}-complete. The class P^{NP} consists of problems solvable by PTIME computations with access to an NP oracle). For ATEL, model checking can be done with a polynomial time (with respect to the size of formula) computation with access to an oracle that is in NP with respect to both the number of states and the number of joint actions. In particular, (Schobbens 2004) proves this upper bound and (Jamroga and Dix 2006) proves a matching lower bound.

Conclusions

We refer the reader to the sections above for references and comparison to related work on each of the topics that we cover. Beside these references, the following are also worth mentioning.

Strategy Logic (Chatterjee, Henzinger, and Piterman 2010) is a (non-epistemic) generalization of ATL for perfect information strategies in which strategies may be explicitly named and quantified. Our logic has implicit quantification over strategies using the strategic agents in the epistemic operators. Our logic could be further generalized to make the reference to strategies explicit, but we note that strategy logic has a non-elementary model checking problem, so this could come at the cost of a large increase in complexity. Work on identification of more efficient variants of quantified strategy logic includes (Mogavero, Murano, and Vardi 2010), who formulate a variant with a 2-EXPTIME-complete model checking problem.

(van Eijck 2013) introduces a variant of propositional dynamic logic (PDL) for describing strategy profiles in normal form games subject to preference relations, but does not cover temporal aspects as we have in this paper. Another approach based on PDL is given in (Ramanujam and Simon 2008), which describes strategies by means of formulas.

(Schnoor 2010) defines a very rich generalization of ATEL for probabilistic environments, that includes variables that refer to *strategy choices*, and in which the strategic operators refer to these variables, so that statements of the form "when coalition A runs the strategy determined by variable S1, and coalition B runs the strategy determined by S2, then probability that ϕ holds is at least δ" can be expressed. Here a strategy choice uniformly maps each state, coalition and formula to a uniform strategy for the coalition. The strategic variables may be quantified, but only in the prefix of the formula. Because of the complexity of this framework, we leave a more detailed comparison for later work, but we note that the epistemic operators in this approach are interpreted with respect to a fixed strategy choice, compared to our approach in which the epistemic operators work over the entire strategy space.

Our focus on this paper has been on an observational, or imperfect recall, semantics for knowledge. Other semantics for knowledge are also worth consideration, but left for future work. We note one issue in relation to the connection to ATEL that we have established, should we consider a perfect recall version of our logic. ATEL operators effectively allow reference to situations in which agents switch their strategy after some actions have already been taken, whereas in our model an agent's strategy is fixed for the entire run. When switching to a new strategy, there is the possibility that the given state is not reachable under this new strategy. We have handled this issue in our translation by assuming that all states are initial, so that the run can be reinitialized if necessary to make the desired state reachable. This is consistent with an imperfect recall interpretation of ATEL, but it is not clear that this approach is available on a perfect recall interpretation. We leave a resolution of this issue to future work.

In several places in the present paper (Proposition 1 and Theorem 1), we have made a technical restriction to formulas not involving the common knowledge operator in order to establish a result about the expressive power of our logic, and remarked that an extension of the logic appears to be required for these results to encompass common knowledge operators. In a subsequent work (Huang and van der Meyden 2014), we have developed an extension that has the required expressiveness, by introducing a capacity for quantifying over strategies.

An Abstraction Technique for the Verification of Multi-Agent Systems Against ATL Specifications

Alessio Lomuscio and Jakub Michaliszyn
Department of Computing, Imperial College London, UK

Abstract

We introduce an abstraction methodology for the verification of multi-agent systems against specifications expressed in alternating-time temporal logic (ATL). Inspired by methodologies such as predicate abstraction, we define a three-valued semantics for the interpretation of ATL formulas on concurrent game structures and compare it to the standard two-valued semantics. We define abstract models and establish preservation results on the three-valued semantics between abstract models and their concrete counterparts. We illustrate the methodology on the large state spaces resulting from a card game.

1 Introduction

In logic-based approaches to multi-agent systems (MAS) there is a long tradition concerned with the development and use of formalisms aimed at expressing the *strategic abilities* of agents in a system. This interest goes back to earlier work in philosophical logic where formalisms such as STIT have been developed to analyse what agents can bring about in a multi-agent system (Belnap and Perloff 1990). Against this context the framework of Alternating-Time Temporal Logic (ATL) was developed in the late 90s in theoretical computer science to reason about paths representing particular outcomes in games (Alur, Henzinger, and Kupferman 2002). For example, by means of an ATL formula one can express whether two agents in a game can always enforce a certain state of affairs irrespective of the actions of the others.

The semantics of ATL is traditionally given in terms of concurrent game structures, which are transition-based systems whereby all choices of the agents as well as their strategies are explicitly provided. Concurrent game structures are very close to interpreted systems, a popular semantics for reasoning about knowledge in multi-agent systems (Fagin et al. 1995). Combining the two approaches provides a natural and intuitive setting for the practical verification of MAS epistemic and ATL specifications under incomplete information (Lomuscio and Raimondi 2006b).

One key attractiveness of ATL is that key system properties such as controllability and realisability can be formulated as model checking particular ATL formulas. In the original setting, i.e., without fairness constraints, the algorithm for model checking models against CTL formulas can easily be extended to ATL, thereby resulting in the ATL model checking problem being linear against the size of the model and the formula to be considered. The complexity increases for ATL* and more powerful logics. Indeed in the past ten years a range of logics which extend ATL have been put forward, ranging from ATL$^+$ to ATL*, to combinations with knowledge, and to the very recent family of strategic logic (Chatterjee, Henzinger, and Piterman 2007; Mogavero et al. 2012), and their complexity analysed. Furthermore, different assumptions can be made on the observability of the states in the game and the states of the players, as well as their ability to recall the moves they played, thereby leading to several possible variants. The precise set-up has considerable consequences on the resulting complexity of the model checking problem with certain cases, e.g., perfect recall under incomplete information, resulting to be undecidable. For more details we refer to (Alur, Henzinger, and Kupferman 2002; Schobbens 2004; Jamroga and Ågotnes 2007; Bulling, Dix, and Chesñevar 2008).

Much is known at theoretical level about these variants. However, *practical* model checking of systems against ATL specifications has somewhat lagged behind. JMOCHA (Alur et al. 2001), a revised version of the original MOCHA model checker for reactive modules against ATL specifications, supports advanced features such as compositional and modular verification. MCMAS (Lomuscio and Raimondi 2006b; Lomuscio, Qu, and Raimondi 2009), a model checker for multi-agent systems, supports epistemic and ATL specifications in the context of incomplete information. However, they both lack abstraction features thereby making them more prone to be constrained by the state-explosion problem.

The aim of this paper is to lay the foundations for an abstraction methodology for verifying multi-agent systems with incomplete information against ATL specifications.

Contribution. Since our overall aim is to develop under-Section 2 by developing a novel three-valued semantics for ATL which we show to be a conservative extension of the classic two-valued semantics. In Section 3 we define abstractions of ATL models. Abstraction is conducted modularly both on the local states and the local actions associated with the agents, thereby generating considerably smaller models. We show that values true and false are preserved in three-valued semantics between abstract and concrete models. We

turn to the model checking problem in Section 4 by exploring its complexity in a three-valued setting and by providing constructive definitions for the initial abstraction and algorithms for successive refinements. We exemplify these constructions in Section 5 by showing how the technique put forward here can reduce the state space considerably. We conclude in Section 6 where we also discuss the future work.

Related work. As discussed above, while model checking systems against ATL specifications has been explored in the literature, practical model checking has received considerable less attention. While model checkers such as JMOCHA and MCMAS have been made available, one of the key problems remains the state-space explosion. To the best of our knowledge the only previous paper in the literature tackling abstraction in the context of ATL is (Köster and Lohmann 2012). However, their approach is based on modular interpreted systems where complete information is assumed. By contrast here we deal with the general class of interpreted systems and we work in a more general, three-valued semantics, thereby laying the foundation for predicate abstraction techniques.

2 Three-Valued Alternating-Time Temporal Logic

In this section we recall the technical set-up for ATL and provide it with a novel, three-valued semantics.

We assume a set of agents $Ag = \{1, \ldots, m\}$. For simplicity, and without loss of generality, note we do not consider the environment here. We use $\Gamma \subseteq Ag$ to denote subsets of agents. By $\overline{\Gamma}$ we denote the complementation of Γ, i.e., $Ag \setminus \Gamma$.

We also assume a set of propositional variables $\mathcal{V}$; by $\overline{\mathcal{V}}$ we denote the set of all the literals containing propositional variables from $\mathcal{V}$, i.e., $\overline{\mathcal{V}} = \{q, \neg q \mid q \in \mathcal{V}\}$.

2.1 Interpreted systems and associated models

We are interested in the following structures.

Definition 1 (Interpreted system). *An* interpreted system *is a tuple $IS = (\{L_i, Act_i, P_i, t_i\}_{i \in Ag}, I, \Pi)$ such that for each agent i:*

- *L_i is a set of possible* local states*;*
- *Act_i is a set of possible* local actions*;*
- *$P_i : L_i \to 2^{Act_i} \setminus \{\emptyset\}$ is a* local protocol*;*
- *$t_i \subseteq L_i \times ACT \times 2^{L_i}$ is a* local transition relation *with $ACT = Act_1 \times \cdots \times Act_m$;*
- *$I \subseteq L_1 \times \cdots \times L_m$ is a set of* global initial states*;*
- *$\Pi : L_1 \times \cdots \times L_m \to \overline{\mathcal{V}}$ is a* labelling function *such that for any q, s we either have $q \notin \Pi(s)$ or $\neg q \notin \Pi(s)$.*

Note that the transition relation is normally considered to be a function. We here consider a more liberal definition to allow for a uniform presentation with abstract models (see Section 2.4). For the same reason the definition of a labelling function is more general than usual as it allows a state to be labelled by neither q nor $\neg q$.

For a tuple $t = (t_1, \ldots, t_m)$, by $t.i$ we denote its ith element t_i, with $i \leq m$. We will use this notation to identify individual local states and local actions.

We associate standard temporal models to interpreted systems.

Definition 2 (Model). *Given an interpreted system $IS = (\{L_i, Act_i, P_i, t_i\}_{i \in Ag}, I, \Pi)$, its* associated model *$M_{IS} = (S, T, I, \Pi)$ is a tuple such that:*

- *$S \subseteq L_1 \times \cdots \times L_m$ is the set of global states reachable via T from the set of initial global states $I \subseteq S$,*
- *$T \subseteq S \times ACT \times S$ is a global transition relation such that $T((l_1, \ldots, l_m), a, (l'_1, \ldots, l'_m))$ iff $t_i(l_i, a, l'_i)$ and $a.i \in P_i(l_i)$ for all $i \in Ag$.*

When IS is clear from the context we write M for M_{IS}.

In the following we assume that all locally enabled joint actions can be executed, i.e., that for all global states $s \in S$ and joint actions $a \in ACT$ such that $a.i \in P_i(s.i)$ for all $i \in Ag$, there exists an $s' \in S$ such that $T(s, a, s')$.

2.2 Alternating-time temporal logic

Alternating-Time Temporal Logic (ATL) was introduced to reason about agents and their strategies in the context of perfect information (Alur, Henzinger, and Kupferman 2002). In this setting agents' strategies depend on the global state of the system. ATL's semantics has been recast on incomplete information in the context of interpreted systems (see, e.g., (Schobbens 2004)).

The syntax of ATL is given by the following BNF:
$\varphi ::= q \mid \mathrm{tt} \mid \neg\varphi \mid \varphi \wedge \varphi \mid \langle\!\langle\Gamma\rangle\!\rangle X\varphi \mid \langle\!\langle\Gamma\rangle\!\rangle(\varphi U \varphi) \mid \langle\!\langle\Gamma\rangle\!\rangle G\varphi$
where q is a propositional variable and $\Gamma \subseteq Ag$. We abbreviate $\langle\!\langle\Gamma\rangle\!\rangle(\mathrm{tt} U \varphi)$ by $\langle\!\langle\Gamma\rangle\!\rangle F\varphi$.

The formula $\langle\!\langle\Gamma\rangle\!\rangle X\varphi$ is read as "$\langle\!\langle\Gamma\rangle\!\rangle$ has a strategy to enforce φ in the next state (irrespective of the actions of the agents in $Ag \setminus \Gamma$)"; $\langle\!\langle\Gamma\rangle\!\rangle G\varphi$ means "$\langle\!\langle\Gamma\rangle\!\rangle$ has a strategy to enforce φ forever in the future"; and $\langle\!\langle\Gamma\rangle\!\rangle \varphi_1 U \varphi_2$ represents "$\langle\!\langle\Gamma\rangle\!\rangle$ has a strategy to enforce that φ_2 holds at some point in the future and can ensure that φ_1 holds until then."

2.3 Two- and three-valued semantics for ATL

Let $IS = (\{L_i, Act_i, P_i, t_i\}_{i \in Ag}, I, \Pi)$ be an interpreted system. A *strategy* for an agent $i \in \Gamma$ is a function $f_i : L_i^+ \to 2^{Act_i} \setminus \{\emptyset\}$ such that for each sequence of states $l_1 \ldots l_s$, all the actions in $f_i(l_1 \ldots l_s)$ are in $P_i(l_s)$.

A strategy is called *memoryless* if it depends only on the last state, i.e., if $f_i(l_1 \ldots l_s l) = f_i(l)$ for any natural number s and any states $l_1, \ldots, l_s, l$.

Given a set of agents Γ and an indexed set of strategies $F_\Gamma = \{f_i \mid i \in \Gamma\}$, we define $out(s, F_\Gamma)$ to be the set of infinite paths $s_0 s_1 \ldots$ such that $s_0 = s$ and for all j there exists an action a such that $T(s_j, a, s_{j+1})$ and for all $i \in \Gamma$, $a.i \in f(s_0.i \ldots s_j.i)$.

Agents anre Interpreted systems with *imperfect recall* are those in which agents are required to use only memoryless strategies, while interpreted systems with *perfect recall* are those in which agents are allowed to use arbitrary strategies.

For a path $p = s_0 s_1 \ldots$, by p^i we denote s_i, the i-th element of p.

The following is the standard semantics for ATL.

Definition 3 (Two-valued semantics). *Given an interpreted system $IS = (\{L_i, Act_i, P_i, t_i\}_{i \in Ag}, I, \Pi)$, its associated*

model M and a global state $s \in S$, the two-valued satisfaction relation $\models_{\overline{2}}$ is inductively defined as follows.

$M, s \models_{\overline{2}} q$ *iff* $q \in \Pi(s)$

$M, s \models_{\overline{2}} \neg\varphi$ *iff* $M, s \not\models_{\overline{2}} \varphi$

$M, s \models_{\overline{2}} \langle\langle\Gamma\rangle\rangle X\varphi$ *iff for some* F_Γ *and all* $p \in out(s, F_\Gamma)$ *we have* $M, p^1 \models_{\overline{2}} \varphi$

$M, s \models_{\overline{2}} \varphi_1 \wedge \varphi_2$ *iff* $M, l \models_{\overline{2}} \varphi_1$ *and* $M, s \models_{\overline{2}} \varphi_2$

$M, s \models_{\overline{2}} \langle\langle\Gamma\rangle\rangle \varphi_1 U \varphi_2$ *iff for some* F_Γ *and all* $p \in out(s, F_\Gamma)$, *there is a* $k \geq 0$ *s.t. we have* $M, p^k \models_{\overline{2}} \varphi_2$ *and for all* $0 \leq j < k, M, p^j \models_{\overline{2}} \varphi_1$

$M, s \models_{\overline{2}} \langle\langle\Gamma\rangle\rangle G\varphi$ *iff for some* F_Γ *and all* $p \in out(s, F_\Gamma)$ *and for all* $i \geq 0$ *we have* $M, p^i \models_{\overline{2}} \varphi$

We now introduce a novel, three-valued semantics for ATL. Each ATL formula φ is associated with three possible values (tt for true, ff for false, uu for undefined) when evaluated on an interpreted system IS at a given state. We will later show that the three-valued semantics agrees with the two-valued one whenever the truth value is not undefined.

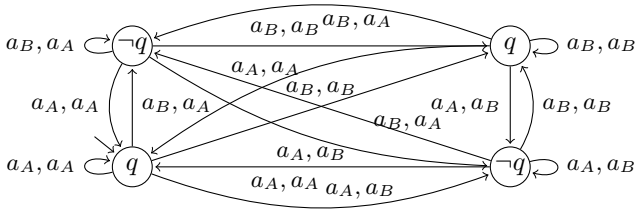
Definition 4 (Three-valued semantics). *Given an interpreted system $IS = (\{L_i, Act_i, P_i, t_i\}_{i \in Ag}, I, \Pi)$, its associated model M and a global state $s \in S$, the three-valued satisfaction relation $\models_{\overline{3}}$ is inductively defined as follows.*

$$M, s \models_{\overline{3}} q = \begin{cases} \mathrm{tt} \textit{ if } q \in \Pi(s), \\ \mathrm{ff} \textit{ if } \neg q \in \Pi(s), \\ \mathrm{uu} \textit{ otherwise} \end{cases}$$

$$M, s \models_{\overline{3}} \neg\varphi = \begin{cases} \mathrm{tt} \textit{ iff } M, s \models_{\overline{3}} \varphi = \mathrm{ff} \\ \mathrm{ff} \textit{ iff } M, s \models_{\overline{3}} \varphi = \mathrm{tt} \\ \mathrm{uu} \textit{ otherwise} \end{cases}$$

$$M, s \models_{\overline{3}} \varphi_1 \wedge \varphi_2 = \begin{cases} \mathrm{tt} \textit{ iff } M, s \models_{\overline{3}} \varphi_1 = \mathrm{tt} \textit{ and } M, s \models_{\overline{3}} \varphi_2 = \mathrm{tt} \\ \mathrm{ff} \textit{ iff } M, s \models_{\overline{3}} \varphi_1 = \mathrm{ff} \textit{ or } M, s \models_{\overline{3}} \varphi_2 = \mathrm{ff} \\ \mathrm{uu} \textit{ otherwise} \end{cases}$$

$$M, s \models_{\overline{3}} \langle\langle\Gamma\rangle\rangle X\varphi = \begin{cases} \mathrm{tt} \textit{ iff for some strategy } F_\Gamma \textit{ and all } p \in out(s, F_\Gamma) \textit{ we have } M, p^1 \models_{\overline{3}} \varphi = \mathrm{tt} \\ \mathrm{ff} \textit{ iff for some strategy } F_{\overline{\Gamma}} \textit{ and all } p \in out(s, F_{\overline{\Gamma}}) \textit{ we have } M, p^1 \models_{\overline{3}} \varphi = \mathrm{ff} \\ \mathrm{uu} \textit{ otherwise} \end{cases}$$



$$M, s \models_{\overline{3}} \langle\langle\Gamma\rangle\rangle \varphi_1 U \varphi_2 = \begin{cases} \mathrm{tt} \textit{ if for some strategy } F_\Gamma \textit{ and all } p \in out(s, F_\Gamma) \textit{ there is } k \in \mathbb{N} \textit{ s.t. } M, p^k \models_{\overline{3}} \varphi_2 = \mathrm{tt} \textit{ and for all } j < k, M, p^j \models_{\overline{3}} \varphi_1 = \mathrm{tt} \\ \mathrm{ff} \textit{ if for some strategy } F_{\overline{\Gamma}} \textit{ and all } p \in out(s, F_{\overline{\Gamma}}), k \in \mathbb{N} \textit{ we have } M, p^k \models_{\overline{3}} \varphi_2 = \mathrm{ff} \textit{ or there is } j < k \textit{ s.t. } M, p^j \models_{\overline{3}} \varphi_1 = \mathrm{ff} \\ \mathrm{uu} \textit{ otherwise} \end{cases}$$

$$M, s \models_{\overline{3}} \langle\langle\Gamma\rangle\rangle G\varphi = \begin{cases} \mathrm{tt} \textit{ iff for some strategy } F_\Gamma \textit{ and all } p \in out(s, F_\Gamma), i \in \mathbb{N} \textit{ we have } M, p^i \models_{\overline{3}} \varphi = \mathrm{tt} \\ \mathrm{ff} \textit{ iff for some strategy } F_{\overline{\Gamma}} \textit{ and all } p \in out(s, F_{\overline{\Gamma}}), \textit{ there is } i \in \mathbb{N} \textit{ s.t. } M, p^i \models_{\overline{3}} \varphi = \mathrm{ff} \\ \mathrm{uu} \textit{ otherwise} \end{cases}$$

We write $IS \models_{\overline{2}} \varphi$ iff for all the initial states s we have that $M, s \models_{\overline{2}} \varphi$. Similarly, $IS \models_{\overline{3}} \varphi = \mathrm{tt}$ iff for all the initial states s, $M, s \models_{\overline{3}} \varphi = \mathrm{tt}$. We illustrate the differences between the two semantics on an example.

Example 1. Consider the interpreted system IS defined on $Ag = \{1, 2\}$. Each agent $i \in \{1, 2\}$ is associated with two actions $Act_i = \{a_A, a_B\}$, two local states $L_i = \{l_A, l_B\}$, a protocol function P_i s.t. $P_i(l) = Act_i$ for any $l \in L_i$, and the transition relation $t_i = \{(l_A, a_A, l_A), (l_A, a_B, l_B), (l_B, a_A, l_A), (l_B, a_B, l_B)\}$.

Assume that $I = \{(l_A, l_A)\}$ and Π is the labelling function such that $\Pi((l_A, l_A)) = \Pi((l_B, l_B)) = \{q\}$ and $\Pi((l_B, l_A)) = \Pi((l_A, l_B)) = \{\neg q\}$. Then, in the model M_{IS} of IS we have $T = \{((l_a, l_b), (a_c, a_d), (l_c, l_d)) \mid a, b, c, d \in \{A, B\}\}$.

Consider a strategy f_1 for agent 1. If $a_A \in f_1((l_A))$, then $out((l_A, l_A), \{f_1\})$ contains a path p such that $p^1 = (l_A, l_B)$. If $a_A \notin f_1((l_A))$, then $a_B \in f_1((l_A, l_A))$, and therefore $out((l_A, l_A), \{f_1\})$ contains a path p' such that $p'^1 = (l_B, l_A)$. Therefore, $IS \not\models_{\overline{2}} \langle\langle 1\rangle\rangle Xq$ and it is not the case that $IS \models_{\overline{3}} \langle\langle 1\rangle\rangle Xq = \mathrm{tt}$.

Note that $\overline{\{1\}} = \{2\}$. Consider a strategy f_2 for agent 2. If $a_B \in f_2((l_A))$, then there is $p \in out((l_A, l_A), \{f_2\})$ s.t. $p^1 = (l_B, l_A)$. Otherwise, $a_A \in f_2((l_A))$ and there is $p \in out((l_A, l_A), \{f_2\})$ s.t. $p^1 = (l_A, l_B)$. So it is not the case that $IS \models_{\overline{3}} \langle\langle 1\rangle\rangle Xq = \mathrm{ff}$, and therefore $IS \models_{\overline{3}} \langle\langle 1\rangle\rangle Xq = \mathrm{uu}$.

In other words, $IS \not\models_{\overline{2}} \langle\langle 1\rangle\rangle Xq$ means that agent 1 has no strategy to guarantee q in the next state, while $IS \models_{\overline{3}} \langle\langle 1\rangle\rangle Xq = \mathrm{ff}$ represents that agent 2 has a strategy to avoid q (so it is not the case).

2.4 Relationship between $\models_{\overline{3}}$ and $\models_{\overline{2}}$

We show that the three-value semantics agrees with the two-valued semantics whenever the three-valued semantics returns tt or ff.

Theorem 5. *Consider an interpreted system IS, an ATL formula φ and a global state s. We have the following:*

1. *If $M_{IS}, s \models_{\overline{3}} \varphi = \mathrm{tt}$, then $M_{IS}, s \models_{\overline{2}} \varphi$.*
2. *If $M_{IS}, s \models_{\overline{3}} \varphi = \mathrm{ff}$, then $M_{IS}, s \not\models_{\overline{2}} \varphi$.*

In the proof we use the following lemma.

Lemma 6. *For any disjoint groups of agents Γ, Γ', any state s and any strategies $F_\Gamma, F_{\Gamma'}$ we have $out(s, F_\Gamma \cup F_{\Gamma'}) \subseteq out(s, F_\Gamma)$.*

The proof follows from the fact that $out(s, F_\Gamma \cup F_{\Gamma'})$ represents the paths that result when agents from Γ play according to F_Γ and agents from Γ' play according to $F_{\Gamma'}$, while $out(s, F_\Gamma)$ represents the paths that occur when agents from Γ play according to F_Γ.

Proof of Theorem 5. The proof is by induction on φ.

If $M_{IS}, s \models_3 q = \mathrm{tt}$, then $q \in \Pi(s)$, and so $M_{IS}, s \models_2 q$.

If $M_{IS}, s \models_3 q = \mathrm{ff}$, then $\neg q \in \Pi(s)$. By the definition of the labelling function, $q \notin \Pi(s)$. Therefore, $M_{IS}, s \not\models_2 q$.

Assume that $M_{IS}, s \models_3 \langle\langle\Gamma\rangle\rangle X\varphi' = \mathrm{tt}$. Then, there is F_Γ such that for all $p \in out(s, F_\Gamma)$ we have $M_{IS}, p^1 \models_3 \varphi' = \mathrm{tt}$. By the inductive hypothesis, we have $M_{IS}, p^1 \models_2 \varphi'$, and therefore $M_{IS}, s \models_2 \langle\langle\Gamma\rangle\rangle X\varphi'$.

Assume that $M_{IS}, s \models_3 \langle\langle\Gamma\rangle\rangle X\varphi' = \mathrm{ff}$. So there is a strategy $F_{\overline{\Gamma}}$ s.t. for all $p \in out(s, F_{\overline{\Gamma}})$ we have $M_{IS}, p^1 \models_3 \varphi' = \mathrm{ff}$. Consider any strategy F_Γ of Γ and a path $p \in out(s, F_\Gamma \cup F_{\overline{\Gamma}})$. By Lemma 6, $p \in out(s, F_{\overline{\Gamma}})$, so $M_{IS}, p^1 \models_3 \varphi = \mathrm{ff}$. By the inductive hypothesis, $M_{IS}, p^1 \not\models_2 \varphi'$. By Lemma 6, $p \in out(s, F_\Gamma)$. So we showed that for any strategy F_Γ there is a path p such that $M_{IS}, p^1 \not\models_2 \varphi'$; so $M_{IS}, s \not\models_2 \langle\langle\Gamma\rangle\rangle X\varphi'$.

Assume that $M_{IS}, s \models_3 \langle\langle\Gamma\rangle\rangle \varphi_1 U \varphi_2 = \mathrm{tt}$. Then, there is F_Γ such that for all $p \in out(s, F_\Gamma)$ there is k s.t. $M_{IS}, p^k \models_3 \varphi_2 = \mathrm{tt}$ and for all $j < k$ we have $M_{IS}, p^j \models_3 \varphi_1 = \mathrm{tt}$. By the inductive hypothesis we have that $M_{IS}, p^k \models_2 \varphi_2$ and for all $j < k$ we have $M_{IS}, p^j \models_2 \varphi_1$. Therefore $M_{IS}, s \models_2 \langle\langle\Gamma\rangle\rangle \varphi_1 U \varphi_2$.

Assume that $M_{IS}, s \models_3 \langle\langle\Gamma\rangle\rangle \varphi_1 U \varphi_2 = \mathrm{ff}$ and $F_{\overline{\Gamma}}$ is such that for all $p \in out(s, F_{\overline{\Gamma}})$ and all k we have $M_{IS}, p^k \models_3 \varphi_2 = \mathrm{ff}$ or there exists $j < k$ s.t. $M_{IS}, p^j \models_3 \varphi_1 = \mathrm{ff}$. Consider any strategy F_Γ of Γ, and let $p \in out(s, F_\Gamma \cup F_{\overline{\Gamma}})$. By Lemma 6, $p \in out(s, F_{\overline{\Gamma}})$ and $p \in out(s, F_\Gamma)$. By the inductive assumption, for all k, $M_{IS}, p^k \not\models_2 \varphi_2$ or there exists $j < k$ s.t. $M_{IS}, p^j \not\models_2 \varphi_1$. Since F_Γ was an arbitrary strategy, we conclude that $M_{IS}, s \not\models_2 \langle\langle\Gamma\rangle\rangle \varphi_1 U \varphi_2$.

The remaining inductive cases can be shown in a similar manner. □

Notice that the above proof remains valid if we consider only memoryless strategies.

In the next Section we will explore how the novel, three-valued semantics introduced here can be used as part of an abstraction methodology in order to verify multi-agent systems against ATL specifications.

3 Abstraction

In this section we provide an abstraction methodology for constructing abstract interpreted systems. We introduce two techniques: *action abstraction* and *state abstraction*.

Recall that a function is *decomposable* if for any $x_1, \ldots, x_m$ we have that $f((x_1, \ldots, x_m)) = (f_1(x_1), \ldots, f_m(x_m))$, for some $f_i, i = 1, \ldots, m$. By $f.i$ we denote the function f_i.

Given an interpreted system IS an *action abstraction function* is a surjective and decomposable function $\alpha : ACT \to ACT^\alpha$, for some set ACT^α. The set ACT is the set of joint actions whereas ACT^α constitutes the set of *abstract joint actions* for the corresponding abstract interpreted system. This enables us to define the action abstraction of an interpreted system as follows.

Definition 7 (Action abstraction). *Given an interpreted system $IS = (\{L_i, Act_i, P_i, t_i\}_{i \in Ag}, I, \Pi)$ and an action abstraction function α, the* action abstraction *of IS w.r.t. α is an interpreted system $IS^\alpha = (\{L_i^\alpha, Act_i^\alpha, P_i^\alpha, t_i^\alpha\}_{i \in Ag}, I^\alpha, \Pi^\alpha)$ such that $I^\alpha = I$, $\Pi^\alpha = \Pi$, and for each agent i:*

- $L_i^\alpha = L_i$,
- $Act_i^\alpha = \alpha.i(Act_i)$,
- $P_i^\alpha(l) = \alpha.i(P_i(l))$ *for all states* $l \in L_i$,
- *for all $l, l' \in l_i$ and $a^\alpha \in ACT^\alpha$, $t_i^\alpha(l, a^\alpha, l')$ iff for some $a \in ACT$ s.t. $\alpha.i(a) = a^\alpha$ we have $t_i(l, a, l')$.*

In other words the application of an action abstraction function results in the reduction of the number of actions in an interpreted system, thereby generating an abstract one.

We now explore a similar concept related to states.

Given an interpreted system IS, a *state abstraction function* is a surjective and decomposable function $\sigma : S \to S^\sigma$, such that for each agent i and any two local states $l, l' \in L_i$, if $\sigma.i(l) = \sigma.i(l')$, then $P_i(l) = P_i(l')$, for some set of states S^σ. The set S is the set of global states of the associated model M_{IS} and S^σ constitutes the set of *abstract global states* for the corresponding abstract interpreted system.

Definition 8 (State abstraction). *Given an interpreted system $IS = (\{L_i, Act_i, P_i, t_i\}_{i \in Ag}, I, \Pi)$ and a state abstraction function σ, the* state abstraction *of IS w.r.t. σ is the interpreted system $IS^\sigma = (\{L_i^\sigma, Act_i^\sigma, P_i^\sigma, t_i^\sigma\}_{i \in Ag}, I^\sigma, \Pi^\sigma)$, where $I^\sigma = \sigma(I)$, $\Pi^\sigma(s^\sigma) = \bigcap_{s \in \sigma^{-1}(\{s^\sigma\})} \Pi(s)$ and for each agent i*

- $L_i^\sigma = \sigma.i(L_i)$,
- $Act_i^\sigma = Act_i$,
- $P_i^\sigma(l^\sigma) = \bigcup_{l \in \sigma.i^{-1}(\{l^\sigma\})} P_i(l)$,
- $t_i^\sigma(l^\sigma, a, l'^\sigma)$ *iff for some l, l' such that $\sigma.i(l) = l^\sigma$ and $\sigma.i(l') = l'^\sigma$ we have $t_i(l, a, l')$.*

Example 2. Assume that we have two states: s labelled by $\{p, \neg q\}$ and s' labelled by $\{p, q\}$ such that $\sigma(s) = \sigma(s')$. The resulting state will be labelled by $\Pi^\sigma(\sigma(s)) = \{p\}$.

Similarly to the case above the application of a state abstraction function results in the reduction of the number of states in an interpreted system, thereby generating an abstract one.

Given an interpreted system IS, an *abstraction function* is a pair $\delta = (\alpha, \sigma)$, where α is an action abstraction function of IS and σ is an state abstraction function of IS^α.

Definition 9 (Abstraction). *Given an interpreted system $IS = (\{L_i, Act_i, P_i, t_i\}_{i \in Ag}, I, \Pi)$ and an abstraction function $\delta = (\alpha, \sigma)$, the* abstraction *of IS w.r.t. δ is the interpreted system IS^δ that is the state abstraction of IS^α w.r.t. σ.*

3.1 Preservation Theorem

If σ is a state abstraction function and p is a path in an interpreted system IS, then by $\sigma(p)$ we denote the path $\sigma(p^0)\sigma(p^1)\ldots$, i.e., the corresponding path in the abstract interpreted system IS^σ.

The following lemma illustrates the relationship between paths in an interpreted system and its state abstraction.

Lemma 10. *Given an interpreted system IS, let σ be a state abstraction function of IS, $s \in S$ be a state and F^σ_Γ be a strategy for a group of agents $\Gamma \subseteq Ag$. Then there is a strategy F_Γ for the agents in Γ such that $\sigma(out(s, F_\Gamma)) \subseteq out(\sigma(s), F^\sigma_\Gamma)$.*

Proof. Consider IS^σ and a strategy $F^\sigma_\Gamma = \{f^\sigma_i \mid i \in \Gamma\}$. Let $F_\Gamma = \{f_i \mid i \in \Gamma\}$ where $f_i(l^0_i \ldots l^k_i) = \sigma.i^{-1}(f^\sigma_i(\sigma.i(l^0_i)) \ldots \sigma.i(l^k_i)))$. It can be checked that F_Γ is a strategy on IS.

Let $p \in out(s, F_\Gamma)$. So for each state p^j there is a joint action a such that $T(p^j, a, p^{j+1})$. By definition we have that $T^\sigma(\sigma(p^j), a, \sigma(p^{j+1}))$ on IS^σ, and therefore $\sigma(p) \in out(\sigma(s), F^\sigma_\Gamma)$. □

Lemma 11. *Given an interpreted system IS, let α be an action abstraction function of IS, $s \in S$ be a state and F^α_Γ be a strategy for a group of agents $\Gamma \subseteq Ag$. Then there is a strategy F_Γ for Γ such that $out(s, F_\Gamma) \subseteq out(s, F^\alpha_\Gamma)$.*

Proof. Let $\alpha^{-1} \circ F^\alpha_\Gamma$ denote the set $\{\alpha^{-1} \circ f^\alpha_i \mid i \in \Gamma\}$, where α^{-1} is the counter-image of the surjective function α.

It can be checked from the definition of action abstraction that $out(s, \alpha^{-1} \circ F^\alpha_\Gamma) \subseteq out(s, F^\alpha_\Gamma)$. □

We prove the following theorem.

Theorem 12. *Let $\delta = (\alpha, \sigma)$ be an abstraction function for an interpreted system IS . Then, for any state $s \in S$*

1. *If $M^\delta_{IS}, \sigma(s) \models_3 \varphi = \mathrm{tt}$, then $M_{IS}, s \models_3 \varphi = \mathrm{tt}$.*
2. *If $M^\delta_{IS}, \sigma(s) \models_3 \varphi = \mathrm{ff}$, then $M_{IS}, s \models_3 \varphi = \mathrm{ff}$.*

Proof. The proof is by induction on φ.

Consider a state s and the case $\varphi = q$. If $M^\delta_{IS}, \sigma(s) \models_3 q = \mathrm{tt}$, then $q \in \Pi^\delta(s)$. It follows by definition that $q \in \bigcap_{s' \in \sigma^{-1}(\sigma(s))} \Pi^\alpha(\sigma(s'))$, and so $q \in \Pi^\alpha(s)$. Since $\Pi^\alpha = \Pi$, $q \in \Pi(s)$, we conclude that $M_{IS}, s \models_3 q = \mathrm{tt}$.

If $M^\delta_{IS}, \sigma(s) \models_3 q = \mathrm{ff}$, then $\neg q \in \Pi^\delta(s)$. By similar considerations we can conclude that $\neg q \in \bigcap_{s' \in \sigma^{-1}(s)} \Pi^\alpha(s')$, so $\neg q \in \Pi^\alpha(s) = \Pi(s)$ and $M_{IS}, s \models_3 q = \mathrm{ff}$.

Assume that $\varphi = \neg\varphi'$. If $M^\delta_{IS}, \sigma(s) \models_3 \neg\varphi' = \mathrm{tt}$, then $M^\delta_{IS}, \sigma(s) \models_3 \varphi' = \mathrm{ff}$. By the inductive assumption $M_{IS}, s \models_3 \varphi' = \mathrm{ff}$, and therefore $M_{IS}, s \models_3 \neg\varphi' = \mathrm{tt}$. Similarly, if $M^\delta_{IS}, \sigma(s) \models_3 \neg\varphi' = \mathrm{ff}$, then $M_{IS}, s \models_3 \neg\varphi' = \mathrm{ff}$.

The case for $\varphi = \varphi_1 \wedge \varphi_2$ is straightforward through by the inductive hypothesis.

The other inductive cases can be shown by using Lemma 10 and 11. We only report the case of $M^\delta_{IS}, \sigma(s) \models_3 \langle\!\langle\Gamma\rangle\!\rangle \varphi_1 U \varphi_2 = \mathrm{tt}$; the others can be proven similarly.

Assume that $M^\delta_{IS}, \sigma(s) \models_3 \langle\!\langle\Gamma\rangle\!\rangle \varphi_1 U \varphi_2 = \mathrm{tt}$ and let $F^\delta_\Gamma = \{f^\delta_i \mid i \in \Gamma\}$ be a strategy such that for all $p^\delta \in out(\sigma(s), F^\delta_\Gamma)$, there is $k \geq 0$ s.t. $M^\delta_{IS}, p^k \models_3 \varphi_2 = \mathrm{tt}$ and for all $0 \leq j < k$ we have $M^\delta_{IS}, p^j \models_3 \varphi_1 = \mathrm{tt}$.

Let F^α_Γ be a strategy obtained by applying Lemma 10 to F^δ_Γ, and F_Γ be a result of applying Lemma 11 to F^α_Γ.

Consider any $p \in out(s, F_\Gamma)$. By Lemmas 10 and 11, $\sigma(p) \in out(\sigma(s), F^\delta_\Gamma)$, and therefore for some $k \geq 0$ we have $M^\delta_{IS}, \sigma(p)^k \models_3 \varphi_2 = \mathrm{tt}$ and for all $0 \leq j < k$ we have $M^\delta_{IS}, \sigma(p)^j \models_3 \varphi_1 = \mathrm{tt}$.

By the inductive hypothesis we have that $M_{IS}, p^k \models_3 \varphi_2 = \mathrm{tt}$ and for all $0 \leq j < k$, $M_{IS}, p^j \models_3 \varphi_1 = \mathrm{tt}$. It follows that $M_{IS}, s \models_3 \langle\!\langle\Gamma\rangle\!\rangle \varphi_1 U \varphi_2 = \mathrm{tt}$. □

Observe that the theorem above holds irrespective of any assumption on the strategies being memoryless or memoryfull.

Remark. There are an interpreted system IS, a state abstraction function σ, an action abstraction function α, and an ATL property φ s.t. $IS \models_2 \varphi$ but $IS^\alpha \not\models_2 \varphi$ and $IS^\sigma \not\models_2 \varphi$.

Indeed, consider the IS from Example 1 but with a different labelling function: $\Pi((l_A, l_A)) = \Pi((l_A, l_B)) = \{q\}$ and $\Pi((l_B, l_A)) = \Pi((l_B, l_B)) = \{\neg q\}$. Let $\varphi = \langle\!\langle 1\rangle\!\rangle X q$. Clearly, $IS \models_2 \varphi$. Consider an action abstraction function α such that $\alpha((a_1, a_2)) = (\epsilon, \epsilon)$ for all $a_1, a_2 \in \{a_A, a_B\}$. We have $IS^\alpha \not\models_2 \varphi$ since in the initial state 1 can only play action ϵ which may lead to the state (l_B, l_B) labelled with $\neg q$. Similarly, consider a state abstraction function σ such that $\sigma((s_1, s_2)) = (\epsilon, \epsilon)$ for all $s_1, s_2 \in \{l_A, l_B\}$. The state abstraction IS^σ of IS w.r.t. σ contains only one state (ϵ, ϵ) s.t. $\Pi^\sigma((\epsilon, \epsilon)) = \emptyset$, and therefore $IS^\sigma \not\models_2 \varphi$.

4 Model Checking Using Abstraction

In this section we put forward a methodology based on the abstraction results of the previous Section to model check multi-agent systems against ATL specifications. Recall that the model checking problem is defined as follows.

Definition 13 (Model checking problem). *Given an interpreted system IS and an ATL specification φ, the* model checking problem *involves establishing whether $IS \models_2 \varphi$.*

The following theorem was stated in (Alur, Henzinger, and Kupferman 2002) and, to the best of our knowledge, showed in (Dima and Tiplea 2011).

Theorem 14. *Model checking interpreted systems with perfect recall and imperfect information against ATL specifications is undecidable.*

However, the problem is decidable if memoryless (as opposed to perfect recall) strategies are considered (Schobbens 2004). Recall that $\Delta^P_2 = \mathrm{P}^{\mathrm{NP}}$ is the class of problems that can be solved in polynomial time by a deterministic Turing machine with an NP oracle.

Theorem 15. *Model checking interpreted systems with imperfect information and memoryless strategies against ATL specifications is decidable in Δ^P_2.*

The above complexity is given in the size of the model associated with an interpreted system (observe that the complexity on the size of the interpreted system itself is likely to be harder (Lomuscio and Raimondi 2006a)). However, note

that models of interpreted systems may be exponential in size of the interpreted system that generates them. Since model checkers typically work on the generated models, this creates the well-known difficulty of the *state-space explosion*.

To mitigate this difficulty in the following we develop a technique that allows us to avoid the construction of the (concrete) model associated with an interpreted system and consider its abstraction instead. By the results of the previous section, in several cases this will prove sufficient.

More specifically we proceed as follows. Given an interpreted system and a formula to be verified, firstly we build an action abstraction, then a state abstraction from it (see Subsection 4.2) and attempt verification on the result (see Subsection 4.1). If the result is either tt or ff we know that (via Theorem 12) this is also the result of the check on the concrete model. Otherwise, we perform a refinement procedure (see Subsection 4.3) to obtain a further abstract model and attempt verification again. We repeat this procedure until we obtain a model in which the specification can be verified.

4.1 Three-valued model checking interpreted systems

We extend the classical model checking problem recalled above into the more general formulation below.

Definition 16 (Three-valued model checking problem). *Given an interpreted system IS, an ATL specification φ and a truth value $b \in \{\mathrm{ff}, \mathrm{uu}, \mathrm{tt}\}$, the* three-valued model checking problem *involves establishing whether $IS \models_3 \varphi = b$.*

We can show that model checking interpreted systems against ATL specifications under a three-valued semantics and memoryless strategies is also in Δ_2^P.

Proposition 17. *Three-valued model checking interpreted systems with imperfect information and memoryless strategies against ATL specifications is decidable in Δ_2^P.*

Proof. For each subformula, starting from the propositions, label all the states with the value of the formula in this state, using the values of its subformulas. This is straightforward in all cases except the subformulas of the form $\langle\langle\Gamma\rangle\rangle$; in these cases call a non-deterministic oracle a polynomial number of times to obtain a strategy as required. Since $\Delta_2^P = P^{NP}$, we obtain the result. □

Notice that the above procedure establishes the value of each subformula in each state. We will use this property later to define the refinement procedure.

4.2 Initial abstraction

Let $A(\varphi)$ denote the set of agents in φ and $\mathcal{V}(\varphi)$ be the set of propositional variables in φ. For an interpreted system IS and a local state $l_i \in L_i$, the labelling of l_i is $\Pi(l_i) = \bigcap_{s \in S, s.i = l_i} \Pi(s)$.

For a set of agents Γ, we define $\alpha^I_{IS}(\Gamma)$ to be the action abstraction function α for IS such that for every agent $i \in \Gamma$ we define $\alpha.i(a_i) = a_i$, and for every $i \notin \Gamma$ we let $\alpha.i(a_i) = \epsilon$. So, in other words, $\alpha^I_{IS}(\Gamma)$ returns an interpreted system disregarding all actions not in Γ.

Given an action abstraction function α and a set of literals V, let $\sigma^I_{IS}(\alpha, V)$ denote the state abstraction function σ for IS^α such that for each agent $i \in Ag$, $\sigma.i(l) = \sigma.i(l')$ iff $\Pi(l) \cap V = \Pi(l') \cap V$ and $P_i^\alpha(l) = P_i^\alpha(l')$. So $\sigma^I_{IS}(\alpha, V)$ defines an interpreted system in which states agreeing on literals in V are collapsed onto a single abstract state as long as all agents have the same protocol in these states.

Definition 18 (Initial abstraction function). *Let IS be an interpreted system and φ be an ATL specification. The* initial abstraction function *for IS is the pair $\delta^I_{IS}(\varphi) = (\alpha^I_{IS}(A(\varphi)), \sigma^I_{IS}(\alpha^I_{IS}(A(\varphi)), \overline{\mathcal{V}(\varphi)}))$. $IS^{\delta^I_{IS}(\varphi)}$ denotes the* initial abstraction *of the interpreted system IS w.r.t. $\delta^I_{IS}(\varphi)$.*

In summary the initial abstraction function collapses all actions of agents not referred to in the specification; from this interpreted system all states with the same labelling and the same protocol are further collapsed.

We exemplify this definition in Section 5.

4.3 Refinement

As mentioned earlier, it may be that $IS^{\delta^I_{IS}(\varphi)} \models_3 \varphi = \mathrm{uu}$, i.e., the initial abstraction is not sufficient to determine the value of φ. In these cases we need to refine $\delta^I_{IS}(\varphi)$. Unlike the classic technique (Clarke et al. 2000), our refinement procedure focuses on the states for which the value of some subformula of φ is uu.

Let $\preceq$ be any linear order on formulas of ATL such that if ψ is a subformula of ψ', then $\psi \preceq \psi'$. Let $Sub(\varphi)$ stand for the set of all the subformulas of φ (including φ itself). An *evaluation* of φ on an interpreted system IS is a function $L : S \times Sub(\varphi) \to \{\mathrm{ff}, \mathrm{uu}, \mathrm{tt}\}$ such that for all $s \in S, \varphi' \in Sub(\varphi)$ we have $L(s, \varphi')$ is the result of the $M_{IS}, s \models_3 \varphi'$. Note that one can easily adjust the model checking algorithm presented in Proposition 17 to return the evaluation.

We now discuss the refinement procedure REFINE (see Algorithm 1) that takes as input an interpreted system IS, an abstraction function δ, a specification φ, an evaluation L of φ on IS^σ and returns an abstraction function δ'.

Firstly, REFINE computes the set Φ of subformulas φ' of φ s.t. for some s^δ s.t. there are at least two states $s, s' \in S$ s.t. $\sigma(s) = \sigma(s') = s^\delta$ we have $L(s^\delta, \varphi) = \mathrm{uu}$. If Φ is not empty, we take the smallest element ψ and split all the abstract states s^δ s.t. $L(s^\delta, \psi) = \mathrm{uu}$ by using the function SPLITS_STATES. If Φ is empty, we refine the action abstraction function.

The function SPLITS_STATES(IS, σ, S_{uu}) defines a state abstraction function σ' that agrees with σ on all the local states not in S_{uu}. For the remaining states, there are two possibilities. If there are two states $s, s' \in S_{\mathrm{uu}}$ and an agent i such that $\sigma.i(s.i) = \sigma.i(s'.i)$ and $\Pi(s.i) \neq \Pi(s'.i)$, then σ' splits the abstracted states into states corresponding to different labelling; otherwise σ' separates all the local states in S_{uu}.

The refinement procedure above focuses mostly on the state abstraction function, revising the action abstraction function only if no further updates to the state abstraction function are useful. This is optimised for ATL specifications of the form $\langle\langle\Gamma\rangle\rangle\varphi'$, where φ' does not contain a further $\langle\langle\rangle\rangle$ operator. Most concrete ATL specifications follow this pattern. Indeed,

Algorithm 1 The refinement procedure.

procedure REFINE(IS, $\delta = (\alpha, \sigma)$, φ, L)
  $MS^\delta \leftarrow \{s^\delta \in S^\delta \mid |\sigma^{-1}(\{s^\delta\})| > 1\}$
  $\Phi \leftarrow \{\varphi' \in Sub(\varphi) \mid \exists s^\delta \in MS^\delta . L(s^\delta, \varphi') = \mathrm{uu}\}$
  if Φ is not empty **then**
    $\alpha' \leftarrow \alpha$
    $S_{\mathrm{uu}} \leftarrow \{s \in S \mid L(\sigma(s), \min_{\preceq}(\Phi)) = \mathrm{uu}\}$
    $\sigma' \leftarrow$ SPLIT_STATES(IS, σ, S_{uu})
  else if $\alpha = \alpha^I_{IS}(A(\varphi))$ **then**
    $\alpha' \leftarrow \alpha^I_{IS}(Ag \setminus A(\varphi))$
    $\sigma' \leftarrow \sigma^I_{IS}(\alpha', \overline{\mathcal{V}(\varphi)})$
  else if $\alpha = \alpha^I_{IS}(Ag \setminus A(\varphi))$ **then**
    $\alpha' \leftarrow id$
    $\sigma' \leftarrow \sigma^I_{IS}(\alpha', \overline{\mathcal{V}(\varphi)})$
  else $\sigma' \leftarrow id$, $\alpha' \leftarrow id$
  return (α', σ')
procedure SPLIT_STATES(IS, σ, S_{uu})
  $split\_all \leftarrow \forall s, s' \in S_{\mathrm{uu}} . \forall i \in Ag . \sigma.i(s.i) = \sigma.i(s'.i) \Rightarrow \Pi(s.i) = \Pi(s'.i)$
  for $i \in Ag, l_i \in L_i$ **do**
    if $\exists s \in S_{\mathrm{uu}}\ s.i = l_i$ **then**
      if $split\_all$ **then** $\sigma'.i(l_i) \leftarrow l_i$
      else $\sigma'.i(l_i) \leftarrow (\sigma.i(l_i), \Pi(l_i))$
    else $\sigma'.i(l_i) \leftarrow \sigma.i(l_i))$
  return σ'

when evaluating whether $M_{IS}, s \models_3 \langle\langle\Gamma\rangle\rangle\varphi' = \mathrm{tt}$ the labels of the actions for the agents not in Γ are irrelevant. This is why the initial abstraction collapses them. Conversely, when evaluating $M_{IS}, s \models_3 \langle\langle\Gamma\rangle\rangle\varphi' = \mathrm{ff}$ the actions that matter are those of $Ag \setminus \Gamma$; this is reflected in the first refinement of the action abstraction function. If none of the above is effective, we use the identity.

4.4 Model Checking with Refinement

In view of the constructions above, we can now give the overall model checking algorithm for verifying an interpreted system IS against an ATL specification φ as the procedure VERIFY at Algorithm 2. The procedure calls the function EVALUATE which labels the structure, as discussed in Proposition 17, and returns the appropriate evaluation function.

Algorithm 2 The verification procedure.

procedure VERIFY(IS, φ)
  $\delta \leftarrow \delta^I_{IS}(\varphi)$
  while $\delta \neq (id, id)$ **do**
    $L \leftarrow$EVALUATE(IS^δ, φ)
    if $\exists s \in I . L(\sigma(s), \varphi) = \mathrm{ff}$ **then return** ff
    else if $\forall s \in I . L(\sigma(s), \varphi) = \mathrm{tt}$ **then return** tt
    else $\delta \leftarrow$REFINE(IS, δ, L)
  return uu

The algorithm proposed first constructs the initial abstraction δ^I_{IS}. A first check is made for the truth value of φ on δ^I_{IS}. If one abstract state corresponding to a concrete initial state does not satisfy φ, by Theorem 12 we deduce that the specification does not hold on the concrete interpreted system. Similarly if φ is satisfied in all abstract states corresponding to all concrete initial states, we deduce that the specification is satisfied on the original model. If neither of these cases holds, we refine the initial abstraction by following the REFINE procedure above and repeat the evaluation tests. Note that the procedure always terminates; in the worst case it will attempt to perform the verification on the original, concrete model.

While in the worst case the procedure is worse than a single initial check on the concrete model, it is possible that either the initial abstraction or one of its refinements will determine the value of the specifications. The reduced models may be much smaller than the original concrete model, which may be too large to be verified even by using symbolic techniques. Even if the concrete model can be handled by concrete techniques, the procedure above offers an attractive methodology for reducing the time and memory footprint of the verification step.

5 Verification of Simbridge

In this section we exemplify the methodology above on *Simbridge*, a simple two player trick-taking game. We encode the game as an interpreted system and verify a specification by using the abstraction technique presented above.

The game is played with a deck of 26 cards (13 red and 13 black). Cards are numbered from 1 to 13. The goal of each player is to win the most number of rounds, or *tricks*.

Each player is initially given 13 cards by the croupier. The game is played in 13 rounds. The first player is called the *lead player* of the first round; in all the other rounds the lead player is the player who won the previous trick. In each round the lead player plays any card from his hand; the other player has to respond by playing a card in the same colour. The player who played the card with the higher number wins the trick. If a player cannot play a card in the colour of the card played by the first player, he can respond by playing any card and he loses the trick. If a player has a card in the required colour but plays a card in a different colour, he loses for cheating.

5.1 Game encoding

We model the game as an interpreted system IS comprising four agents: Croupier, Player 1, Player 2 and Scorekeeper.

Croupier. The game begins with Croupier distributing the cards to the players as follows. For each card, starting from 1 Red, Croupier assigns the card to a player by either using the action 1 or 2. If a player has already been given 13 cards, all remaining cards are given, one by one, to the other player. After distributing all the cards, Croupier plays the action ϵ for the rest of the game.

Croupier's 14^2 local states are tuples where each local state (k, l) represents the situation where Player 1 was given k cards and Player 2 was given l cards. The Croupier's protocol is defined as follows: in a state (k, l) Croupier can perform action 1 (resp. 2) if $k < 13$ (resp. $l < 13$). If action 1 (resp. 2) is performed, Croupier moves to the state $(k + 1, l)$

Structure	Actions	States
Original structure (IS)	2187	10^{27}
Initial abstraction (IS^{σ})	3	10^{3}
Refinement (IS^{R})	3	10^{8}

Table 1: Estimated sizes of the interpreted systems from Section 5.

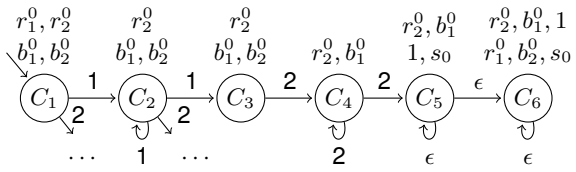


Figure 1: A fragment M^{δ}_{IS}, the model associated with the initial abstraction.

(resp. $(k, l+1)$) regardless on the other agents' actions. Once Croupier is in the state $(13, 13)$ he loops in this state by performing the action ϵ. Note that in this formalisation Croupier does not remember the cards' distribution.

Players. The players are symmetrical and follow the same formalisation. We represent the player's local states as (lp, pc, H), where H is the set of cards in the player's hand, $lp \in \{1, 2, C\}$ and $pc \in \{\mathrm{Red}_1, \ldots, \mathrm{Black}_{13}\} \cup \{\emptyset\}$. If $lp = C$ then the game is in the phase when the cards are being distributed and pc represents the previously distributed card. If $lp \neq C$, then tricks are being played, lp represents the current lead player and pc encodes the first card played in the current round. It can be computed that there are approximately 2^{25} combinations; so each player has approximately 2^{31} possible local states.

The set of local actions contains ϵ, which players use when it is not their turn, and the actions $\mathrm{Red}_1, \ldots, \mathrm{Black}_{13}$ that the players use to play a card when it is their turn. We assume that the protocol only insists on playing cards in the players' hands, i.e., players may not follow the colour played.

The transitions are defined as expected. Players begin with $lp = C$ and update their state while cards are being distributed. Then players start playing cards from their hands and update their state accordingly.

Scorekeeper. The scorekeeper's local states contain the states $Cheated_1$, $Cheated_2$ to represent situations where some of the players have cheated during the game, and tuples of the form (lp, pc, SG) where $lp \in \{1, 2, C\}$ represents the lead player, $pc \in \{\mathrm{Red}_1, \ldots, \mathrm{Black}_{13}\} \cup \{\emptyset\}$ represents the first card played in the current round, if $lp \neq C$ and the last card distributed if $lp = C$. SG is a tuple $SG = (S, R1, R2, B1, B2)$ representing the *state of the game* after each round where no player has cheated. Ri represents the number of red cards in the hand of Player i; Bi represents the number of black cards in the hand of Player i; S represents the number of tricks won by Player 2. Some of the local states of Scorekeeper are not reachable during a game (e.g., states where $R1 + R2 > 13$). By considering this we can estimate that there are approximately $2.5 \times 10^6 \approx 2^{21}$ states possible local states for Scorekeeper.

Scorekeeper starts in the state $(C, \emptyset, (0, 0, 0, 0, 0))$ and then updates his states on the basis of the actions of Croupier and the players.

Global states and variables. We can define the set of global states for the system by considering tuples containing the local states for the agents defined above. The initial states for the system are those obtained by considering the initial local states of the agents defined above. We can ascertain there are at least $196 \cdot 2^{31} \cdot 2^{31} \cdot 2^{21} \approx 10^{27}$ global states defined as above. This constitutes a size that would normally not be verifiable even by an advanced, symbolic model checker.

We use the following propositional variables: 1, 2, s^i, r_1^i, r_2^i, b_1^i, b_2^i for $i \in \{0, \ldots, 13\}$. Their truth value depends on the Scorekeeper's state. So if in a global state the Scorekeeper is in the local state $(lp, pc, (S, R1, R2, B1, B2))$, then the variables $lp, pc, s^S, r_1^{R1}, r_2^{R2}, b_1^{B1}, b_2^{B2}$ hold at that state. The variable ch_i holds at any global state where Scorekeeper's local state includes $Cheated_i$.

5.2 A specification of interest

From the description above it is easy to see that Croupier can ensure that Player 1 wins the game. Croupier can for instance give all the red cards to Player 1; since Player 1 starts the game, Player 2 will never win a trick.

For convenience we use the following Boolean formulas.

$$\begin{aligned} GameOver &= ((1 \vee 2) \wedge r_1^0 \wedge r_2^0 \wedge b_1^0 \wedge b_2^0) \vee ch_1 \vee ch_2 \\ Wins_1 &= s^0 \vee \cdots \vee s^6 \vee ch_2 \end{aligned}$$

$GameOver$ represents that all rounds have been played, i.e., either the cards have been distributed and no player has any card left, or a player has cheated. $Wins_1$ encodes a situation where Player 1 has won the game, i.e., either Player 2 has cheated or he has won fewer than seven tricks.

Consider the following specifications:

$$\Phi_1 = \langle\!\langle Croupier \rangle\!\rangle G(\neg GameOver \vee Wins_1)$$
$$\Phi_2 = \langle\!\langle Croupier \rangle\!\rangle F(GameOver \wedge Wins_1)$$

The first formula states that Croupier has a strategy to ensure that forever in the future either Player 1 wins or the game does not end. The second states that Croupier can force the system to reach a final state where Player 1 has won the game. We now use the abstraction technique to verify the system against both specifications. As we show below, the initial abstraction is sufficient to verify Φ_1, whereas to verify Φ_2 we need to employ the refinement procedure.

5.3 Abstraction for Φ_1

Consider the initial abstraction function $\delta = (\alpha, \sigma)$ for Φ_1. Since $A(\Phi_1) = \{Croupier\}$, the initial action abstraction α collapses the actions of all the agents except $Croupier$. This entails that the set of abstract actions in IS^{δ} is $ACT^{\delta} = \{(\epsilon, \epsilon, \epsilon, \epsilon), (\epsilon, 1, \epsilon, \epsilon), (\epsilon, 2, \epsilon, \epsilon)\}$.

The initial abstraction function is built by considering the variables $\mathcal{V}(\Phi_1) = \{1, 2, r_1^0, r_2^0, b_1^0, b_2^0, ch_1, ch_2, s^0, \ldots, s^6\}$. We do not present the whole abstract model, but only the fraction that is needed to establish the value of Φ_1.

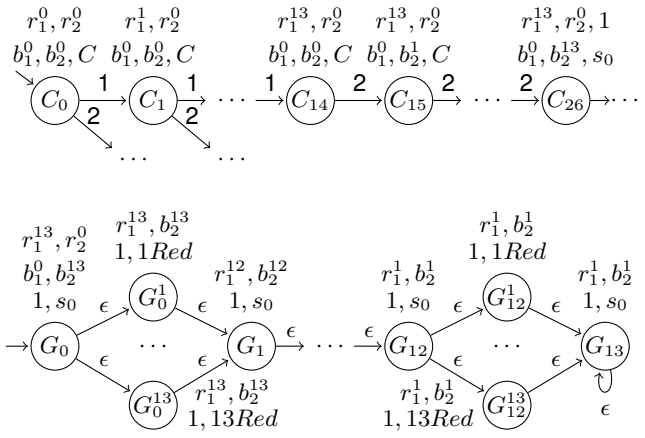

Figure 2: A fragment of the refined structure. For readability, some labels are omited. G_0 and C_{26} denote the same state.

We first describe the part of the structure representing the card distribution. Figure 1 depicts five states of this structure. C_1 is the initial state of M_{IS}^{δ} corresponding to exactly one state in M_{IS}. The abstract state C_2 corresponds to the states in M_{IS} representing situations in which Player 1 received between 1 and 12 red cards and Player 2 did not receive any. State C_3 corresponds to exactly the state in M_{IS} in which Player 1 received 13 red cards and Player 2 did not receive any. Note that the only difference between these states is that Croupier's protocol in C_3 does not allow for 1 to be played. States C_4 and C_5 represent configurations in which Player 1 has all the red cards, and Player 2 received either between 1 and 12 (C_4), or 13 (C_5) black cards.

Consider $F = \{f_{Croupier}\}$ where $f_{Croupier}$ is the following strategy for Croupier: select action 1 in states C_1 and C_2, play action 2 in states C_3 and C_4, and ϵ in all the other states. Then, in $out(C_1, F)$ we have $C_1C_2^{\omega}$, $C_1C_2^+C_3C_4^{\omega}, C_1C_2^+C_3C_4^+C_5^{\omega}, C_1C_2^+C_3C_4^+C_5^+C_6^{\omega}$. It can be easily verified that all the paths satisfy $G\neg(GameOver \wedge Wins_2)$.

Therefore, we have that $IS^{\delta} \models_3 \Phi_1 = \mathrm{tt}$; so by Theorems 5 and 12 we deduce that $IS \models_2 \Phi_1$. The system IS^{δ} is much smaller than IS; its number of states can be bounded by the number of possible valuations of variables from $\mathcal{V}(\Phi_1)$ multiplied by the number of possible protocols; this results in $242 \cdot 4 \approx 10^3$ states. This is a size that can easily be verified on a model checker.

5.4 Abstraction for Φ_2

Since $\mathcal{V}(\Phi_2) = \mathcal{V}(\Phi_1)$ the initial abstraction function δ is the same as the δ for Φ_1 (see Figure 1). It can be checked that Croupier does not have a strategy to force $GameOver$. For example consider $F = \{f_{Croupier}\}$ where $f_{Croupier}$ is a strategy according to which action 1 is selected in C_1 and C_2. Then we have that $C_1C_2^{\omega} \in out(C_1, F)$, but $GameOver$ never holds on this path.

Note that the subformulas of Φ_2 are $\langle\!\langle Croupier \rangle\!\rangle F(GameOver \wedge Wins_1)$, $GameOver \wedge Wins_1$, $GameOver$, $Wins_1$, and all the variables in $GameOver$ and $Wins_1$. Of these, the only subformula that is undefined in some of the states of the abstracted structure is Φ_2. Φ_2 is not undefined only where $GameOver$ is true. It follows that we cannot establish whether Φ_2 holds on the system.

We now therefore execute the refinement procedure REFINE. This returns the same action abstraction function $\alpha' = \alpha$ and the state abstraction function σ' such that $\sigma'(s) = \sigma(s)$ for s satisfying $GameOver$ and $\sigma'(s) = (\sigma(s), \Pi(s))$ for all the remaining states. Let IS^R be the abstract system obtained by refining the initial abstraction by means of (α', σ').

Like IS^{δ}, the system IS^R has only three global actions; its number of states can be bounded by $30079730 \cdot 4 \approx 10^8$. A fragment of this structure is presented in Figure 2. This is a size that can easily be verified by a modern model checker.

Consider now $F = \{f_{Croupier}\}$ where $f_{Croupier}$ is a strategy for Croupier that selects action 1 in states $C_0, \ldots, C_{13}$, action 2 in states $C_{14}, \ldots, C_{25}$ and ϵ at other points. Figure 2 shows that $out(C_0, F)$ consists of the paths of the form $C_0 \ldots C_{26}G_0G_0' \ldots G_{12}G_{12}'G_{13^{\omega}}$, where $G_i' = (G_i^1 + \cdots + G_i^{13})$. It can be checked that all these paths satisfy $F(GameOver \wedge Wins_1)$. It follows that Φ_2 is satisfied in the refinement and therefore, by Theorem 12, we have that it also holds on the concrete model IS.

6 Conclusions

Model checking multiagent systems is now a well-established area of research with results ranging from theoretical investigations to sophisticated implementations. While two notable implementations, jMOCHA and MCMAS, support ATL as a specification language, neither provides abstraction functionalities. Yet, it is well known that abstraction is a fundamental technique to apply when verifying concrete systems.

Abstraction, including refinement, has been developed for epistemic specifications (Cohen et al. 2009) and, of course, temporal ones (Clarke, Grumberg, and Long 1994; Clarke et al. 2000). But in the context of ATL specifications, most of the work has so far focused on the theoretical aspects of the model checking problem, including realistic settings with incomplete information. Yet, to use ATL specifications in practice there is a compelling need for powerful abstraction techniques to reduce the state-spaces of concrete systems. In this paper we intended to make a contribution in this direction.

Our long-term research objective is to verify concrete systems via under-/over-approximations. We have laid the foundations of this by defining a novel three-valued semantics for ATL. We have shown this to be a conservative extension of the classical two-valued one. We have then provided a constructive definition to derive a first, coarse, yet potentially very effective abstraction, and a refinement algorithm that splits states potentially resolving uncertainty in the truth value of the specifications being checked. Applying the procedure to a card game of incomplete information. That showed the first abstraction reduced the state-space by a factor of over 10^{24} to a well-manageable state-space of approximately 10^3. The first specification of interest was satisfied on the first abstraction; the second required us to execute the refinement

algorithm which resulted in a model of approximately 10^8 states. The refined model enabled us to decide on the truth of the second specification; also note that state-spaces in the region of 10^8 can be verified by a model checker for ATL such as MCMAS.

How to Progress Beliefs in Continuous Domains

Vaishak Belle and **Hector J. Levesque**

Dept. of Computer Science
University of Toronto
Toronto, Ontario M5S 3H5, Canada
{vaishak, hector}@cs.toronto.edu

Abstract

When Lin and Reiter introduced the progression of basic action theories in the situation calculus, they were essentially motivated by long-lived robotic agents functioning over thousands of actions. However, their account does not deal with probabilistic uncertainty about the initial situation nor with effector or sensor noise, as often needed in robotic applications. In this paper, we obtain results on how to progress continuous degrees of belief against continuous effector and sensor noise in a semantically correct fashion. Most significantly, and perhaps surprisingly, we identify conditions under which our account is not only as efficient as the filtering mechanisms commonly used in robotics, but considerably more general.

Introduction

Reiter's (2001) reconsideration of the situation calculus (McCarthy and Hayes 1969) has proven enormously useful for the design of logical agents, essentially paving the way for *cognitive robotics* (Lakemeyer and Levesque 2007). Among other things, it incorporates a simple monotonic solution to the frame problem, leading Reiter to define the notion of *regression* for basic action theories (Waldinger 1977). But for long-lived agents like robots, Lin and Reiter (1997) argue that the notion of *progression*, that of continually updating the current view of the state of the world, is perhaps better suited. They show that progression is always second-order definable, and in general, it appears that second-order logic is unavoidable (Vassos and Levesque 2008). However, Lin and Reiter also identify some first-order definable cases by syntactically restricting situation calculus basic action theories, and since then, a number of other special cases have been studied (Liu and Lakemeyer 2009).

While Lin and Reiter intended their work to be used on robots, one criticism leveled at their work, and indeed at much of the work in cognitive robotics, is that the theory is far removed from the kind of continuous uncertainty and noise seen in typical robotic applications. What exactly filtering mechanisms (such as Kalman filters (Thrun, Burgard, and Fox 2005)) have to do with Lin and Reiter's progression has gone unanswered, although it has long been suspected that the two are related.

This paper remedies this situation. Building on a recent extension to the situation calculus for dealing with continuous uncertainty by Belle and Levesque (2013a) (henceforth BL), we investigate progression in continuous domains. In this paper, we make the following contributions:

1. We introduce a property of basic action theories called *invertibility*, closely related to invertible functions in real analysis (Trench 2003). We identify syntactic restrictions on basic action theories that guarantee invertibility.
2. For our central result, we show a first-order *progression* of continuous degrees of belief against continuous noise in effectors and sensors for action theories that are invertible.
3. Finally, we prove that this account of progression is *efficient*. Perhaps surprisingly, under the additional assumption of context-completeness (Liu and Levesque 2005), it is as efficient as commonly used filtering mechanisms in the robotics literature, while considerably more general.

For the structure of this paper, we begin by introducing the formalism, followed by results along the lines of the above three points and conclude after discussion and related work.

The Situation Calculus

The language $\mathcal{L}$ of the situation calculus is a many-sorted dialect of the predicate calculus, with sorts for *physical actions*, *sensing actions, situations* and *objects*, which is a catch-all sort for everything else. A situation represents a history as a sequence of actions. A set of initial situations correspond to the ways the world might be before any action; successor situations are obtained as a result of doing actions. We use α to denote terms of the action sort, and so the term $do(\alpha, s)$ denotes the unique situation obtained on doing α in s. The term $do(\vec{\alpha}, s)$, where $\vec{\alpha}$ is the sequence $\alpha_1 \cdots \alpha_n$, abbreviates $do(\alpha_n, do(\ldots, do(\alpha_1, s)\ldots))$. Initial situations, then, are those without a predecessor:

$$Init(s) \doteq \neg\exists a, s'.\ s = do(a, s').$$

We let the constant S_0 denote the actual initial situation and use the variable ι to range over initial situations only.

To reason about changing properties, $\mathcal{L}$ is assumed to include *fluents*, whose last argument is always a situation term. Without loss of generality, we restrict ourselves to functional

fluents. In addition, we assume that $f_1, \ldots, f_k$ are all the fluents in $\mathcal{L}$, and that these take no arguments other than a single situation term.[1] Note that this is not a propositional theory in that we allow the *values* of the fluents $f_1, \ldots, f_k$ to range over any set. As we are primarily interested in continuous domains, we will make the simplifying assumption that fluents are all real-valued.

Following (Reiter 2001), we call a formula ϕ *uniform* in a situation term σ if σ is the only situation term in ϕ and *rooted* in σ if every situation term in ϕ is of the form $do(\vec{\alpha}, \sigma)$ for some action sequence $\vec{\alpha}$.[2] We often suppress the situation argument in a formula ϕ, or use a distinguished variable *now*. Either way, $\phi[\sigma]$ is used to denote the formula with that variable replaced by the situation term σ.

Basic Action Theory

Again following Reiter, we model dynamic domains by means of a set of sentences $\mathcal{D}$ called a *basic action theory*, consisting of:[3]

- sentences $\mathcal{D}_0$ describing what is true initially;
- precondition axioms describing the executability of actions using a distinguished symbol *Poss*;[4]
- successor state axioms that describe the change to fluents after actions, of the form $f(do(a, s)) = u \equiv \gamma_f(a, u)[s]$;
- domain-agnostic foundational axioms and the unique name axioms for actions, the details of which need not concern us here (Reiter 2001).

We often lump the components in $\mathcal{D}$ other than $\mathcal{D}_0$ as Σ. Properties of the formalism follow as entailments of $\mathcal{D}$, for which standard Tarskian models suffice. We will however be assuming that models assign the usual interpretations to $=, <, >, 0, 1, +, \times, /, -, e, \pi$ and x^y (exponentiation).

The language $\mathcal{L}$ used in this paper is the situation calculus as characterized in (Reiter 2001). Nonetheless, it is very useful to have certain abbreviations that will macro expand to $\mathcal{L}$-formulas. These abbreviations are used as logical terms, that is, as arguments to functions or predicates. If E is such an expression, its expansion is characterized by a definition of the form $E = u \doteq \phi(u)$, where u is a variable, and $\phi(u)$ is an $\mathcal{L}$-formula with u free. This should be interpreted as follows. Let $\rho(u)$ be any atomic formula with u free. Then the expression $\rho(E)$ should be understood as standing for the formula $\exists u(\phi(u) \wedge \rho(u))$. To see this in action, consider the definition of the *conditional-if* expression: $u = \text{If } \exists z\phi \text{ Then } t_1 \text{ Else } t_2$ defined as $(\exists z\phi \supset \forall z(\phi \supset u = t_1)) \wedge (\neg\exists z\phi \supset u = t_2)$. This allows us to write, for example,

$$P(a, \text{If } Q(f, 3) \text{ Then } 4 \text{ Else } 5, b)$$

meaning $(Q(f, 3) \supset P(a, 4, b)) \wedge (\neg Q(f, 3) \supset P(a, 5, b))$. As a consequence of this convention, we will be able to write Reiter's successor state axioms as equality-expressions, and use the RHS as terms than can be substituted in formulas.

For example, imagine a robot moving in a 2-dimensional plane, parallel to a wall, as shown in Figure 1. Let its coordinate be given by (h, v), where h and v are real-valued fluents. Consider an action $mv(z)$ that moves the robot away from the X-axis by z units. Its effect on v might be described by:

$$v(do(a, s)) = u \equiv \exists z(a = mv(z) \wedge u = v(s) + z) \vee u = v(s) \wedge \neg\exists z(a = mv(z)).$$

This says that $mv(z)$ is the only action affecting v, thereby incorporating a solution to the frame problem (Reiter 2001). We would now equivalently write this as:

$$v(do(a, s)) = \text{If } \exists z(a = mv(z)) \text{ Then } v(s) + z \text{ Else } v(s). \quad (1)$$

Thus, successor state axioms axioms are henceforth assumed to be of the form $f(do(a, s)) = E_f(a)[s]$.

We will also use expressions $\int_x t$ and $\sum_x t$ for integration and summation, which are abbreviations defined using second-order logic in BL and (Bacchus, Halpern, and Levesque 1999). Finally, we will often refer to common density functions, such as $\mathcal{N}$ and $\mathcal{U}$ (Gaussian and uniform respectively), which are simply abbreviations for $\mathcal{L}$-terms built from arithmetic symbols and reals.

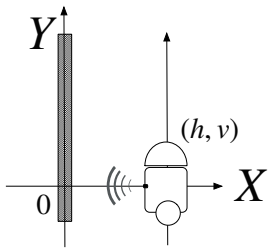

Figure 1: Robot moving parallel to the wall.

Noise and Likelihood

Building on (Bacchus, Halpern, and Levesque 1999), our treatment of noisy acting and sensing will benefit from Reiter's solution to the frame problem. It will involve a new distinguished symbol l for likelihood, where the modeler provides l-axioms in $\mathcal{D}$, one per action $A(\vec{x})$, of the form:

$$l(A(\vec{x}), s) = \Upsilon_A(\vec{x})[s].$$

Let us illustrate its usage with noisy sensors. (Noisy actions are discussed later.) The concern here is that the value read from a sensor may differ from the true value, but in some reasonable way. Imagine a sonar sensor aimed at the wall, and so its reading would correspond to the true value of fluent h. If noisy, one might assume that the likelihood of a reading z is obtained from a normal curve whose mean is h. We then say it has additive Gaussian noise, and this is modeled as:

$$l(sonar(z), s) = \mathcal{N}(z; h, 4)[s] \quad (2)$$

[1] See BL for a discussion of this particular limitation.

[2] Formulas that are rooted in σ are about σ and its future. More general formulas about the future of a situation are considered in (Vassos and Levesque 2008), but not here.

[3] Free variables, here and everywhere else, are assumed to be implicitly quantified from the outside.

[4] For simplicity, we will say no more about *Poss* here, and assume that actions are always executable.

which gives the sensor's reading a variance of 4. Note that the l-axioms are more expressive than those typically seen in probabilistic formalisms, and can be context-dependent. For example, to model a sensor with systematic bias at subzero temperatures, we might have

$$l(sonar(z), s) = \text{If } temp(s) > 0 \text{ Then } \mathcal{N}(z; h, 1) \text{ Else } \mathcal{N}(z; h+2, 1).$$

Degrees of Belief

Probabilistic uncertainty about the initial situation and changing degrees of belief are captured using a single distinguished symbol p. The p fluent can be seen as a numeric variant of the K fluent in the Scherl and Levesque scheme (2003). Intuitively, $p(s', s)$ gives us the probabilistic *density* that the agent attributes to s' when at s. In fully discrete domains, p is the *mass* given to s'.

As part of $\mathcal{D}_0$, the modeler would provide a characterization of the density attributed by the agent to the initial situations. For example,

$$p(\iota, S_0) = \mathcal{U}(h; 2, 12) \times \mathcal{N}(v; 0, 1)[\iota] \tag{3}$$

says that the agent does not know the initial values of h and v, but thinks of them as drawn independently from a uniform distribution on [2, 12], and from a standard normal. Since p is just like any other fluent, the framework is more expressive than many probabilistic formalisms. For example,

$$\begin{array}{c} \forall \iota (p(\iota, S_0) = \mathcal{U}(h; 2, 3)[\iota]) \\ \vee \\ \forall \iota (p(\iota, S_0) = \mathcal{U}(h; 10, 20)[\iota]) \end{array} \tag{4}$$

says that the agent takes h to be uniformly distributed on [2,3] or on [10,20], but without saying which.

To give p the intended properties, the following nonnegative constraint is assumed to be included in $\mathcal{D}$ (Bacchus, Halpern, and Levesque 1999):

$$\forall \iota, s.\ p(s, \iota) \geq 0 \wedge (p(s, \iota) > 0 \supset Init(s)). \tag{P1}$$

This says that p values are never negative, and that they are non-zero only for initial situations. While this is a stipulation about initial situations, the following successor state axiom for p ensures that the nonnegative constraint holds everywhere:

$$p(s', do(a, s)) = \text{If } \exists s''.\ s' = do(a, s'') \wedge Poss(a, s'') \text{ Then } p(s'', s) \times l(a, s'') \text{ Else } 0 \tag{P2}$$

That is, the density of a situation s' relative to $do(a, s)$ is the density of its predecessor s'' times the likelihood of a contingent on the successful execution of a at s''. One consequence of (P1) and (P2) is that $(p(s', s) > 0)$ will be true only when s' and s share the same history of actions.

As discussed in BL, to deal with continuity, the following axiom explicating a precise space of initial situations is needed (Baker 1989; Levesque, Pirri, and Reiter 1998):

$$[\forall \vec{x} \exists \iota \bigwedge f_j(\iota) = x_j] \wedge [\forall \iota, \iota'. \bigwedge f_j(\iota) = f_j(\iota') \supset \iota = \iota'] \tag{P3}$$

This states that for every combination of fluents values, there is a unique initial state where the fluents have these values.

With l and p axioms specified in $\mathcal{D}$, the *degree of belief* in a formula is defined as follows:[5]

Definition 1: Let ϕ be a formula and σ be a situation term, both rooted in *now*. Then $Bel(\phi, \sigma[S_0])$ is defined as

$$\frac{1}{\eta} \int_{\vec{x}} \text{If } \exists \iota \bigwedge f_j(\iota) = x_j \wedge \phi[\sigma[\iota]] \text{ Then } p(\sigma[\iota], \sigma[S_0]) \text{ Else } 0$$

where η is the *normalization* factor and is the same expression as the numerator but with ϕ replaced by *true*.

This says that belief is the result of integrating the density function p over all possible initial values for the real-valued fluents, and hence by (P3), over all possible initial situations. Note that this definition of belief is restricted to cases where the situation term is rooted in S_0.

To summarize, all that was needed to reason about degrees of belief and continuity in the situation calculus were the following components:

- $\mathcal{D}_0$ as usual (possibly mentioning p);
- the action components and foundational axioms as before, including the l-axioms, and p-constraints (P1), (P2) and (P3) (lumped together as Σ);
- abbreviations for *Bel*, integrals, and summation.

It is easy to see that this framework generalizes the categorical knowledge treatment of (Scherl and Levesque 2003). It can also be shown that the belief change mechanism exhibited by the framework subsumes Bayesisan conditioning (Pearl 1988). Finally, the scheme is also applicable to discrete domains: for a discrete fluent f, one would simply replace $\int_x$ with $\sum_x$ ranging over the possible values of f.

Noisy actions

The account of belief in BL left noisy actions for future work. The idea behind noisy actions is that an agent might attempt a physical move of 3 units, say, but as a result of the limited accuracy of effectors, actually move 3.094 units. Thus, unlike sensors, where the reading is nondeterministic, *observable,* but does not affect fluents, the outcome of noisy actions is nondeterministic, *unobservable* and changes fluent properties. Of course, when attempting to move 3 units, the agent knows that an actual move by 3.094 units is much more likely than 30.94 units.

We suggest a simple specification of noisy actions where instead of an action like $mv(x)$, we use an action $mv'(x, y)$ where x is the intended motion (3 units) known to the agent and y is the actual motion (perhaps 3.094 units) unknown to the agent. The successor state axiom for h would be written to reflect the fact that its value is changed by the y value. Unlike noise-free actions where the likelihood is always 1, noisy actions would have non-trivial l-axioms like this one:

$$l(mv'(x, y), s) = \mathcal{N}(y; x, 1 + wet)[s].$$

[5]This is a minor reworking of the definition given in BL, but as it turns out, it has the advantage of working seamlessly with noisy actions as well.

This is a context-dependent axiom that says that the actual value moved is normally distributed around the intended value, but with a variance that depends on the *wet* fluent (a measure of how wet the floor is).

To capture the fact that the agent need not know the actual amount moved, we use *fluents arguments* to the action. For example, to find out the degree of belief in ϕ after a noisy move action, instead of asking for the value of

$$Bel(\phi, do(mv'(3, 3.094), S_0)),$$

we instead ask for the value of something like

$$Bel(\phi, do(mv'(3, g(S_0)), S_0)),$$

where g is a fluent whose value is not known, that stands for the actual amount moved. The fluent g here represents nature's choice of a value, and as it is unaffected by any action, its successor state axiom should be $g(do(a, s)) = g(s)$. The fluent will have different values in different initial states, of course, and so the likelihood of the corresponding mv' action will also vary, as will the density given to the successor situation by (P2). The definition of belief will then integrate over all possible values of g as appropriate.

In general, a fluent can be used like this to handle any argument to an action whose value is not known to the agent. We believe this account is much simpler than the version of noisy actions given in (Bacchus, Halpern, and Levesque 1999) which relied on Golog.

Invertible Action Theories

What we are after is an account of progression for belief in the presence of continuous noise. However, subtleties arise with the p fluent even in simple domains. For example, imagine a noise-free action *towall*(z) that moves the robot towards the wall but stopping when the robot hits the wall:

$$h(do(a, s)) = \text{If } \exists z(a = towall(z)) \text{ Then } \max(0, h(s) - z) \text{ Else } h(s). \quad (5)$$

If the robot were to begin with (3) and perform the action *towall*(4), beliefs about the new value of h become much more complex. Roughly, those points where $h \in [2, 4]$ initially are mapped to a single point $h = 0$ that should then obtain a probability *mass* of .2, while the other points retain their initial *density* of .1. In effect, a probability density on h is transformed into a mixed density / distribution (and the (P3) assumption no longer holds). BL deal with this issue using *regression*: beliefs are regressed to the initial state where (P3) does hold, and all the actual belief calculations can be done in the initial state (Belle and Levesque 2013b).

In this paper, we develop a logical theory of progression for basic action theories where such mixed distributions do not arise. In this section, we provide a simple definition to support this, and then discuss general syntactic restrictions that satisfy this requirement.

Definition 2: Given a basic action theory $\mathcal{D}$, a fluent f is said to be *invertible* if there is an expression $H_f(a)$ uniform in *now* such that $\mathcal{D} \models f(s) = H_f(a)[do(a, s)]$. We say that $\mathcal{D}$ is invertible if every fluent in the theory is invertible.

Intuitively, a fluent is invertible when we can find a dual formulation of its successor state axiom, that is, where we can characterize the *predecessor* value of a fluent in terms of its current value.

There are three syntactic conditions on a basic action theory $\mathcal{D}$ that are sufficient to guarantee its invertibility:

i. There is an ordering on fluents such that all the fluents that appear in $E_f(a)$ other than f are earlier in the ordering.

ii. Any situation term in $E_f(a)$ appears as an argument to one of the fluents.

iii. The mapping from the value of $f(s)$ to the value of $f(do(a, s))$ given by $E_f(a)$ is bijective (Trench 2003). (This is understood in the usual set-theoretic sense.)

Before considering some examples, here is the result:

Theorem 3: *If a basic action theory satisfies (i), (ii) and (iii) above, then it is invertible.*

Proof sketch: The proof is by induction on the ordering given by (i). By (iii), we can take $f(do(a, s)) = E_f(a)[s]$ and solve for $f(s)$, obtaining an equation $f(s) = H$, where H mentions $f(do(a, s))$ and possibly other fluents $f'(s)$ that appear earlier in the ordering. By induction, each $f'(s)$ in H can be replaced by $H_{f'}(a)[do(a, s)]$. By (ii), the result will then be uniform in $do(a, s)$, and thus we obtain a formula $H_f(a)$ where $\mathcal{D} \models f(s) = H_f(a)[do(a, s)]$ as desired. ∎

Example 4: Consider (1). This trivially satisfies (i) and (ii). The mapping from $v(s)$ to $v(do(a, s))$ is bijective and so (iii) is satisfied also. (In general, any $E_f(a)$ that is restricted to addition or multiplication by constants will satisfy (iii).) So the fluent is invertible and we have $v(s) = H_v(a)[do(a, s)]$, where $H_v(a)$ is If $\exists z(a = mv(z))$ Then $v - z$ Else v.

Example 5: Consider (5). Here the mapping is not bijective because of the *max* function and the fluent h is not invertible. If $h(do(\alpha, s)) = 0$ where $\alpha = towall(4)$, then the value of $h(s)$ cannot be determined and can be anything less than 4.

Example 6: Consider a successor state axiom like this:

$$v(do(a, s)) = \text{If } \exists z(a = mv(z)) \text{ Then } (v(s))^z \text{ Else } v(s).$$

For $\alpha = mv(2)$, we obtain a squaring function, which is not bijective. Indeed, from $v(do(\alpha, s)) = 9$, one cannot determine whether $v(s)$ was -3 or 3. So the fluent is not invertible.

Example 7: Consider this successor state axiom:

$$v(do(a, s)) = \text{If } \exists z(a = rapid(z)) \wedge wax(s) \leq .3 \text{ Then } v(s) + (fuel(s))^z \text{ Else } v(s).$$

Suppose further:

$$fuel(do(a, s)) = \text{If } \exists z(a = fill(z)) \text{ Then } z \cdot fuel(s) \text{ Else } fuel(s).$$

$$wax(do(a, s)) = \text{If } a = clean \text{ Then } wax(s)/10 \text{ Else } wax(s).$$

Here, the fuel tank and the wax on the floor determine the distance moved, and one can clean the floor wax and fill the tank. This theory is invertible, and $H_v(a)$ is given by

$$H_v(a) = \text{If } \exists z(a = rapid(z)) \wedge wax \leq .3 \text{ Then } v - fuel^z \text{ Else } v.$$

That is, because *rapid*(z) does not affect *wax* and *fuel*, we simply invert the successor state axiom for v and relativize everything to $do(a, s)$. If (say) the action *rapid(z)* also affected *fuel*, by the ordering in (i), we would first obtain the H-expression for *fuel* and use it in the H-expression for v.

Finally, note that the bijection property does not prevent us from using non-bijective functions, such as squares, in the successor state axiom of v, provided that these only apply to the other fluents. (The remaining fluents essentially behave as constants at any given situation.) In our experience, many commonly occurring successor state axioms are invertible.

Progression

In this section we propose a definition of progression that applies to any invertible basic action theory. Note that the definition of invertibility imposes no constraint on $\mathcal{D}_0$. So the definition in this section is general in that the p may appear in $\mathcal{D}_0$ in an unrestricted way, such as in (4). Given such a theory $\mathcal{D}_0 \cup \Sigma$ and a ground action α, we define a transformation $\mathcal{D}_0'$ such that $\mathcal{D}_0' \cup \Sigma$ agrees with $\mathcal{D}_0 \cup \Sigma$ on the future of α. Then, in the next section, we will consider how $\mathcal{D}_0'$ grows as a result of this progression.

Classical Progression

Let us first consider the simpler case of progression for a $\mathcal{D}_0$ that does not mention the p fluent (and the quantification over initial situations that comes with it), and so where $\mathcal{D}_0$ is uniform in S_0. In this case, because we are assuming a finite set of nullary fluents, any basic action theory can be shown to be *local-effect* (Liu and Lakemeyer 2009), where progression is first-order definable. The new theory is computed by appealing to the notion of *forgetting* (Lin and Reiter 1994). If the basic action theory is invertible, however, the progression can *also* be defined in another way. Let $\mathcal{D}_0'$ be $\mathcal{D}_0$ but with any $f(S_0)$ term in it replaced by $H_f(\alpha)[S_0]$.

Theorem 8: *Let $\mathcal{D}_0 \cup \Sigma$ be any invertible basic action theory not mentioning p and α any ground action. Then for any $\mathcal{L}$-formula ϕ rooted in now*

$$\mathcal{D}_0 \cup \Sigma \models \phi[do(\alpha, S_0)] \;\; \textit{iff} \;\; \mathcal{D}_0' \cup \Sigma \models \phi[S_0].$$

Example 9: Consider (1), and the $H_v(a)$ from Example 4. Suppose $\mathcal{D}_0 = \{v(S_0) > 10\}$. Then:

$$\begin{aligned}\mathcal{D}_0' &= (H_v(mv(3))[S_0]) > 10\\ &= (\textsc{If}\ \exists z(mv(z) = mv(3))\\ &\qquad \textsc{Then}\ v(S_0) - z\ \textsc{Else}\ v(S_0)) > 10\\ &= (v(S_0) - 3 > 10)\\ &= (v(S_0) > 13).\end{aligned}$$

Therefore, as expected, the progression of $v(S_0) > 10$ wrt a noise-free motion of 3 units is $v(S_0) > 13$. (The unique name axiom and arithmetic are used in the simplification.)

Progressing Degrees of Belief

There are two main complications when progressing beliefs wrt noisy sensors and actions. First, the p fluent will have to take the likelihood of the action α into account. Second, $\mathcal{D}_0$ need not be uniform in S_0, since p typically requires quantification over initial situations (as in (3), for example). This leads to the following definition:

Definition 10: Let $\mathcal{D}_0 \cup \Sigma$ be an invertible basic action theory and α be a ground action of the form $A(\vec{t})$ where $\vec{t}$ is uniform in *now*.[6] Then $Pro(\mathcal{D}_0, \alpha)$ is defined as $\mathcal{D}_0$ with the following substitutions:

- $p(\iota, S_0)$ is replaced by $\dfrac{p(\iota, S_0)}{\Upsilon_A(\vec{t})[\iota]}$;
- every other fluent term $f(u)$ is replaced by $H_f(\alpha)[u]$.

Here, $\Upsilon_A(\vec{x})$ refers to the RHS of the likelihood axiom for $A(\vec{x})$.

The main result of this paper is the correctness of this definition of progression:

Theorem 11: *Under the conditions of the definition above, let $\mathcal{D}_0' = Pro(\mathcal{D}_0, \alpha)$. Suppose that $\mathcal{D}_0 \models (\Upsilon_A(\vec{t}) \neq 0)[S_0]$. Then for any $\mathcal{L}$-formula ϕ rooted in now,*

$$\mathcal{D}_0 \cup \Sigma \models \phi[do(\alpha, S_0)] \;\; \textit{iff} \;\; \mathcal{D}_0' \cup \Sigma \models \phi[S_0].$$

Proof sketch: The proof is based on ideas in (Lin and Reiter 1997). To show that $\mathcal{D}_0' \cup \Sigma$ is the progression of $\mathcal{D}_0 \cup \Sigma$, we need to show that for any model M, M is a model of $\mathcal{D}_0' \cup \Sigma$ iff there is a model M' of $\mathcal{D}_0 \cup \Sigma$ such that for any ϕ, $M \models \phi[S_0]$ iff $M' \models \phi[do(\alpha, S_0)]$. We then use the fact that for any situation term σ, $f(\sigma)$ and $f(do(\alpha, \sigma))$ are related precisely to each other in terms of $E_f(\alpha)$ and $H_f(\alpha)$ to satisfy this model-theoretic property. ∎

This theorem gives us the desired property for *Bel* (which is defined in terms of p) as a corollary:

Corollary 12: *Suppose $\mathcal{D}_0, \Sigma, \mathcal{D}_0', \phi$, and α are as above. Then for all real numbers n:*

$$\begin{aligned}&\mathcal{D}_0 \cup \Sigma \models \textit{Bel}(\phi, do(\alpha, S_0)) = n\\ &\qquad \textit{iff} \quad \mathcal{D}_0' \cup \Sigma \models \textit{Bel}(\phi, S_0) = n.\end{aligned}$$

Thus the degree of belief in ϕ after a physical or sensing action is equal to the initial belief in ϕ in a progressed theory.

We now present some examples, considering, in turn, noise-free actions, noisy sensing and finally noisy actions.

Example 13: Let us consider an action theory with a vertical action *mv*(z), a sensing action *sonar*(z) and two horizontal actions: *towards* moves the robot halfway towards the wall and *away* moves the robot halfway away from the wall. Formally, let $\mathcal{D}_0 \cup \Sigma$ be an action theory where $\mathcal{D}_0$ contains just (3), and Σ includes

- foundational axioms and (P1)-(P3) as usual;
- a l-axiom for *sonar*(z), namely (2);
- l-axioms for the other actions, which are noise-free, and so these simply equal 1;
- a successor state axiom for v, namely (1);
- the following successor state axiom for h:

$$\begin{aligned}&h(do(a, s)) =\\ &\quad \textsc{If}\ a = \textit{away}\ \textsc{Then}\ 3/2 \cdot h(s)\\ &\quad \textsc{Else If}\ a = \textit{towards}\ \textsc{Then}\ 1/2 \cdot h(s)\\ &\quad \textsc{Else}\ h(s).\end{aligned}$$

[6] In the most common case (like noise-free or sensing actions), the arguments to the action would simply be a vector of constants.

We noted that (5) does not satisfy our invertibility property. This variant, however, is invertible. The H-expression for v was derived in Example 4. The H-expression for h is:

$$H_h(a) = \text{If } a = \mathit{away} \text{ Then } 2/3 \cdot h \text{ Else If } a = \mathit{towards} \text{ Then } 2 \cdot h \text{ Else } h.$$

We now consider the progression of $\mathcal{D}_0$ wrt the action *away*. First, the instantiated H-expressions would simplify to:

- $H_h(\mathit{away}) = 2/3 \cdot h$;
- $H_v(\mathit{away}) = v$.

Next, since *away* is noise-free, we have $\Upsilon_{\mathit{away}} = 1$. Putting this together, we obtain $\mathcal{D}_0' = \mathit{Pro}(\mathcal{D}_0, \mathit{away})$ as:

$$\begin{aligned} p(s, S_0) &= \mathcal{U}(2/3 \cdot h; 2, 12) \times \mathcal{N}(v; 0, 1)\ [s] \\ &= \mathcal{U}(h; 3, 18) \times \mathcal{N}(v; 0, 1)\ [s] \end{aligned}$$

That is, the new p is one where h is uniformly distributed on $[3, 18]$ and v is independently drawn from a standard normal distribution (as before). This leads to a *shorter* and *wider* density function, as depicted in Figure 2. Here are three simple properties to contrast the original *vs.* the progressed:

- $\mathcal{D}_0 \cup \Sigma \models \mathit{Bel}(h \geq 9, S_0) = .3$.

  The *Bel* term expands as:

  $$\frac{1}{\eta} \int_x \int_y \text{If } \exists \iota (h = x \wedge v = y \wedge h \geq 9)[\iota] \text{ Then } \mathcal{U}(h; 2, 12) \times \mathcal{N}(v; 0, 1)[\iota] \text{ Else } 0$$

  which simplifies to the integration of a density function:

  $$\begin{aligned} &\frac{1}{\eta} \int_x \int_y \begin{cases} .1 \times \mathcal{N}(y; 0, 1) & \text{if } x \in [2, 12], x \geq 9 \\ 0 & \text{otherwise} \end{cases} \\ = &\frac{1}{\eta} \int_x \int_y \begin{cases} .1 \times \mathcal{N}(y; 0, 1) & \text{if } x \in [9, 12] \\ 0 & \text{otherwise} \end{cases} \\ = &.3. \end{aligned}$$

  Only those situations where $h \in [2, 12]$ initially are given non-zero p values and by the formula in the *Bel*-term, only those where $h \geq 9$ are to be considered.

- $\mathcal{D}_0 \cup \Sigma \models \mathit{Bel}(h \geq 9, \mathit{do}(\mathit{away}, S_0)) = .6$.

  For any initial situation ι, $h[\mathit{do}(\mathit{away}, \iota)] \geq 9$ only when $h[\iota] \geq 6$, which is given an initial belief of .6.

- $\mathcal{D}_0' \cup \Sigma \models \mathit{Bel}(h \geq 9, S_0) = .6$.

  Basically, *Bel* simplifies to an expression of the form:

  $$\frac{1}{\eta} \int_x \int_y \begin{cases} 1/15 \cdot \mathcal{N}(y; 0, 1) & \text{if } x \in [3, 18], x \geq 9 \\ 0 & \text{otherwise} \end{cases}$$

  giving us .6.

Example 14: Let $\mathcal{D}_0 \cup \Sigma$ be exactly as above, and consider its progression wrt *towards*. It is easy to verify that for instantiated H-expressions we get:

- $H_h(\mathit{towards}) = 2 \cdot h$;
- $H_v(\mathit{towards}) = v$;

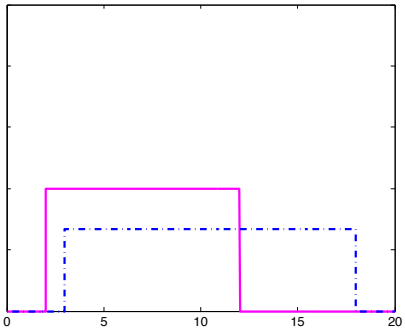

Figure 2: Belief change about h: initially (solid magenta) and after moving away (dotted blue).

Here too, because *towards* is noise-free, $\Upsilon_{\mathit{towards}}$ is simply 1, which is to say the $\mathcal{D}_0' = \mathit{Pro}(\mathcal{D}_0, \mathit{towards})$ is defined as:

$$\begin{aligned} p(s, S_0) &= \mathcal{U}(2 \times h; 2, 12) \times \mathcal{N}(v; 0, 1)\ [s] \\ &= \mathcal{U}(h; 1, 6) \times \mathcal{N}(v; 0, 1)\ [s]. \end{aligned}$$

The new distribution on h is *narrower* and *taller*, as shown in Figure 3. Here we might contrast $\mathcal{D}_0$ and $\mathcal{D}_0'$ as follows:

- $\mathcal{D}_0 \cup \Sigma \models \mathit{Bel}(h \in [2, 3], S_0) = .1$.
- $\mathcal{D}_0' \cup \Sigma \models \mathit{Bel}(h \in [2, 3], S_0) = .2$.

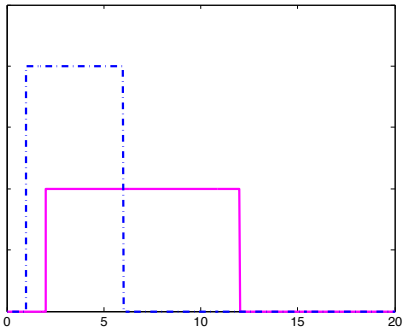

Figure 3: Belief change about h: initially (solid magenta) and moving towards the wall (dotted blue).

Example 15: Let $\mathcal{D}_0 \cup \Sigma$ be as in the previous examples. Consider its progression wrt the action *sonar*(5). Sensing actions do not affect fluents, so for H-expressions we have:

- $H_h(\mathit{sonar}(5)) = h$;
- $H_v(\mathit{sonar}(5)) = v$.

Here $\mathit{sonar}(z)$ is noisy, and we have $\Upsilon_{\mathit{sonar}}(5) = \mathcal{N}(5; h, 4)$. This means that the progression $\mathcal{D}_0' = \mathit{Pro}(\mathcal{D}_0, \mathit{sonar}(5))$ is

$$\frac{p(\iota, S_0)}{\mathcal{N}(5; h, 4)[\iota]} = \mathcal{U}(h; 2, 12) \times \mathcal{N}(v; 0, 1)[\iota],$$

which simplifies to the following:

$$p(\iota, S_0) = \mathcal{U}(h; 2, 12) \times \mathcal{N}(v; 0, 1) \times \mathcal{N}(5; h, 4)\ [\iota].$$

As can be noted in Figure 4, the robot's belief about h's true value around 5 has sharpened. Consider, for example, that:

- $\mathcal{D}_0 \cup \Sigma \models Bel(h \leq 9, S_0) = .7$.
- $\mathcal{D}'_0 \cup \Sigma \models Bel(h \leq 9, S_0) \approx .97$.

If we were to progress $\mathcal{D}'_0$ further wrt a second sensing action, say *sonar*(5.9), we would obtain the following:

$$p(\iota, S_0) = \mathcal{U}(h; 2, 12) \times \mathcal{N}(v; 0, 1) \times \mathcal{N}(5; h, 4) \times \mathcal{N}(5.9; h, 4)\ [\iota].$$

As can be seen in Figure 4, the robot's belief about h would sharpen significantly after this second sensing action. If we let $\mathcal{D}''_0 = Pro(\mathcal{D}'_0, sonar(5.9))$ then:

- $\mathcal{D}''_0 \cup \Sigma \models Bel(h \leq 9, S_0) \approx .99$.

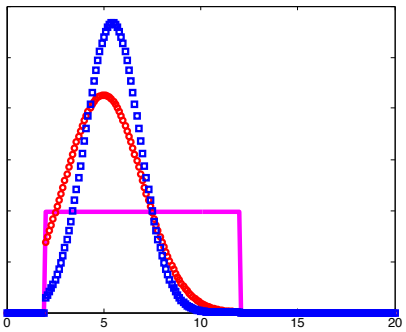

Figure 4: Belief change about h: initially (solid magenta), after sensing 5 (red circles), and after sensing twice (blue squares).

Example 16: Let $\mathcal{D}_0$ be the conjunction of (3) and $v(S_0) = 3$. Let Σ be the union of:

- (P1)-(P3) and domain-independent foundational axioms;
- a successor state axiom for h as above;
- a noisy move action mv' with the following l-axiom:

$$l(mv'(x, y), s) = \mathcal{N}(y; x, 2)$$

- a successor state axiom for v using this noisy move:

$$v(do(a, s)) = \text{If } \exists x, y(a = mv'(x, y)) \text{ Then } v(s) + y \text{ Else } v(s).$$

(Recall that for a noisy move $mv'(x, y)$, x is the intended motion and y is the actual motion.) This is inverted using the same idea as in Example 4.

Consider the progression of $\mathcal{D}_0 \cup \Sigma$ wrt $mv'(2, g(S_0))$. The simplified H-expressions are as follows:

- $H_h(mv'(2, g)) = h$;
- $H_v(mv'(2, g)) = v - g$.

By definition, occurrences of $v(u)$ in $\mathcal{D}_0$ are to be replaced by $H_v(mv'(2, g))[u]$. Also, $\Upsilon_{mv'}(2, z) = \mathcal{N}(z; 2, 2)$. Therefore, $\mathcal{D}'_0 = Pro(\mathcal{D}_0, mv'(2, g(S_0)))$ is defined to be

$$(v - g)[S_0] = 3 \wedge \left(\frac{p(\iota, S_0)}{\mathcal{N}(g; 2, 2)[\iota]} = \mathcal{U}(h; 2, 12) \times \mathcal{N}(v - g; 0, 1)[\iota]\right)$$

This simplifies to the conjunction of these two sentences:

- $v(S_0) = 3 + g(S_0)$; and
- $p(\iota, S_0) = \mathcal{U}(h; 2, 12) \times \mathcal{N}(v; g, 1) \times \mathcal{N}(g; 2, 2)\ [\iota]$.

Thus the noisy action has had two effects: the actual position has shifted by $g(S_0)$ units, and the belief about the position has also shifted by an amount g drawn from a normal distribution centered around 2. This leads to a *shifted* and *wider* curve seen in Figure 5. As expected, the agent is considerably less confident about its position after a noisy move. Here, for example, are the degrees of belief about being located within 1 unit of the best estimate (that is, the mean):

- $\mathcal{D}_0 \cup \Sigma \models Bel(v \in [-1, 1], S_0) \approx .68$.
- $\mathcal{D}'_0 \cup \Sigma \models Bel(v \in [1, 3], S_0) \approx .34$.

Basically, *Bel* expands to an expression of the form

$$\frac{1}{\eta} \int_{x,y,z} \begin{cases} .1\mathcal{N}(y; z, 1) \cdot \mathcal{N}(z; 2, 2) & \text{if } x \in [2, 12], y \in [1, 3] \\ 0 & \text{otherwise} \end{cases}$$

where η is

$$\int_{x,y,z} \begin{cases} .1\mathcal{N}(y; z, 1) \cdot \mathcal{N}(z; 2, 2) & \text{if } x \in [2, 12] \\ 0 & \text{otherwise} \end{cases}$$

leading to .34.

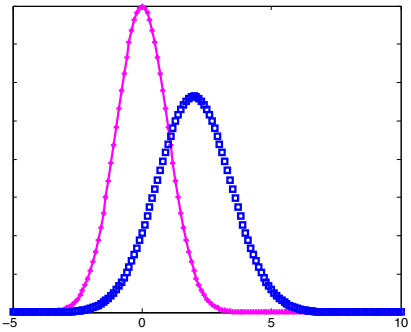

Figure 5: Belief change about v: initially (solid magenta) and after a noisy move of 2 units (blue squares).

Constant Growth

As seen in the examples, the result of progression is a theory $\mathcal{D}'_0$ which is essentially obtained by adding H-expressions, and so, its size is linear in the size of the *action theory*:

Theorem 17: *Suppose $\mathcal{D} = \mathcal{D}_0 \cup \Sigma$ is any invertible basic action theory. After the iterative progression of $\mathcal{D}_0 \cup \Sigma$ wrt a sequence σ, the size of the new initial theory is $O(|\mathcal{D}| \times |\sigma|)$.*

Therefore, progression is both computable and efficient in the sense of (Liu and Lakemeyer 2009). But for realistic robotic applications, even this may not be enough, especially over millions of actions. Consider, for example, that to calculate a degree of belief it will be necessary to integrate the numerical expression for p. What we turn to in this section is a special case that would guarantee that over any length of action sequences, the size of the progressed theory does not change beyond a constant factor. It will use the notion of *context-completeness* (Liu and Levesque 2005) and a few simplification rules.

Definition 18: Suppose $F \subseteq \{f_1, \ldots, f_k\}$ is any set of fluents, and $\mathcal{D}_0 \cup \Sigma$ is any invertible basic action theory. We say that $\mathcal{D}_0$ is *complete* wrt F if for any $\phi \in \mathcal{L}_F$, either $\mathcal{D}_0 \models \phi$ or $\mathcal{D}_0 \models \neg\phi$, where $\mathcal{L}_F$ is the sublanguage of $\mathcal{L}$ restricted to the fluents in F.

Definition 19: An invertible basic action theory $\mathcal{D}_0 \cup \Sigma$ is said to be *context-complete* iff

- for every fluent f, $\mathcal{D}_0$ is complete wrt every fluent other than f appearing in the successor state axiom of f;
- $\mathcal{D}_0$ is complete wrt every fluent appearing in a conditional expression in the likelihood axioms.

That is, there is sufficient information in $\mathcal{D}_0$ to simplify all the conditionals appearing in the context formulas of the successor state axioms and the likelihood axioms.

STRIPS actions are trivially context-complete, and so are Reiter's *context-free* successor state axioms where only rigid symbols appear in the RHS (Reiter 2001). In Example 7, if $\mathcal{D}_0$ is complete wrt the fluents *fuel* and *wax*, then the theory would be context-complete. Note that $\mathcal{D}_0$ does not need to be complete wrt the fluent v in that example, and this is precisely why they are interesting. Indeed, both (5) and (1) are also context-complete because, by definition, E_f may mention f, and (say) use its previous value.[7] The reader may further verify that all the density change examples developed in the paper are context-complete.

As a result of context-completeness, the body of the successor state axiom for a fluent f would simplify to an expression involving only f. As a consequence, H-expressions simplify to expressions of the form:

$$f(s) = \theta(f(do(a, s)))$$

where $\theta(x)$ is some rigid $\mathcal{L}$-term, possibly an arithmetic expression, with a single free variable x. Analogously, if $A(\vec{t})$ is any ground action, then,

$$\Upsilon_A(\vec{t}) = \delta(\vec{t}, \vec{f}).$$

where $\delta(\vec{x}, \vec{y})$ is some rigid $\mathcal{L}$-term, possibly an arithmetic expression, with free variables $\vec{x} \cup \vec{y}$. So in a progression, every fluent f would be replaced by an arithmetic expression using only f, resulting in a theory that is linear in the size of the *initial theory* $\mathcal{D}_0$ only:

Theorem 20: *Suppose $\mathcal{D}_0 \cup \Sigma$ is any invertible basic action theory that is also context-complete. After the iterative progression of $\mathcal{D}_0 \cup \Sigma$ wrt a sequence σ, the size of the new initial theory is $O(|\mathcal{D}_0| \times |\sigma|)$.*

This can make a substantial difference in the size of the expression for p. Nevertheless, after n actions, we might still end up with an expression consisting of a product of n terms. We now simplify this computation further by appealing to the analytical tractability of *conjugate distributions* (Box and Tiao 1973; Bertsekas and Tsitsiklis 2008), such as Gaussians, where the product of two Gaussians is definable as another Gaussian. We show how this helps with an example.

[7] Strictly speaking, our notion of context-completeness is inspired by, but not the same as the one in (Liu and Levesque 2005). This pertains to the clarification just made: we allow successor state axioms to use the fluent's previous value.

Example 21: Let $\mathcal{D}_0 \cup \Sigma$ be as in Example 16. We noted its progression wrt $mv'(2, g(S_0))$ includes:

$$p(\iota, S_0) = \mathcal{U}(h; 2, 12) \times \mathcal{N}(v; g, 1) \times \mathcal{N}(g; 2, 2)\ [\iota].$$

If we progress this sentence further wrt a second noisy action $mv'(3, g'(S_0))$, we would obtain:

$$p(\iota, S_0) = \mathcal{U}(h; 2, 12) \times \mathcal{N}(v - g'; g, 1) \times \mathcal{N}(g; 2, 2) \times \mathcal{N}(g'; 3, 2)\ [\iota] \quad (6)$$

By letting g^* be a new fluent symbol such that $g^* = g + g'$, it follows that (6) is equivalent to the following:

$$p(\iota, S_0) = \mathcal{U}(h; 2, 12) \times \mathcal{N}(v; g^*, 1) \times \mathcal{N}(g^*; 5, 4)\ [\iota].$$

Analogously, after any number n of noisy moves, we would only need to integrate over 3 variables *vs.* $n + 2$ in (6).

Theorem 22: *Suppose $\mathcal{D}_0 \cup \Sigma$ is any invertible action theory that is context-complete and the likelihood axioms are normal distributions. After the iterative progression of $\mathcal{D}_0 \cup \Sigma$ wrt a sequence σ, the size of the new initial theory is $O(|\mathcal{D}_0|)$.*

That is, the size of the progression does not grow beyond a constant factor. This result is easily adapted to other conjugate distributions. Essentially, like other *filtering* techniques (Thrun, Burgard, and Fox 2005), such as Kalman filters, we conclude that progression can be made very efficient. But unlike some of these other techniques, we are not limited to Gaussians. More significantly, unlike all other probabilistic formalisms, we can allow arbitrary context formulas, and under the reasonable assumption of context-completeness, still remain efficient.

Related Work and Discussion

This work builds on Lin and Reiter's (1997) notion of progression. Other advances on progression have been made since then (Liu and Lakemeyer 2009; Vassos 2009), mainly by appealing to the notion of *forgetting* (Lin and Reiter 1994). We were motivated by concerns about continuity, and this led to the notion of invertible theories. These theories allowed us to perform first-order progression by inverting successor state axioms in a way that, as far as we know, has not been investigated before. Although we restricted $\mathcal{L}$ to nullary real-valued fluents, we suspect that invertibility and its connection to progression may apply more generally. This is left for future investigations.

The progression of categorical knowledge against noise-free effectors and sensors is considered in (Liu and Wen 2011; Lakemeyer and Levesque 2009). The progression of discrete degrees of belief wrt context-completeness is considered in (Belle and Lakemeyer 2011). In the fluent calculus (Thielscher 2001), a dual form of successor state axioms is used, leading naturally to a form of progression. However, continuity is not considered in any of these.

The form of progression considered here follows Lin and Reiter and differs from weaker forms including the one proposed by Liu and Levesque (2005), and the notion of *logical filtering* (Shirazi and Amir 2005; Hajishirzi and Amir 2010),

which is a form of (approximate) progression.[8] Interestingly, logical filtering is inspired by Kalman filters (Thrun, Burgard, and Fox 2005), although the precise connection is not considered. In situation calculus terminology, Kalman filters and its variants are derived using *strongly* context-free (Reiter 2001) noisy actions and sensors, with additive Gaussian noise, over normally distributed fluents. See, for example, (Belle and Levesque 2013b). Indeed, as discussed in BL, the framework used here is significantly more general than probabilistic formalisms used in the robotics and uncertainty literature, including Dynamic Bayesian Networks (Boyen and Koller 1998; Darwiche and Goldszmidt 1994) and hybrid control structures (McIlraith et al. 2000), among others.

See BL for a discussion of how the formalism used here also differs from other logical accounts for reasoning about uncertainty, such as probabilistic logics (Fagin and Halpern 1994), Markov logics (Richardson and Domingos 2006; Choi, Guzman-Rivera, and Amir 2011), probabilistic planning languages (Kushmerick, Hanks, and Weld 1995; Younes and Littman 2004; Sanner 2011), dynamic logics (Van Benthem, Gerbrandy, and Kooi 2009), and previous first-order proposals (Mateus et al. 2001; Thielscher 2001; Martin and Thielscher 2009; Fritz and McIlraith 2009; Poole 1998). In essence, none of these address continuous uncertainty and continuous noise in a general way.

Conclusions

Lin and Reiter developed the notion of progression, with long-lived agents in mind. However, their account does not deal with probabilistic uncertainty nor with noise, as seen in real-world robotic applications. In the work here, we consider semantically correct progression in the presence of continuity. By first identifying what we called invertible basic action theories, we obtained a new way of computing progression. Under the additional restriction of context-completeness, progression is very efficient. Most significantly, by working within a richer language, we have obtained progression machinery that, to the best of our knowledge, has not been discussed elsewhere, and goes beyond existing techniques. The unrestricted nature of the specification of the p fluent, for example, which we inherit from (Bacchus, Halpern, and Levesque 1999), allows for agents whose beliefs are not determined by a unique distribution.

One major topic for future investigation is an implementation. But apart from simply progressing a theory, we would also like to support the numerical calculation of degrees of belief. For this, we may need to appeal to numerical integration techniques such as Monte Carlo sampling (Murphy 2012), and so we would also like to study formal constraints on $\mathcal{D}_0$ which guarantee that sampling can be done in an effective manner.

[8] In (Shirazi and Amir 2005; Hajishirzi and Amir 2010), the notion of a *permuting action* is introduced for computing their form of progression, which bears some similarity to invertible fluents. However, as mentioned above, our work on continuity led itself to invertibility. Neither continuous uncertainty nor continuous noise is considered in (Shirazi and Amir 2005; Hajishirzi and Amir 2010).

Abstract

Among the most frequent reasoning tasks in the situation calculus are projection queries that query the truth of conditions in a future state of affairs. However, in long running action sequences solving the projection problem is complex. The main contribution of this work is a new technique which allows the length of the action sequences to be reduced by reordering independent actions and removing dominated actions; maintaining semantic equivalence with respect to the original action theory. This transformation allows for the removal of actions that are problematic with respect to progression, allowing for periodical update of the action theory to reflect the current state of affairs. We provide the logical framework for the general case and give specific methods for two important classes of action theories. The work provides the basis for handling more expressive cases, such as the reordering of sensing actions in order to delay progression, and forms an important step towards facilitating ongoing planning and reasoning by long-running agents. It provides a mechanism for minimising the need for keeping the action history while appealing to both regression and progression.

Introduction

In this paper we are concerned with reasoning about action and change in the general case where information about the environment is represented as a first-order logical theory. In practical settings two of the most typical reasoning tasks required are: performing *projection* queries that query the truth of conditions in a future state of affairs; and *updating* or *progressing* the world representation to reflect the current state of affairs after a sequence of actions has been performed.

To illustrate optimised reasoning for these tasks we focus on the logical language of the situation calculus (McCarthy and Hayes 1969; Reiter 2001), where the environment is formalized as an action theory including a set of first-order sentences for specifying the initial state of the environment and a set of first-order axioms for specifying the effects of named actions with respect to the changing properties of the environment. The first task amounts to the question of whether a first-order sentence corresponding to the projection query is entailed by the action theory, while the second involves finding a new updated first-order representation of the world which is typically referred to as progression.

Copyright © 2014, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

These two tasks are very much connected as a proper solution for progression ensures that the truth value of all possible projection queries is preserved in the updated representation of the environment. However, solving the progression problem in the general case is quite tricky, in fact requiring the use of second-order axioms (Lin and Reiter 1997; Vassos and Levesque 2008; 2013) for the updated representation. The identified problematic cases that require second-order logic are mathematically involved and are rarely encountered, occurring infrequently in practice.

Consequently, syntactically restricted forms of action theories have been investigated in order to ensure that a first-order progression exists and can be effectively computed. Examples for first-order progressable action theories include those with *local-effect actions* (Liu and Levesque 2005; Vassos, Lakemeyer, and Levesque 2008) which restrict actions to affect only ground atoms that are composed exclusively by using arguments of the action. A type of first-order 'surgery' can be performed to the initial theory, removing the truth values of (finitely many) ground atoms—i.e., by *forgetting* in the sense of (Lin and Reiter 1994)—and setting their new values accordingly. A map of progressable action theory classes can be found in (Vassos and Patrizi 2013), however, they are quite limited and a wide range of cases do not fit in the identified classes—for which we have no means of performing a (logically correct) first-order update.

In practice this means that if the desired action theory includes even a single action that does not fit into the identified progressable cases, then updating of the action theory cannot be guaranteed: from the time that a problematic action α_1 is executed no more updating can be performed. Of course, projection queries can still be decided by the original action theory by forming appropriate entailment queries of the form: 'Will ϕ be true after actions $\langle \alpha_1, \ldots, \alpha_n, \beta_1, \ldots, \beta_m \rangle$ are performed in the initial state of the environment?', where $\alpha_1, \ldots, \alpha_n$ are the actions that have been already executed (for which the action theory unfortunately cannot be updated due to α_1) and $\beta_1, \ldots, \beta_m$ are the ones with respect to which we want to project in the future.

Although *regression* can be used to answer history-based queries, for many practical cases where the action theory is used by long-living agents in order to reason about their actions, such approaches become infeasible as the history of actions constantly increases.

An important observation is that similar to action α_1, that makes further updates impossible, there can be another action, α_k, that brings the environment to a state of affairs that is easier to represent and reason about. For example, α_k could be a *reseting* action that brings the environment to the initial state of affairs, or one that essentially *subsumes* the effects of α_1 in a way that the new representation is first-order progressable—via setting all problematic atoms to a fixed or sensed truth value. Current approaches do not consider this type of reasoning with respect to the action history, leaving out a wide range of practical cases that can be handled by such a hybrid approach to progression.

We therefore investigate sufficient and necessary conditions for transforming and simplifying the history of actions in a logically correct way by combining two basic types of operations: *swapping independent actions* in the action history; and *eliminating dominated actions* by removing them entirely from the action history. This transformation will often allow to remove actions that are problematic with respect to progression, thus allowing to periodically update the action theory to reflect the current state of affairs.

We provide a mechanism for minimising the need for keeping the action history $\langle \alpha_1, \ldots, \alpha_n \rangle$ of the *actions that have already been executed*, and having a representation of the environment that is *as much up-to-date as possible*. In case reasoning over the past history of events is also required then a separate mechanism that keeps track of the true action history and the original action theory can be employed. Importantly, our proposed mechanism can also be used to reason about and plan for the actions needed in order for a progression to become feasible when the length of the history of actions reaches a certain limit.

Finally, our approach can be also useful in cases where all actions fall in the first-order progressable classes—for the purpose of obtaining computational benefits. Since the updating of the action theory is typically a much more computationally demanding procedure than that of projection, it can be beneficial to keep a history of executed actions up to some fixed (past horizon) length anticipating that a future action may greatly simplify the history. Depending on the characteristics of the domain and the projection queries that are needed, such an approach has the potential to save a lot of computational resources. For instance, in cases where there is a large degree of uncertainty in the form of incomplete or disjunctive information which would, under normal circumstances, lead to an exponential growth of the progressed theory with respect to the number of actions executed, a later sensing action that settles uncertainty would lead to larger computational savings, as compared to those consumed in order to perform projection queries using the longer history of executed actions.

Our contribution is a framework for specifying transformations in a logically correct way in the general case. A promising new class of global-effect actions is introduced, termed *resetting* actions, which facilitate transformation based on dominance principles. We specify practical procedures for realizing the proposed transformations, allowing for swapping and elimination of actions for handling non-progressable instances; or the interleaving of regression and progression as required. We illustrate how such theories correspond to common agent planning tasks, using a slightly modified `Sokoban` domain.

Formal preliminaries

The logical language of situation calculus

The language $\mathcal{L}$ of the situation calculus as presented in (Reiter 2001) is a three-sorted first-order logic language with equality and some limited second-order features. The sorts are: *action*, *situation*, and a catch-all sort *object* for everything else depending on the domain of application.

Similar to a normal one-sorted first-order language, $\mathcal{L}$ includes function and predicate symbols. In this case since there are three sorts, each of the symbols has a type that specifies the sorts for the arguments it takes. The situation calculus includes symbols only of certain types each of which has a special role in the representation of the world and its dynamics.

An action term or simply an *action* represents an atomic action that may be performed in the world. For example consider the action $move(l_1, l_2)$ that may be used to represent that a robot moves from location l_1 to location l_2. A situation term or simply a *situation* represents a world history as a sequence of actions. The constant S_0 is used to denote the *initial situation* where no actions have occurred. Sequences of actions are built using the function symbol *do*, such that $do(\alpha, \sigma)$ represents the successor situation resulting from performing action α in situation σ.

A *relational fluent* is a predicate whose last argument is a situation, and thus whose truth value can change from situation to situation. For example, $RobotAt(l, \sigma)$ may be used to represent that the robot lies at location l in situation σ. In order to simplify the analysis we have restricted the language $\mathcal{L}$ so that there are no functional fluent symbols in $\mathcal{L}$, that is, functions whose last argument is a situation. This is not a restriction on the expressiveness of $\mathcal{L}$ as functional fluents can be represented by relational fluents with a few extra axioms.

Actions need not be executable in all situations, and the predicate atom $Poss(\alpha, \sigma)$ states that action α is executable in situation σ. For example, $Poss(move(l_1, l_2), \sigma)$ is intended to represent that the action $move(l_1, l_2)$ can be executed in situation σ. The language $\mathcal{L}$ also includes the binary predicate symbol $\sqsubset$ which provides an ordering on situations. The atom $s \sqsubset s'$ means that the action sequence s' can be obtained from the sequence s by performing one or more actions in s. We will typically use the notation $\sigma \sqsubseteq \sigma'$ as a macro for $\sigma \sqsubset \sigma' \vee \sigma = \sigma'$.

In this paper, we shall restrict our attention to a language $\mathcal{L}$ with a finite number of relational fluent symbols that only take arguments of sort object (apart their last situation argument), an infinite number of constant symbols of sort object $\mathcal{C} = \{c_1, c_2, \ldots\}$, and a finite number of function symbols of sort action that take arguments of sort object. We adopt the following notation with subscripts and superscripts: α and a for terms and variables of sort action; σ and s for terms and variables of sort situation; t and x, y, z, w for terms and variables of sort object. Also, we use A for action function symbols, F, G for fluent symbols, and b, c, d, e for constants

of sort object. Finally, we will typically write $\phi(\vec{x})$ to state that the free variables of the formula are among $\vec{x}$.

The well-formed first-order formulas of $\mathcal{L}$ are defined inductively similarly to a normal one-sorted language but also respecting that each parameter has a unique sort. As far as the second-order formulas of $\mathcal{L}$ are concerned, only quantification over relations is allowed and the well-formed formulas are defined inductively similarly to a normal second-order language.

Often we will focus on sentences that refer to a particular situation. For this purpose, for any situation term σ, we define the set of *uniform formulas in* σ to be all those (first-order or second-order) formulas in $\mathcal{L}$ that do not mention any other situation terms except for σ, do not mention *Poss*, and where σ is not used by any quantifier (Lin and Reiter 1997). Finally, we use δ to denote a sequence of actions of the form $\langle \alpha_1, \ldots, \alpha_n \rangle$, and $do(\delta, S_0)$ as a shorthand for the situation term $do(\alpha_n, \cdots do(\alpha_1, S_0))$.

Basic action theories

Within the language $\mathcal{L}$, one can formulate action theories that describe how the world changes as the result of the available actions. We focus on a variant of the *basic action theories (BATs)* (Reiter 2001) of the following form:[1]

$$\mathcal{D} = \mathcal{D}_{ap} \cup \mathcal{D}_{ss} \cup \mathcal{D}_{una} \cup \mathcal{D}_0 \cup \mathcal{D}_{fnd},$$

where:

1. $\mathcal{D}_{ap}$ is the set of action precondition axioms (PAs), one per action symbol A, of the form $Poss(A(\vec{y}), s) \equiv \Pi_A(\vec{y}, s)$, where $\Pi_A(\vec{y}, s)$ is first-order and uniform in s. PAs characterize the conditions under which actions are physically possible.
2. $\mathcal{D}_{ss}$ is the set of successor state axioms (SSAs), one per fluent symbol F, of the form $F(\vec{x}, do(a, s)) \equiv \Phi_F(\vec{x}, a, s)$, where $\Phi_F(\vec{x}, a, s)$ is first-order and uniform in s. SSAs describe how fluents change between situations as the result of actions.
3. $\mathcal{D}_{una}$ is the set of unique-names axioms for actions.
4. $\mathcal{D}_0$, the *initial knowledge base (KB)*, is a set of first-order sentences uniform in S_0 describing the initial situation S_0.
5. $\mathcal{D}_{fnd}$ is the set of domain independent axioms of the situation calculus, formally defining the legal situations. A second-order induction axiom is included in $\mathcal{D}_{fnd}$.

Probably the most interesting component of a basic action theory is the set successor state axioms, which together encode the dynamics of the domain being represented. Technically, SSAs are meant to capture the effects and non-effects of actions. To achieve that in a parsimonious way, one typically follows the well-known solution to the frame problem by means of successor state axioms of the following form (Reiter 2001):

$$F(\vec{x}, do(a, s)) \equiv \gamma^+_F(\vec{x}, a, s) \vee F(\vec{x}, s) \wedge \neg\gamma^-_F(\vec{x}, a, s),$$

where both $\gamma^+_F(\vec{x}, a, s)$ and $\gamma^-_F(\vec{x}, a, s)$ are first-order formulas uniform in s encoding the positive and negative effects, respectively, of action a on fluent F at situation s.

[1] For legibility, we typically omit leading universal quantifiers.

Transforming situation calculus histories

In this section we provide the logical foundations for two basic operations that will allow to transform an action history in a way that is logically correct with respect to a basic action theory $\mathcal{D}$.

Swapping consecutive actions

We start with the logical specification of the notion of consecutive actions being *swappable* in an action history of the form $do(\delta, S_0)$, where δ is a sequence of ground actions. We will introduce two versions of the notion, *just-in-time swappable* and *always swappable*. For the following definitions let $\mathcal{D}$ be a basic action theory of the type we introduced in the previous section, and let δ be $\langle \alpha_1, \ldots, \alpha_k, \alpha_{k+1}, \ldots, \alpha_n \rangle$, where k is in $\{1, \ldots, n-1\}$, and each of the elements of δ is a ground action term.

Definition 1. We say that actions α_k and α_{k+1} are *just-in-time swappable* in δ wrt $\mathcal{D}$ iff for all fluents $F(\vec{x}, s)$ in $\mathcal{L}$ the following holds:

$$\mathcal{D} \models \forall \vec{x}.\ F(\vec{x}, do(\langle \alpha_1, \ldots, \alpha_k, \alpha_{k+1} \rangle, S_0)) \equiv F(\vec{x}, do(\langle \alpha_1, \ldots, \alpha_{k+1}, \alpha_k \rangle, S_0)).$$

So, we can swap actions α_k and α_{k+1} in δ as long as in all models of $\mathcal{D}$ it happens that the interpretation of all fluent atoms is preserved in the two versions of the action history. The *just-in-time* terminology is used to stress that it may be due to the axioms in this particular instance of $\mathcal{D}_0$ and the action sequence δ that ensure that this condition holds, while in fact actions α_k and α_{k+1} would not necessarily be swappable if another $\mathcal{D}_0$ and δ were assumed.

Example 1. Consider the case of fluent $F(s)$ that is only affected by actions set_F and $unset_F$ such that set_F has a conditional effect that makes $F(s)$ true when $G(s)$ holds, and $unset_F$ has the conditional effect that makes $F(s)$ false when $G(s)$ holds. The SSA for $F(s)$ is then as follows:

$$F(do(a, s)) \equiv (a = set_F \wedge G(s)) \vee F(s) \wedge \neg(a = unset_F \wedge G(s)).$$

Consider now an action sequence δ as above in which action α_k is set_F and α_{k+1} is $unset_F$, assuming there are also other fluents and actions in the language. By looking at the SSA for $F(s)$ we can conclude that these actions may have "conflicting" effects and therefore they should not be considered swappable in general, as the order of applying these two actions may result to a different truth value for $F(s)$.

Nonetheless, if we also take into account $\mathcal{D}_0$ and the particular course of action that takes us to the situation where α_k and α_{k+1} are performed, we may conclude that we can actually swap the actions. For instance, consider a $\mathcal{D}_0$ that includes the fact $\neg G(S_0)$, and the following SSA for $G(s)$:

$$G(do(a, s)) \equiv a = set_G \vee G(s) \wedge \neg(a = unset_G).$$

In the case that none of the actions $\alpha_1, \ldots, \alpha_{k-1}$ is set_G then condition $G(s)$ is in fact not satisfied in the situation when α_k is performed, and also in the resulting situation in which α_{k+1} is performed. As a result, actions α_k and α_{k+1}

have no effect in the truth value of $F(s)$, and actually no effects whatsoever in δ in every model of $\mathcal{D}$. For the same reason, reversing the order of these two actions also results in no effects in the truth value of any fluent atom, and we can conclude that they can be safely swapped, or more precisely that α_k and α_{k+1} are just-in-time swappable in δ wrt $\mathcal{D}$.[2]

Note then that if none of the actions $\alpha_1, \ldots, \alpha_{k-1}$ is $unset_G$ and exactly one is set_G then condition $G(s)$ is satisfied in the situation when α_k is performed, and also in the resulting situation in which α_{k+1} is performed. As a result, actions α_k and α_{k+1} have conflicting effects and are not just-in-time swappable in δ wrt $\mathcal{D}$.

Definition 1 is a precise characterization of when two consecutive actions may be swapped in a particular action sequence without affecting the interpretations of fluents. In order to check this in general one needs to look into the properties of the situation where the actions are performed and verify that no conflict arises. As we saw in Example 1 the same actions for the same $\mathcal{D}$ may be just-in-time swappable in one sequence of actions and not in another.

There can be also cases of actions that the actual situation in which they are performed does not play any role as for example actions that may only affect different fluents. We can capture this notion which we call *always swappable* with a similar definition that removes the dependency on the particular $\mathcal{D}_0$ the action sequence δ as follows.

Definition 2. We say that actions α and α' are *always swappable* wrt $\mathcal{D}$ iff for all fluents $F(\vec{x}, s)$ in $\mathcal{L}$ the following holds:

$$\mathcal{D} - \mathcal{D}_0 \models \forall \vec{x}.\, F(\vec{x}, do(\langle \alpha, \alpha' \rangle, S_0)) \equiv F(\vec{x}, do(\langle \alpha', \alpha \rangle, S_0)).$$

Essentially, Definition 2 requires that starting from any possible extension for all fluents, applying the two actions in question will have the same effect regardless of the order the actions are applied.

Example 2. Actions set_F and $unset_F$ are not always swappable wrt $\mathcal{D}$, and also the same holds for all α, α' such that $\alpha \in \{set_F, unset_F\}$ and $\alpha' \in \{set_G, unset_G\}$. On the other hand, if we assume that $\mathcal{D}$ also includes the following successor state axiom for H, $H(do(a, s)) \equiv a = set_H \vee H(s) \wedge \neg(a = unset_H)$, then for all α, α' such that $\alpha \in \{set_F, unset_F, set_G, unset_G\}$ and $\alpha' \in \{set_H, unset_H\}$, α, α' are always swappable wrt $\mathcal{D}$.

As we will see later, this distinction will become important when we specify algorithmic ways to decide whether consecutive actions are swappable. Next, we show some straightforward results about projection that follow from these definitions. The *simple projection* problem is deciding whether a condition about a particular situation in the future holds (Reiter 2001), and the next theorem shows that swapping actions according to our definitions preserves the result for any extension of the action sequence in the question.

Theorem 1. *Let δ be $\langle \alpha_1, \ldots, \alpha_k, \alpha_{k+1}, \ldots, \alpha_n \rangle$, where k is in $\{1, \ldots, n-1\}$, and each of the elements of δ is a ground action term. Let $\phi(s)$ be a (first-order or second-order) formula in $\mathcal{L}$ that is uniform in s. If actions α_k and α_{k+1} are always swappable wrt $\mathcal{D}$ or just-in-time swappable in δ wrt $\mathcal{D}$ then the following holds:*

$$\mathcal{D} \models \phi(do(\langle \alpha_1, \ldots, \alpha_k, \alpha_{k+1}, \ldots, \alpha_n \rangle \cdot \zeta, S_0)) \equiv \phi(do(\langle \alpha_1, \ldots, \alpha_{k+1}, \alpha_k, \ldots, \alpha_n \rangle \cdot \zeta, S_0)),$$

where ζ is any sequence of ground action terms.

Proof. For the case of just-in-time swappable we work as follows. Let M be an arbitrary model of $\mathcal{D}$. We show by induction on the situation terms σ such that $do(\langle \alpha_1, \ldots, \alpha_{k-1} \rangle, S_0) \sqsubseteq \sigma$, that for all fluents F and all sequences of action terms ζ, $M \models F(\vec{x}, do(\langle \alpha_1, \ldots, \alpha_k, \alpha_{k+1} \rangle \cdot \zeta, S_0)$ iff $M \models F(\vec{x}, do(\langle \alpha_1, \ldots, \alpha_{k+1}, \alpha_k \rangle \cdot \zeta, S_0)$. For the base case we use Definition 1 and the induction step is straightforward. The theorem then follows by induction on the construction of the formulas ϕ that are uniform in s.

For the case of always swappable let M be an arbitrary model of $\mathcal{D}$. Since $\mathcal{D} - \mathcal{D}_0$ admits all possible extensions for the fluents in S_0 it follows that there is a model M' of $\mathcal{D} - \mathcal{D}_0$ with the same domain for all sorts as M such that for all μ and for all fluents F, $M, \mu \models F(\vec{x}, do(\langle \alpha_1, \ldots, \alpha_{k-1} \rangle, S_0))$ iff $M', \mu \models F(\vec{x}, S_0)$. By Definition 2 then it follows that $M \models F(\vec{x}, do(\langle \alpha_1, \ldots, \alpha_k, \alpha_{k+1} \rangle, S_0)$ iff $M \models F(\vec{x}, do(\langle \alpha_1, \ldots, \alpha_{k+1}, \alpha_k \rangle, S_0)$, from which point we proceed as in the case of just-in-time swappable actions. □

Theorem 1 shows that swapping actions that are just-in-time or always swappable in δ preserves the entailment of any projection query that refers to some particular situation that comes after $do(\delta, S_0)$. This generalizes to more expressive sentences that refer to situations that come after $do(\delta, S_0)$, not necessary being uniform in one situation.

For example, we can show that swapping actions preserves sentences that may also quantify over future situations such as in the set $\mathcal{L}^F_\sigma$ defined in (Vassos and Levesque 2013), which is a form of the so-called *generalized projection task*. For σ being $do(\alpha, S_0)$, an example of a sentence in $\mathcal{L}^F_\sigma$ is the following: $\forall s(do(\alpha, S_0) \sqsubseteq s \supset \psi(s))$, which states that after executing action α in S_0 then $\psi(s)$ remains true always for all the future situations s from that point on.

Theorem 2. *Let $\mathcal{L}^F_\sigma$ be the set of first-order formulas that refer to the future of σ as defined in (Vassos and Levesque 2013) that allows limited quantification over situations, and $\phi(\sigma)$ be a sentence in $\mathcal{L}^F_\sigma$ for σ being $do(\delta, S_0)$. If actions α_k and α_{k+1} are always or just-in-time swappable in δ wrt $\mathcal{D}$ then the following holds:*

$$\mathcal{D} \models \phi(do(\langle \alpha_1, \ldots, \alpha_k, \alpha_{k+1}, \ldots, \alpha_n \rangle \cdot \zeta, S_0)) \equiv \phi(do(\langle \alpha_1, \ldots, \alpha_{k+1}, \alpha_k, \ldots, \alpha_n \rangle \cdot \zeta, S_0)),$$

where ζ is any sequence of ground action terms.

Proof. Similar to the proof of Theorem 1 except that we do induction on the construction of the formulas ϕ in $\mathcal{L}^F_\sigma$. □

Also it is easy to show that always swappable implies just-in-time swappable but not the opposite.

[2] In fact they could also be eliminated as we will see later.

Corollary 1. *If actions α_k and α_{k+1} are always swappable wrt $\mathcal{D}$ then for any sequence of actions δ in which they appear consecutively they are just-in-time swappable in δ wrt $\mathcal{D}$, but the opposite is not true.*

We now turn our attention to how swappable actions may be detected in practice. Definitions 1 and 2 provide a semantical account of the requirement that characterizes when two actions can be safely swapped in an action sequence. In particular, as we noted earlier, for just-in-time swappable actions we need to be able to project on the situation where the actions are applied and check the effects of actions conditioned on the action history. On the other hand, the notion of actions being always swappable is decoupled from the action history, allowing us to check for a simpler condition. The following theorem shows an equivalent characterization of always swappable actions in terms of the effects of the actions and their successor state axioms.

Theorem 3. *Actions α and α' are always swappable wrt $\mathcal{D}$ iff for all fluents $F(\vec{x}, s)$ in $\mathcal{L}$ the following holds:*

$$\begin{aligned}\mathcal{D} - \mathcal{D}_0 \models \forall \vec{x}\{&(\gamma_F^+(\vec{x}, \alpha, S_0) \vee \gamma_F^+(\vec{x}, \alpha', do(\alpha, S_0)) \\ &\equiv \gamma_F^+(\vec{x}, \alpha', S_0) \vee \gamma_F^+(\vec{x}, \alpha, do(\alpha', S_0))) \\ &\wedge (\gamma_F^-(\vec{x}, \alpha, S_0) \vee \gamma_F^-(\vec{x}, \alpha', do(\alpha, S_0)) \\ &\equiv \gamma_F^-(\vec{x}, \alpha', S_0) \vee \gamma_F^-(\vec{x}, \alpha, do(\alpha', S_0)))\} \\ \wedge \neg\exists \vec{x}\{&\gamma_F^+(\vec{x}, \alpha, S_0) \wedge \gamma_F^-(\vec{x}, \alpha', S_0) \\ &\vee \gamma_F^+(\vec{x}, \alpha', S_0) \wedge \gamma_F^-(\vec{x}, \alpha, S_0)\}.\end{aligned}$$

Proof (sketch). Observe that two actions are not always swappable only if in some model the application of one action in S_0 changes the truth value of the effect formulas of the other action or if they have conflicting effects. The first condition is covered by the universally quantified formula that covers all the cases, and the second condition is covered by the negated existentially quantified formula.

In the case of *context-free* actions such that γ_F^+ and γ_F^- do not depend on s, this is simplified as follows.

Corollary 2. *Let $\mathcal{D}$ be a basic action theory such that all successor state axioms are context-free in the sense that they have the following form: $F(\vec{x}, do(a, s)) \equiv \gamma_F^+(\vec{x}, a) \vee F(\vec{x}, s) \wedge \neg\gamma_F^-(\vec{x}, a)$. Actions α and α' are always swappable wrt $\mathcal{D}$ iff for all fluents $F(\vec{x}, s)$ in $\mathcal{L}$ the following holds:*

$$\begin{aligned}\mathcal{D} - \mathcal{D}_0 \models \neg\exists \vec{x}\{&\gamma_F^+(\vec{x}, \alpha, S_0) \wedge \gamma_F^-(\vec{x}, \alpha', S_0) \\ &\vee \gamma_F^+(\vec{x}, \alpha', S_0) \wedge \gamma_F^-(\vec{x}, \alpha, S_0)\}.\end{aligned}$$

These results allow us to reduce the semantic notion expressed in Definition 2 into a more concrete one about the effects of actions as expressed in the positive and negative effect formulas γ^+ and γ^- in the successor state axioms of the fluents in $\mathcal{L}$. Even though this condition is still an entailment question about the effects of actions, as we will see later for special cases of successor state axioms we will be able to further reduce it to simpler tests that we can easily evaluate.

Next we proceed to a similar analysis for actions that can be considered redundant and can be safely omitted.

Eliminating actions

Now we turn our attention to simplifying the action history by *eliminating* an action α_k that is *dominated* by actions $\alpha_{k+1}, \ldots, \alpha_n$ in a sequence of ground action terms δ of the form $\langle \alpha_1, \ldots, \alpha_k, \alpha_{k+1}, \ldots, \alpha_n \rangle$. As in the case of swappable actions, we identify two versions for this notion.

Definition 3. We say that action α_k is *just-in-time dominated* by α_{k+1} in δ wrt $\mathcal{D}$ iff for all fluents $F(\vec{x}, s)$ in $\mathcal{L}$ the following holds:

$$\begin{aligned}\mathcal{D} \models \forall \vec{x}.\, F(\vec{x}, do(\langle \alpha_1, \ldots, \alpha_{k-1}, \alpha_k, \alpha_{k+1} \rangle, S_0)) \equiv \\ F(\vec{x}, do(\langle \alpha_1, \ldots, \alpha_{k-1}, \alpha_{k+1} \rangle, S_0)).\end{aligned}$$

Example 3. Consider the fluent $F(x, s)$ with the following successor state axiom:

$$\begin{aligned}F(x, do(a, s)) \equiv\ & a = set_F(x) \vee a = resetTrue_F \wedge G(s) \vee \\ & F(s) \wedge \neg(a = unset_F(x) \vee a = resetFalse_F).\end{aligned}$$

Action $set_F(c)$ sets the truth value of atom $F(c, s)$ to true, $unset_F(x)$ sets it to false, and there are two resetting actions that set all atoms to true and false. Action $resetTrue_F$ is conditional and only has this global effect when $G(s)$ holds, while $resetFalse_F$ is unconditional. Assume that $G(s)$ has the same successor state axiom as in Example 1. Consider the action δ: $\langle unset_G, unset_F(c), set_F(c), resetTrue_F \rangle$. Then, $unset_F(c)$ is just-in-time dominated by $set_F(c)$ in δ wrt to $\mathcal{D}$, but $set_F(c)$ is not just-in-time dominated by $resetTrue_F$ in δ wrt to $\mathcal{D}$.

Similarly to always swappable actions we introduce the notion of *always dominated* actions that removes the dependency on the particular $\mathcal{D}_0$ and the action sequence δ as follows.

Definition 4. We say that action α is *always dominated* by α' wrt $\mathcal{D}$ iff for all fluents $F(\vec{x}, s)$ in $\mathcal{L}$ the following holds:

$$\mathcal{D} - \mathcal{D}_0 \models \forall \vec{x}.\, F(\vec{x}, do(\langle \alpha, \alpha' \rangle, S_0) \equiv F(\vec{x}, do(\alpha', S_0)).$$

Example 4. Consider the action sequence δ': $\langle set_G, unset_F(c), set_F(c), resetFalse_F \rangle$. Then $set_F(c)$ is always dominated by $resetFalse_F$ in δ wrt to $\mathcal{D}$.

Similar to the analysis of swappable actions, the notions of just-in-time and always dominated actions preserve the entailment of first-order (and second-order) sentences that refer to situations after δ. The next theorem shows this for sentences of the simple projection problem like Theorem 1, and a similar theorem can be obtained for more expressive sentences for the generalized progression problem such as the one addressed in Theorem 2.

Theorem 4. *Let δ be $\langle \alpha_1, \ldots, \alpha_k, \alpha_{k+1}, \ldots, \alpha_n \rangle$, where k is in $\{1, \ldots, n-1\}$, and each of the elements of δ is a ground action term. Let $\phi(s)$ be a (first-order or second-order) formula in $\mathcal{L}$ that is uniform in s. If action α_k is always dominated by α_{k+1} wrt $\mathcal{D}$ or just-in-time dominated by α_{k+1} in δ wrt $\mathcal{D}$ then the following holds:*

$$\begin{aligned}\mathcal{D} \models \phi(do(\langle \alpha_1, \ldots, \alpha_{k-1}, \alpha_k, \alpha_{k+1}, \ldots, \alpha_n \rangle \cdot \zeta, S_0)) \equiv \\ \phi(do(\langle \alpha_1, \ldots, \alpha_{k-1}, \alpha_{k+1}, \ldots, \alpha_n \rangle \cdot \zeta, S_0)),\end{aligned}$$

where ζ is any vector of ground action terms.

Also it is easy to show that always domination implies just-in-time domination but not the opposite.

Corollary 3. *If action α_k is always dominated by α_{k+1} wrt $\mathcal{D}$ then for any vector of actions δ in which they appear consecutively and α_{k+1} is after α_k, α_k is just-in-time dominated by α_{k+1} in δ wrt $\mathcal{D}$, but the opposite is not true.*

The following theorem shows an equivalent characterization of always domination of actions in terms of the effects of the actions and their successor state axioms.

Theorem 5. *Action α is always dominated by α' wrt $\mathcal{D}$ iff for all fluents $F(\vec{x}, s)$ in $\mathcal{L}$ the following holds:*

$$\begin{aligned}\mathcal{D} - \mathcal{D}_0 \models \forall \vec{x}\{&\gamma_F^+(\vec{x}, \alpha', S_0) \equiv \gamma_F^+(\vec{x}, \alpha', do(\alpha, S_0)) \\ &\wedge \gamma_F^-(\vec{x}, \alpha', S_0) \equiv \gamma_F^-(\vec{x}, \alpha', do(\alpha, S_0))\} \\ \wedge \forall \vec{x}\{&(\gamma_F^+(\vec{x}, \alpha, S_0) \vee \ \gamma_F^-(\vec{x}, \alpha, S_0)) \\ &\supset (\gamma_F^+(\vec{x}, \alpha', S_0) \vee \gamma_F^-(\vec{x}, \alpha', S_0))\}.\end{aligned}$$

Proof (sketch). Observe that α is not always dominated by α' only if in some model the application of α in S_0 changes the truth value of the effect formulas of α' or if some of the effects of α is not reset by α'.

In the case of *context-free* actions such that γ_F^+ and γ_F^- do not depend on s, this is simplified as follows.

Corollary 4. *Let $\mathcal{D}$ be a basic action theory such that all successor state axioms are context-free in the sense that they have the following form: $F(\vec{x}, do(a, s)) \equiv \gamma_F^+(\vec{x}, a) \vee F(\vec{x}, s) \wedge \neg\gamma_F^-(\vec{x}, a)$. Action α is always dominated by α' wrt $\mathcal{D}$ iff for all fluents $F(\vec{x}, s)$ in $\mathcal{L}$ the following holds:*

$$\begin{aligned}\mathcal{D} - \mathcal{D}_0 \models \forall \vec{x}\{&(\gamma_F^+(\vec{x}, \alpha, S_0) \vee \ \gamma_F^-(\vec{x}, \alpha, S_0)) \\ &\supset (\gamma_F^+(\vec{x}, \alpha', S_0) \vee \gamma_F^-(\vec{x}, \alpha', S_0))\}.\end{aligned}$$

These notions provide the logical specification for transforming and simplifying action histories in a way that preserves the entailment of first-order projection queries. What becomes interesting then is identifying efficient procedures that can identify when sets of actions can be swapped and when an action can be eliminated for certain classes of action theories $\mathcal{D}$.

Action theories with single-value fluents and resetting actions

We now turn our attention to basic action theories with relational fluents that have a function-like behavior in the following sense. For each fluent $F(\vec{y}, s)$, we distinguish the last argument of sort object as the *output* of the fluent and the rest of the arguments of sort object as the *input*. In order to make this explicit we will write $F(\vec{x}, v, s)$ where v is the the output and $\vec{x}$ is input. We will also require that in every model of the action theory for every input $\vec{x}$ there is exactly one object for v (up to equality) such that $F(\vec{x}, v, s)$ holds. We call fluents of this type *single-value fluents*.

Definition 5. *Single-value* fluents are fluents for which the following holds:

$$\mathcal{D} \models \forall \vec{x}, v\{F(\vec{x}, v, s) \supset \neg\exists v'(F(\vec{x}, v', s) \wedge v' \neq v)\}.$$

This is a very common case in many practical domains, such as those involving mobile agents (i.e. a mobile agent can be in only one position in any given situation).[3] The next definition introduces the single-value successor state axioms which preserve this property.

Definition 6. The successor state axiom for $F(\vec{x}, v, s)$ has *resetting-actions* iff $\gamma_F^+(\vec{x}, v, a, s)$ is a disjunction of formulas of the form:

$$\exists \vec{z}(a = A(\vec{y}) \wedge v = y_i \wedge \phi(\vec{y}, s)),$$

and $\gamma_F^-(\vec{x}, v, a, s)$ is a disjunction of formulas of the form:

$$\exists \vec{z}(a = A(\vec{y}) \wedge \neg v = y_i \wedge \phi(\vec{y}, s)),$$

where A is an action symbol, $\vec{y}$ contains $\vec{x}$, $\vec{z}$ corresponds to the remaining variables of $\vec{y}$, y_i is a variable in $\vec{y}$, and $\phi(\vec{y}, s)$ (called a *context formula*) is a first-order formula uniform in s, and γ_F^+,γ_F^- come in pairs in the sense that for each disjunct in γ_F^+ there is one in γ_F^- that is identical except for the atom $v = y_i$ and vice versa. As in the case of functional fluents in (Reiter 2001), we also require the following sentence be entailed by $\mathcal{D}$:

$$\mathcal{D} \models \gamma_F^+(\vec{x}, v, \alpha, s) \supset \neg\exists v'(v' \neq v \wedge \gamma_F^-(\vec{x}, v', \alpha, s)).$$

A basic action theory $\mathcal{D}$ is one of resetting-actions if every SSAs in $\mathcal{D}_{ss}$ is a resetting SSA.

Note that the positive effects of a resetting SSA are in fact local-effect as they have exactly the same form, requiring that any affected atom is built using arguments of action $A(\vec{y})$, while the negative effects are a special form of global effects. Similarly to (Liu and Levesque 2005), the instantiation of a local-effect SSA on a ground action term can be simplified using the unique names axioms for actions as follows.

Lemma 1. *Let α be the ground action term $A(\vec{e})$, where $\vec{e}$ is a vector of constants and suppose that the SSA for F is resetting. Then $\gamma_F^+(\vec{x}, v, \alpha, s)$ is logically equivalent to a formula of the following form:*

$$(\vec{x} = \vec{c}_1 \wedge v = d_1 \wedge \phi_1(s)) \vee \cdots \vee (\vec{x} = \vec{c}_m \wedge v = d_m \wedge \phi_m(s)),$$

where each of the $\vec{c}_1, \ldots, \vec{c}_m$ is a vector of constants contained in $\vec{e}$, and $\phi_1(s), \ldots, \phi_m(s)$ are first-order and uniform in s. Each combination of $\vec{c}_i$, $\vec{d}_i$ must be distinct, and for any $\vec{x} = \vec{c}_i$, at most one $\phi_i(s)$ can hold for any model of s. Similarly, $\gamma_F^-(\vec{x}, \alpha, s)$ is logically equivalent to a formula of the following form:

$$\begin{aligned}&(\vec{x} = \vec{c}_1 \wedge \neg v = d_1 \wedge \phi_1(s)) \vee \cdots \\ &\vee (\vec{x} = \vec{c}_m \wedge \neg v = d_m \wedge \phi_m(s)).\end{aligned}$$

An example follows.

Example 5. Consider a modified instance of the Sokoban problem such that the surface of any cell can be either clean or oily. Consider three actions: $move(x)$, which moves the

[3] We note that a "regular" relational fluent could still be expressed by means of special constants *true* and *false* and with some extra syntactical machinery.

player to position x, $push(b, x, y)$, which pushes block b from position x to position y and $clean(x, t)$, which sets the truth value of x being oily to t. We use three fluents: *PlAt*(x, s), which says the player is in position x in situation s, *BlAt*(b, x, s), which says that block b is in position x in situation s and *Oily*(x, t, s), which says the surface of x contains oil where t is a variable that will take an object representing True or False. There are also appropriate $Poss$ axioms for walls, connectivity, and other necessary restrictions. The successor state axioms for this problem are as follows:

$$\begin{aligned}
&\textit{PlAt}(v, do(a, s)) \equiv \exists x(a = move(x) \wedge v = x)\\
&\quad \vee \exists b, x, y(a = push(b, x, y) \wedge v = x)\\
&\quad \vee \textit{PlAt}(v, s) \wedge \neg(\exists x(a = move(x) \wedge \neg v = x)\\
&\quad \vee \exists b, x, y(a = push(b, x, y) \wedge \neg v = x))\\
&\textit{BlAt}(b, v, do(a, s)) \equiv \exists x, y(a = push(b, x, y) \wedge v = y)\\
&\quad \vee \textit{BlAt}(b, v, s) \wedge \neg\exists x, y(a = push(b, x, y) \wedge \neg v = y)\\
&\textit{Oily}(x, v, do(a, s)) \equiv \exists t(a = clean(x, t) \wedge v = t))\\
&\quad \vee \textit{Oily}(x, v, s) \wedge \neg\exists t(a = clean(x, t) \wedge \neg v = t))
\end{aligned}$$

We begin by introducing the notion of the *effect set* of an action. The idea is to represent a set of situation-suppressed ground fluent atoms that will be affected by an action, as well as the conditions under which the fluent atom will be affected. This is formalised as follows:

Definition 7. Let α_k be a ground resetting action. The *effect set* of α_k is the following set:

$$\begin{aligned}
\Phi_k = \{\phi \supset F(\vec{c}, d) \mid\\
\vec{x} = \vec{c} \wedge \phi \wedge v = d \text{ appears in } \gamma_F^+(\vec{x}, v, \alpha, s)\}.
\end{aligned}$$

Without loss of generality, we assume that the ground versions of the γ^+ and γ^- formulas are simplified according to Lemma 1. The effect sets can then be obtained directly. We observe the following fundamental property of the effect set:

Lemma 2. *Let $F(\vec{x}, v, s)$ be a single-value fluent with positive and negative successor state axioms $\gamma_F^+(\vec{x}, v, \alpha, s)$ and $\gamma_F^-(\vec{x}, v, \alpha, s)$ respectively. Let M be any model of $\mathcal{D}$. Let α_k be a ground resetting action with effect set Φ_k. Then for all $\vec{x} = \vec{c}, v = d$: $M \models \gamma_F^+(\vec{x}, v, \alpha_k, s)$ iff there exists a $\phi \supset F(\vec{c}, d)$ in Φ_k such that $M \models \phi$.*
$M \models \gamma_F^-(\vec{x}, v, \alpha_k, s)$ iff there exists a $\phi \supset F(\vec{c}, e)$ in Φ_k such that $d \neq e$ and $M \models \phi$.

Proof. From the construction of the effect set and the form of the successor state axioms. □

Resetting actions without contexts

We begin by considering a subset of resetting actions where each ϕ_i is $true$. This allows us to reorder or eliminate actions without needing to consider the effects that one action can have on the contexts of the other. We introduce a procedure for determining whether two context-free actions are swappable by directly inspecting their effect sets:

Theorem 6. *Let actions α_1 and α_2 be consecutive resetting actions without contexts with effect sets Φ_1 and Φ_2 respectively. Then α_1 and α_2 are always swappable iff for all elements of Φ_1 of the form $true \supset F(\vec{c}, d_1)$ there is no element of Φ_2 of the form $true \supset F(\vec{c}, d_2)$ such that $d_1 \neq d_2$.*

Proof. From Corollary 2 and Lemma 2. □

While this is a restricted class of actions, it is nonetheless sufficient to cover a number of interesting cases, such as the Sokoban example.

Example 6. Consider the SSAs used in Example 5 and a sample action sequence $\langle move(pos_1), clean(pos_1, F)\rangle$. We first calculate the effect sets for each action: $\Phi_1 = \{true \supset \textit{PlAt}(pos_1)\}$, $\Phi_2 = \{true \supset \textit{Oily}(pos_1, F)\}$. From Theorem 6 we can observe that $move(pos_1)$ and $clean(pos_1, F)$ are always swappable.

We now introduce a procedure for determining whether one resetting action without a context always dominates another by directly inspecting their effect sets.

Theorem 7. *Let actions α_1 and α_2 be consecutive resetting actions without contexts with effect sets Φ_1 and Φ_2 respectively. Then α_2 always dominates α_1 iff for all elements of Φ_1 of the form $true \supset F(\vec{c}, d_1)$ there exists an element of Φ_2 of the form $true \supset F(\vec{c}, d_2)$.*

Proof. From Corollary 4 and Lemma 2 □

Note that determining whether actions can be just-in-time eliminated purely by inspection of the successor state axioms is not possible. This is because of the possibility that some or all of those fluent atoms already held the same value before the action was taken. In the extreme case, for example, that an action occurred twice and identically set all fluent atoms, the second occurrence of that action could be said to be dominated by *any* subsequent action.

Below is an example demonstrating the idea of always-dominating for resetting actions without contexts.

Example 7. Consider the SSAs used in Example 5 and a sample action sequence $\langle move(pos_1), push(b_1, pos_2, pos_3)\rangle$. We first calculate the effect sets for each action: $\Phi_1 = \{true \supset \textit{PlAt}(pos_1)\}$, $\Phi_2 = \{true \supset \textit{PlAt}(pos_2), true \supset \textit{BlAt}(b_1, pos_2)\}$. From Theorem 7 we can observe that $push(b_1, pos_2, pos_3)$ dominates $move(pos_1)$ and thus the action sequence can be simplified to $\langle push(b_1, pos_2, pos_3)\rangle$.

Resetting actions with conjunctive queries as contexts

We now consider a larger class of resetting actions where the context formulas ϕ_i consist of a quantifier-free conjunction of ground fluent atoms. We require that each context formula ϕ_i is satisfiable in the sense that if an element $F(\vec{c}, d)$ is mentioned then neither $\neg F(\vec{c}, d)$ nor $F(\vec{c}, e)$ is mentioned for some $e \neq d$. Reasoning about the properties of these actions is not so straightforward, as determining the value of a context formula for an action requires detailed inspection of the knowledge base. Moreover, the application of one action

can affect the contexts of another. We introduce the following sound but incomplete method for determining whether a pair of conjunctive resetting actions are always swappable:

Theorem 8. *Let actions α_1 and α_2 be consecutive conjunctive resetting actions with effect sets Φ_1 and Φ_2 respectively. Then α_1 and α_2 are always swappable if:*

- *For all elements of Φ_1 of the form $\phi_1 \supset F_1(\vec{c_1}, d_1)$, there does not exist an element of Φ_2 of the form $\phi_2 \supset F_2(\vec{c_2}, d_2)$ such that $F_1 = F_2, \vec{c_1} = \vec{c_2}$, $d_1 \neq d_2$, $\phi_1 \wedge \phi_2$ is satisfiable.*
- *For all elements of Φ_1 of the form $\phi_1 \supset F_1(\vec{c_1}, d_1)$, there does not exist an element of Φ_2 of the form $\phi_2 \supset F_2(\vec{c_2}, d_2)$ such that ϕ_2 mentions $F_1(\vec{c_1}, e)$ for some e.*
- *For all elements of Φ_2 of the form $\phi_2 \supset F_2(\vec{c_2}, d_2)$, there does not exist an element of Φ_1 of the form $\phi_1 \supset F_1(\vec{c_1}, d_1)$ such that ϕ_1 mentions $F_2(\vec{c_2}, e)$ for some e.*

Proof (sketch). The first point above corresponds with the second condition of Theorem 3 and follows from Lemma 2. For the second condition of Theorem 3, we consider a slightly stronger requirement such that $\gamma^+_F(\vec{x}, v, \alpha_1, S_0) \equiv \gamma^+_F(\vec{x}, \alpha_1, do(\alpha_2, S_0))$ and $\gamma^+_F(\vec{x}, v, \alpha_2, S_0) \equiv \gamma^+_F(\vec{x}, \alpha_2, do(\alpha_1, S_0))$ for all $\vec{c}, v$ and similarly for negative SSAs. From Lemma 2, any $F(\vec{c}, d)$ for which there is no $\phi \supset F(\vec{c}, e)$ in Φ_1 for some e cannot affect $\gamma^+_F(\vec{x}, v, \alpha_2, S_0) \equiv \gamma^+_F(\vec{x}, \alpha_2, do(\alpha_1, S_0))$, and similarly for the other conditions.

This result is incomplete due to the possibility that for all models, a pair of context formulas in Φ_1 and Φ_2 referring to the same fluent may be unsatisfiable, or that one may imply the other. We expect such cases to be uncommon in practice, however, as in the majority of cases we expect to reorder actions that do not affect the same fluents. We now consider the complexity of always-swapping for conjunctive queries:

Theorem 9. *The complexity of determining whether two conjunctive resetting actions are always swappable is $O(nm)$ where n is the number of elements in the effect set and m is the number of elements in the context formula ϕ. For resetting actions without contexts, this reduces to $O(n)$.*

Proof. The first item in Theorem 8 requires that for each of the n elements of the effect set, the satisfiability of $\phi_1 \wedge \phi_2$ for any corresponding element in the other set is determined. Since $\phi_1 \wedge \phi_2$ is a conjunctive query, this can be done in $O(nm)$ time. The second and third points require each of the $n \times m$ members of an effect set to be checked for membership in the other effect set, with a complexity of $O(nm)$. For resetting actions without contexts, the second and third points are not required, and the first part does not require a satisfiability check. This reduces to $O(n)$, as the problem is essential checking set membership. □

We also note that the satisfiability check can be omitted while still retaining a sound result. To demonstrate, we consider a version of the Sokoban example used previously, modified to include conjunctive contexts. Imagine now that pushing a box over an oily surface will cause it to move one additional unit further than expected. We modify the formalism as follows:

Example 8. Let the push action now take five arguments, $push(b, x, y, z, t)$ where t is a variable that will take an object representing a truth value. This action will push block b from position x to position y. If the surface of y is oily, the block will be moved to z instead. The successor state axiom for *BlAt* is now as follows:

$$\begin{aligned}
&\textit{BlAt}(b, v, do(a, s)) \equiv \\
&\exists x, y, z(a = push(b, x, y, z, t) \wedge v = y \wedge \neg \textit{Oily}(y, t, s)) \\
&\vee \exists x, y, z(a = push(b, x, y, z, t) \wedge v = z \wedge \textit{Oily}(y, t, s)) \\
&\vee \textit{BlAt}(b, v, s) \wedge \neg\{ \\
&\exists x, y, z(a = push(b, x, y, z, t) \wedge \neg v = y) \wedge \neg \textit{Oily}(y, t, s) \\
&\vee \exists x, y, z(a = push(b, x, y, z, t) \wedge \neg v = z \wedge \textit{Oily}(y, t, s))\}
\end{aligned}$$

Consider now an action sequence $\langle clean(pos_1, F), push(b_1, pos_2, pos_3, pos_4, T)\rangle$. We firstly calculate the effect sets of the two actions: $\Phi_1 = \{true \supset \textit{Oily}(pos_1, F)\}$ $\Phi_2 = \{\neg \textit{Oily}(pos_3, T) \supset \textit{BlAt}(b_1, pos_3), \textit{Oily}(pos_3, T) \supset \textit{BlAt}(b_1, pos_4), true \supset \textit{PlAt}(pos_2)\}$. Now using Theorem 8, we can observe that $clean(pos_1, F)$ and $push(b_1, pos_2, pos_3, pos_4, T)$ are always swappable.

We now propose a method for identifying when one resetting action is always dominated by a subsequent action, and can thus be removed.

Theorem 10. *Let α_1 and α_2 be consecutive conjunctive resetting actions with effect sets Φ_1 and Φ_2 respectively. Let $\phi_1[F(\vec{c})]$ refer to the disjunction of all ϕ_1 for which $\phi_1 \supset F(\vec{c}, d)$ is in Φ_1 for any d and $\phi_2[F(\vec{c})]$ refer to the disjunction of all ϕ_2 for which $\phi_2 \supset F(\vec{c}, d)$ is in Φ_2 for any d. Then α_2 always dominates α_1 iff for all $\vec{c}$, $\phi_1[F(\vec{c})] \supset \phi_2[F(\vec{c})]$ is valid and for all elements of Φ_1 of the form $\phi_1 \supset F_1(\vec{c_1}, d_1)$, there is no element of Φ_2 of the form $\phi_2 \supset F_2(\vec{c_2}, d_2)$ such that ϕ_2 mentions $F_1(\vec{c_1}, e)$ for some e and $\phi_1 \wedge \phi_2$ is satisfiable.*

Proof (sketch). Focus firstly on the second part of Theorem 5. From Lemma 2, $\gamma^-_F(\vec{x}, v, \alpha_1, S_0) \vee \gamma^+_F(\vec{x}, v, \alpha_1, S_0)$ iff there exists a $\phi_1 \supset F(\vec{x}, v')$ in Φ_1 such that ϕ_1 is $true$ (similarly for α_2). Now $(\gamma^-_F(\vec{x}, v, \alpha_1, S_0) \vee \gamma^+_F(\vec{x}, v, \alpha_1, S_0)) \supset (\gamma^-_F(\vec{x}, v, \alpha_2, S_0) \vee \gamma^+_F(\vec{x}, v, \alpha_2, S_0))$ is valid iff $\phi_1[F(\vec{c})] \supset \phi_2[F(\vec{c})]$ is valid for all models. For the first part of Theorem 5, for each $\phi_2 \supset F_2(\vec{c_2}, d_2)$ in Φ_2, consider a model, M such that every $F(\vec{x}, y)$ mentioned in ϕ_2 holds with the exception of some $F(\vec{c}, d)$ for which $\phi_1 \supset F(\vec{c}, d)$ appears in Φ_1. Then $\gamma^+_F(\vec{x}, v, \alpha_2, S_0) \not\equiv \gamma^+_F(\vec{x}, v, \alpha_2, do(\alpha_1, S_0))$ for $x = c_2, v = d_2$ iff ϕ_1 is also satisfiable M. The approach is similar for the case of $F(\vec{c}, e)$ in ϕ_1 as well as for the negative effects.

We now consider the complexity of always-dominating for conjunctive queries:

Theorem 11. *The complexity of determining whether one conjunctive-resetting action dominates another is $O(n.2^{mk})$ where n is the number of elements in the effect set, k is the number of times a $\phi \supset F(\vec{c}, d)$ appears in the effect set for fixed $\vec{c}$ but varying d and m is the number of elements in the context formula ϕ. For resetting actions without contexts, this reduces to $O(n)$.*

Proof. The first condition in Theorem 10 requires that for each of the n elements of the effect set, the validity of $\phi_1[F(\vec{c})] \supset \phi_2[F(\vec{c})]$ is determined. Each $\phi[F(\vec{c})]$ contains $m \times k$ terms, the complexity of determining the validity for each formula of this type is thus $O(2^{mk})$. For the second part, each of the $n \times m$ elements of the contexts in Φ_2 must be checked for membership in Φ_1. If found, the satisfiability of $\phi_1 \wedge \phi_2$ must be determined. Since $\phi_1 \wedge \phi_2$ is a conjunctive query, the satisfiability check can be done in $O(m)$ time. The total complexity is thus $O(n.2^{mk}) + O(nm^2)$. For resetting actions without contexts, the second part is not required, and the first part does not require a validity check. This reduces to $O(n)$, as the problem is essential checking set membership. □

We expect such a method to be feasible in practice, as it is exponential only in the size of the context formulas and the number of times a particular $F(\vec{c})$ appears in the effect set. We now show an example of dominating conjunctive resetting actions.

Example 9. Using the successor state axioms developed in Example 8, consider now an action sequence $\langle push(b_1, pos_1, pos_2, pos_3, T),$
$push(b_1, pos_2, pos_3, pos_4, T)\rangle$. We firstly calculate the effect sets of the two actions: $\Phi_1 = \{\neg \mathit{Oily}(pos_2, T) \supset \mathit{BlAt}(b_1, pos_2), \mathit{Oily}(pos_2, T) \supset \mathit{BlAt}(b_1, pos_3), true \supset \mathit{PlAt}(pos_1)\}$ $\Phi_2 = \{\neg \mathit{Oily}(pos_3, T) \supset \mathit{BlAt}(b_1, pos_3), \mathit{Oily}(pos_3, T) \supset \mathit{BlAt}(b_1, pos_4), true \supset \mathit{PlAt}(pos_2)\}$. Now using Theorem 10, $push(b_1, pos_2, pos_3, pos_4, T)$ always dominates $push(b_1, pos_1, pos_2, pos_3, T)$.

Discussion and Related Work

To the best of our knowledge this is the first approach that looks into formalizing operations over an action history that preserves truth of (simple and generalized) projection queries in the final situation. It helps us handle cases which cannot be easily progressed, or actions which can result in a non-progressible theory, by swapping and eliminating actions—achieving transformed theories which can be later progressed. Note that the work does not extend the known classes of progressable theories (Vassos and Patrizi 2013), in contrast the work contributes to a setting where regression and progression can be invoked and interleaved in sensible ways. It is potentially applicable to a wide range of queries, for different action languages.

A similar approach in spirit is nonetheless employed in the *implementations* of reasoning systems that rely on constraints solvers. In particular, for reasoning about action the `Flux` system for implementing fluent calculus theories (Thielscher 2004) uses (among other things) constraints to represent the effects implied to fluents with arithmetic arguments. These constraints specify how the old value of fluents relates to the new one, and are appended to the constraint store as the action history grows. Periodically, `Flux`'s constraint store invokes heuristic techniques for simplifying the history by eliminating redundant constraints.

There are, nonetheless, parallels to work being done in classical planning. In particular (Chrpa, McCluskey, and Osborne 2012) identifies pairs of actions as being either *independent*, *shared*, *nested* or *interleaved*, and goes on to define conditions under which these different types of actions can be removed from a sequence. Working in the classical planning domain, however, allows Chrpa to consider a clear and finite set of effects for each action, which is not the case in the Situation Calculus. Also, in order to realise the modified plan, Chrpa is required to consider the preconditions of each action, whereas by focusing on the projection problem one is able to bypass these, allowing more actions to be dominated. Finally, Chrpa does not consider the possibility of reordering actions.

Symmetry breaking, and the related issue of planning landmarks, have also been shown to be promising for achieving efficiency in planning domains (Domshlak, Katz, and Shleyfman 2013). Interestingly, dominance relations are known to entail the special case of symmetry in constraint programming (Chu, Garcia del la Banda, and Stuckey 2012). Dominance relations might therefore form a basis of a range of constraint optimisation techniques for action languages. This paper follows these insights by realising re-ordering for action histories for a wide range of rich theories.

There are a number of settings where transformation could be effectively used, including *sensing* actions and reasoning about the domination of *sets of actions*. Sensing actions provide new information about the value of fluents and could dominate earlier actions. It may therefore be possible to delay progression, in the event that progression is not possible in one situation due to missing information about certain fluents, until later when sensing actions can learn fluent values which dominate the effects of earlier actions. If we can delay progression until *after* sensing actions are performed, this could facilitate the progression of the action theory at a later time. The dominance of sets of actions over one another could significantly extend the number of cases under which dominance was possible and facilitate new ways of reordering and elimination on set theoretic grounds.

The generality of our approach has the potential to be utilised for wider classes of action theory. For example, the approach could be extended beyond conjunctive queries towards arbitrary context formulas. The extension of the approach to an even wider class of global effect actions, would also be very useful, as global effect theories are known to be particularly problematic with respect to progression.

Conclusions

This work takes the important step of formalizing the transformation of theories of action in order to optimise frequently executed reasoning tasks. The transformation allows action sequences to be shortened, via the swapping and reordering of independent actions and elimination of dominating actions. This can facilitate easier, more optimised, forms of reasoning. Our technique is potentially applicable to a wide range of rich first order theories.

We have identified a new class of action theory which allows for a restricted form of global effects–resetting actions–which falls outside of any known progressable theory of action. It overcomes problems with progression commonly encountered in the agent reasoning tasks illustrated. Our

technique facilitates a new approach for tackling situations falling outside the known classes of progressable theories, and can also be used for optimising the progression of theories known to be progressable. It also enables more efficient entailment queries to be answered by progressing where possible, only performing regressing where necessary.

Abstract

Verification of dynamic systems that manipulate data, stored in a database or ontology, has lately received increasing attention. A plethora of recent works has shown that verification of systems working over unboundedly many data is decidable even for very rich temporal properties, provided that the system is *state-bounded*. This condition requires the existence of an overall bound on the amount of data stored in each single state along the system evolution. In general, checking state-boundedness is undecidable. An open question is whether it is possible to isolate significant classes of dynamic systems for which state-boundedness is decidable. In this paper we provide a strong negative answer, by resorting to a novel connection with variants of Petri nets. In particular, we show undecidability for systems whose data component contains unary relations only, and whose action component queries and updates such relations in a very limited way. To contrast this result, we propose interesting relaxations of the sufficient conditions proposed in the concrete setting of Data-Centric Dynamic Systems, building on recent results on chase termination for tuple-generating dependencies.

1 Introduction

The formalization and verification of dynamic systems that manipulate data, stored in a database or ontology, has lately received an increasing attention from both a foundational and a practical point of view (Calvanese, De Giacomo, and Montali 2013). In particular, business process management has progressively shifted its focus from a purely control-flow perspective that under-specifies (if not completely abstracts away) the data component, to a data-aware perspective where data have the same importance as system dynamics (Dumas 2011). This comprehensive view of dynamic systems has given rise to a series of paradigms, such as data-centric workflows (Vianu 2009) and business artifacts (Hull 2008), where the static (i.e., data-related) and dynamic (i.e., process-related) system aspects are jointly modelled and managed.

The verification of a data-aware dynamic system is notoriously challenging: as soon as it can incorporate (possibly unbounded) data from the external environment, e.g., due to interaction with external services or humans, the transition system representing its execution becomes infinite-state, and verification turns out to be undecidable even for propositional reachability properties (Deutsch et al. 2009; Belardinelli, Lomuscio, and Patrizi 2012; Bagheri Hariri et al. 2013b; 2013a). To mitigate this problem, an extensive amount of research has been devoted to find suitable classes of data-aware dynamic systems for which verification of first-order temporal properties becomes decidable. In particular, a plethora of recent works has shown that verification of data-aware dynamic systems working over unboundedly many data is decidable even for very rich temporal logics, provided that the system is *state-bounded*. For example, Belardinelli, Lomuscio, and Patrizi (2012) show decidability of verification of state-bounded (there called b-bounded) artifact centric multiagent systems (ACMASs) for a first-order, epistemic variant of CTL, with active domain quantification that applies across time points. Bagheri Hariri et al. (2013b) give a key decidability result for the verification of state-bounded Data-Centric Dynamic Systems (DCDSs) against a first-order variant of the μ-calculus with a limited form of quantification across time. Within the research line of reasoning about actions, De Giacomo, Lesperance, and Patrizi (2012) show that (state-)bounded Situation Calculus theories can be verified against a first-order variant of the μ-calculus, without quantification across states. Notably, in all these cases state-boundedness guarantees the existence of a faithful (sound and complete) finite-state abstraction of the system, paving the way for the application of standard model checking tools.

Intuitively, state boundedness requires the existence of an overall bound on the amount of data stored in each single state of the system (a database instance or an ABox) along the system evolution. As shown by Bagheri Hariri et al. (2013b), checking state-boundedness is in general undecidable. The proof is given for the specific framework of DCDSs, but can be straightforwardly applied to other similar frameworks, such as ACMASs. Due to undecidability of state-boundedness, the existing works have either: *(i)* assumed that the system is state-bounded (Belardinelli, Lomuscio, and Patrizi 2012); *(ii)* explicitly enforced state-boundedness by blocking those actions that would lead to exceed the bound (De Giacomo, Lesperance, and Patrizi 2012; Solomakhin et al. 2013); *(iii)* studied sufficient conditions that can be checked over the dynamic component of the system (actions and/or processes) to test whether they guarantee state-boundedness (Bagheri Hariri et al. 2013b).

An open question is whether it is possible to isolate significant classes of dynamic systems for which state-boundedness is decidable. In this paper we study this problem, devising a novel connection between variants of Petri nets (Transfer/Reset nets) (Dufourd, Finkel, and Schnoebelen 1998; Dufourd, Jancar, and Schnoebelen 1999) and DCDSs, and inter-reducing the problem of checking whether a DCDS is state-bounded to the problem of checking whether a Transfer/Reset/Petri net is bounded (i.e., ensures that the number of tokens present in each place of the net never exceeds a given bound). Observe that DCDSs are expressively equivalent to business artifact formalisms for business process specification deployed in industrial settings (Bagheri Hariri et al. 2013b; Solomakhin et al. 2013). Thanks to the connection between DCDSs and Petri nets, we provide a strong negative answer to the aforementioned open question: we show undecidability of DCDSs with unary relations, queried in a very limited way (i.e., without using joins, and with a very limited usage of inequalities). Furthermore, we show that undecidability is mainly related to the possibility for relations to lose their content during the application of a single action, and that decidability is obtained if this is prevented (though with an intractable complexity lower bound). Also in this case, the provided results can be transferred to other similar frameworks, such as ACMASs.

To contrast this negative result, we improve the sufficient (syntactic) conditions proposed by Bagheri Hariri et al. (2013b) to check whether a DCDS is state-bounded, by defining a hierarchy of sufficient conditions that progressively refine the analysis of how data are manipulated by the action component of the DCDS. To do so, we take inspiration from recent results on chase termination for tuple-generating dependencies, and in particular from the *safety* (Meier, Schmidt, and Lausen 2009) and *stratified* (Deutsch, Nash, and Remmel 2008) extensions of *weak-acyclicity* (Fagin et al. 2005).

It is interesting to observe that all our results can be lifted from the pure relational setting we consider here, to a knowledge-based setting as the one presented in (Bagheri Hariri et al. 2013a). This can be immediately done when the data component is a full-fledged ontology expressed in a Description Logic that allows for rewriting queries posed over the ontology as unions of conjunctive queries posed over the data only (Calvanese et al. 2007).

2 Data-Centric Dynamic Systems

We recall the main aspects of Data-Centric Dynamic Systems (DCDSs). For a comprehensive treatment, the reader is referred to (Bagheri Hariri et al. 2013b).

A DCDS $\mathcal{S}$ is a pair $\langle \mathcal{D}, \mathcal{P} \rangle$, where $\mathcal{D}$ is the data component of $\mathcal{S}$, and $\mathcal{P}$ is its process component. The data component $\mathcal{D}$ is a tuple $\mathcal{D} = \langle \mathcal{C}, \mathcal{R}, \mathcal{E}, I_0 \rangle$, where: *(i)* $\mathcal{C}$ is a countably infinite set of constants; *(ii)* $\mathcal{R}$ is a *database schema*, i.e., a sets of relation schemas; *(iii)* $\mathcal{E}$ is a set of *equality constraints* over $\mathcal{R}$; *(iv)* I_0 is the *initial database instance* of $\mathcal{S}$, i.e., a database instance conforming to $\mathcal{R}$ and $\mathcal{E}$, and made up of values in $\mathcal{C}$. Given a relation $R \in \mathcal{R}$ and a database instance I conforming to $\mathcal{R}$, we denote with $|R|_I$ the number of R-tuples contained in I.

The process layer $\mathcal{P}$ defines the progression mechanism for the DCDS. It is constituted by a process, which queries the current data maintained by $\mathcal{D}$ and determines which actions are executable; actions, in turn, query and update $\mathcal{D}$, possibly introducing new values from the external environment, by issuing service calls. Technically, $\mathcal{P} = \langle \mathcal{F}, A, \varrho \rangle$, where *(i)* $\mathcal{F}$ is a finite set of *functions*, each representing the interface to a (nondeterministic) *external service*; *(ii)* A is a finite set of *actions*, whose execution updates the data layer, and may involve external service calls; *(iii)* ϱ is a finite set of *condition-action rules* that form the specification of the overall *process*, which tells at any moment which actions can be executed. By considering a finite set $\mathfrak{A}$ of action names, an *action* $\alpha \in A$ is an expression $\alpha(p_1, \ldots, p_n) : \{e_1, \ldots, e_m\}$, where: *(i)* $\alpha(p_1, \ldots, p_n)$ is its *signature*, constituted by a name $\alpha \in \mathfrak{A}$ and a sequence $p_1, \ldots, p_n$ of *parameters*, to be substituted with values when the action is invoked, and *(ii)* $\{e_1, \ldots, e_m\}$, also denoted as $\text{EFFECT}(\alpha)$, is a set of *specifications of effects*, which are assumed to take place simultaneously. Each e_i has the form $q_i^+ \wedge Q_i^- \rightsquigarrow E_i$, where:

- $q_i^+ \wedge Q_i^-$ is a query over $\mathcal{R}$ whose terms are variables, action parameters, and constants from I_0, where q_i^+ is a union of conjunctive queries, and Q_i^- is an arbitrary FO formula whose free variables are among those of q_i^+. Intuitively, q_i^+ selects the tuples to instantiate the effect with, and Q_i^- filters away some of them.
- E_i is the effect, i.e., a set of facts for $\mathcal{R}$, which includes as terms: terms in the active domain of I_0, free variables of q_i^+ and Q_i^- (including action parameters), and Skolem terms formed by applying a function $f \in \mathcal{F}$ to one of the previous kinds of terms. Such Skolem terms involving functions represent external (nondeterministic) service calls and are interpreted as the returned value chosen by an external user/environment when executing the action.

The *process* ϱ is a finite set of *condition-action rules*, of the form $Q \mapsto \alpha$, where α is an action in A and Q is a FO query over $\mathcal{R}$ whose free variables are exactly the parameters of α, and whose other terms can be quantified variables or constants mentioned in I_0.

Execution semantics. The execution semantics of a DCDS $\mathcal{S}$ is a possibly infinite transition system $\Upsilon_{\mathcal{S}}$ whose states are labeled by database instances. It represents all possible computations that the process layer can do on the data layer. Specifically, $\Upsilon_{\mathcal{S}} = \langle \mathcal{C}, \mathcal{R}, \Sigma, s_0, db, \Rightarrow \rangle$, where: *(i)* Σ is a set of states; *(ii)* $s_0 \in \Sigma$ is the initial state; *(iii)* db is a function that, given a state $s \in \Sigma$, returns the database of s, which is made up of values in $\mathcal{C}$ and conforms to $\mathcal{R}$; *(iv)* $\Rightarrow \subseteq \Sigma \times \mathfrak{A} \times \Sigma$ is a transition relation over states, labeled by action names.

Given a DCDS $\mathcal{S} = \langle \mathcal{D}, \mathcal{P} \rangle$ with $\mathcal{D} = \langle \mathcal{C}, \mathcal{R}, \mathcal{E}, I_0 \rangle$ and $\mathcal{P} = \langle \mathcal{F}, A, \varrho \rangle$, the transition system $\Upsilon_{\mathcal{S}}$ is intuitively constructed as follows. Starting from I_0, all condition-action rules in ϱ are evaluated, determining which actions are executable, and with which ground parameter assignments. Nondeterministically, one such action with parameter assignment $\alpha\rho$ is selected and executed over I_0. To do so, every effect of α (partially grounded with the parameter assignment ρ)

is evaluated, by calculating all the answers of its left-hand side, and grounding the right-hand side accordingly. If the right-hand side contains service calls, they are issued, receiving back for each of them a value nondeterministically chosen from $\mathcal{C}$. This value is then used to substitute the service call with the actual result. The overall set of ground facts obtained in this way finally constitutes the next database instance. Notice that upon the execution of $\alpha\rho$, the content of a relation is lost unless it is explicitly maintained through dedicated effects of α. The transition system construction then proceeds by constructing all possible successors, each of which is obtained by selecting one of the executable actions with parameters, and one result for each of the involved service calls. The construction then recursively proceeds over this newly generated states. For a formal description of the execution semantics, see (Bagheri Hariri et al. 2013b).

State-Boundedness. Let $\mathcal{S} = \langle \mathcal{D}, \mathcal{P} \rangle$ be a DCDS with $\mathcal{D} = \langle \mathcal{C}, \mathcal{R}, \mathcal{E}, I_0 \rangle$ and $\mathcal{P} = \langle \mathcal{F}, A, \varrho \rangle$. We say that $\mathcal{S}$ is *state-bounded* if every state of $\Upsilon_{\mathcal{S}}$ is labeled with a database instance whose size does not exceed a pre-defined bound. We say that $\mathcal{S}$ is *structurally state-bounded* if, for every database instance I_0' conforming to $\mathcal{R}$ and $\mathcal{E}$, and made up of values in $\mathcal{C}$, $\langle \mathcal{D}', \mathcal{P} \rangle$ is state-bounded, where $\mathcal{D}' = \langle \mathcal{C}, \mathcal{R}, \mathcal{E}, I_0' \rangle$.

3 Relating DCDSs and Reset Transfer Nets

In this section we introduce variants of Petri nets and draw a formal correspondence with some specific classes of DCDSs. In Section 4 we leverage on this connection to provide key results related to (structural) state-boundedness of DCDSs. We assume the reader has knowledge of standard Petri nets.[1]

3.1 Reset Transfer Nets

Reset Transfer nets (RT nets) are a restricted form of Reset Post G-nets, introduced for the first time in (Dufourd, Finkel, and Schnoebelen 1998). Intuitively, a (standard) Petri net can consume and produce a fixed amount of tokens when a transition fires, while all the remaining tokens are left untouched. The "reset" dimension of RT nets extends this behavior by allowing to instantaneously emptying the content of some places when a transition fires. The "transfer" dimension of RT nets supports instead the possibility of instantaneously transferring the entire content of some place to another place when a transition fires. These specific classes exactly correspond to those defined in (Dufourd, Finkel, and Schnoebelen 1998). An RT net combines the capabilities of R and T nets.

A (marked) *RT net* is a tuple $N = \langle P, T, F, m_0 \rangle$, where:

- P is a set of *places*;
- T is a set of *transitions* (with $P \cap T = \emptyset$);
- $F : P \times T \cup T \times P \to P \cup \{0, 1\}$ is a *flow function* mapping each pair place/transition (called *pre-arc*) and transition/place (called *post-arc*) to either a place name or the integers 0 or 1,[2] with the following constraints:
  - for each place $p \in P$ and transition $t \in T$, $F(p, t) \in \{0, 1, p\}$;
  - for each transition $t \in T$ and place $p_2 \in P$, if $F(t, p_2) = p$, then the following two conditions hold: *(i)* $F(p, t) = p$, *(ii)* for each place $p_3 \in P$ with $p_3 \neq p_2$, $F(t, p_3) \neq p$.
- m_0 is the *initial marking*, i.e., a multiset of places $m_0 \in \mathbb{B}(P)$, with $\mathbb{B}(P) : P \to \mathbb{N}$ the set of multisets over the set P of places.

Given a place $p \in P$ and a transition $t \in T$, we say that p is an *input place* for t if $F(p, t) = 1$, and that (p, t) is a *reset arc* if $F(p, t) = p$. Symmetrically, given a place $p_2 \in P$ and a transition $t \in T$, we say that p_2 is an *output place* for t if $F(t, p_2) = 1$, and that (t, p_2) is a *copy arc* if $F(t, p_2) = p$ for some $p \in P$. In this latter case, the pre-arc (p, t) and the post-arc (t, p_2) form together a *transfer arc*[3].

An *RT net* $N = \langle P, T, F, m_0 \rangle$ is a:

- *Reset Petri net (R net)* if for each $t \in T$ and $p \in P$, $F(t, p) \in \{0, 1\}$;
- *Transfer Petri net (T net)* if for each $p \in P$ and $t \in T$ such that $F(p, t) = p$, there exists $p_2 \in P$ such that $F(t, p_2) = p$;
- *Petr net* if for each $p \in P$ and $t \in T$, $F(p, t) \in \{0, 1\}$ and $F(t, p) \in \{0, 1\}$.

Execution Semantics. Given a marking m and a place p, notation $m(p) \in \mathbb{N}$ represents the number of tokens assigned by m to p, i.e., the number of times p appears in m. Instrumental to the definition of the net execution semantics is the notion of "token transfer" induced by an arc of the net for a given marking. This is formally captured by the function TRANSF, defined as follows: given an RT net $N = \langle P, T, F, m_0 \rangle$, for every marking m over P, place $p \in P$, and transition $t \in T$, we have

$$\text{TRANSF}_m(p, t) = \begin{cases} m(p) & \text{if } F(p, t) = p \\ F(p, t) & \text{otherwise} \end{cases}$$

$$\text{TRANSF}_m(t, p) = \begin{cases} m(p') & \text{if } F(t, p) = p' \\ F(t, p) & \text{otherwise} \end{cases}$$

Given a marking m and a transition $t \in T$, we say that t is *enabled* (or *fireable*) in m, written $m[t\rangle$, if, for every place $p \in P$, we have that $m(p) \geq \text{TRANSF}_m(p, t)$. Given a transition t and two markings m and m', we say that t fires in m producing m', written $m[t\rangle m'$, if and only if: *(i)* t is enabled in m, *(ii)* m' is such that for every $p \in P$,

$$m'(p) = m(p) - \text{TRANSF}_m(p, t) + \text{TRANSF}_m(t, p)$$

The execution semantics of an RT net $N = \langle P, T, F, m_0 \rangle$ is defined in terms of a transition system $\text{RG}(N) = \langle M, m_0, \to \rangle$ (called *reachability graph*), where $M \subseteq \mathbb{B}(P)$ is a set of markings, and $\to \subseteq M \times T \times M$ is a transition relation labeled with elements from T. Specifically, M and $\to$ are defined by mutual induction as the smallest sets satisfying the following properties: *(i)* $m_0 \in M$; *(ii)* if $m \in M$, then for every transition $t \in T$ and marking m' such that $m[t\rangle m'$, we have $m' \in M$ and $m \xrightarrow{t} m'$. An RT net N is *bounded* if and only if each marking in $\text{RG}(N)$ is bounded or, equivalently, $\text{RG}(N)$ contains a finite number of markings.

[1] Here Petri net is used to identify a Place Transition (P/T) net.

[2] Admitting arbitrary integers does not increase the expressive power of the model.

[3] Remember that, by definition, in this case we have $F(p, t) = p$.

An RT net $N = \langle P, T, F, m_0 \rangle$ is *structurally bounded* if its boundedness does not depend on the initial marking, i.e., for every $m'_0 \in \mathbb{B}(P)$, $\langle P, T, F, m'_0 \rangle$ is bounded.

3.2 From RT Nets to DCDSs

We formally define a translation from RT Nets to DCDSs, and then provide an informal account for it. Specifically, we introduce a translation function N-TO-D that, given an RT net $N = \langle P, T, F, m_0 \rangle$, produces a DCDS $\text{N-TO-D}(N) = \langle \mathcal{D}_N, \mathcal{P}_N \rangle$ whose execution semantics weakly reproduces that of $\text{RG}(N)$. The data layer is $\mathcal{D}_N = \langle \mathcal{C}, \mathcal{R}_N, \emptyset, I_0^N \rangle$, where

- $P_i/1 \in \mathcal{R}_N$ if and only if $p_i \in P$;
- I_0^N is such that $\{P_i(d_1), \ldots, P_i(d_k) \mid d_j \neq d_h \text{ for } j, h \in \{1, \ldots, k\} \text{ and } j \neq h\} \subseteq I_0^N$ if and only if $p^k \in m_0$.

The process layer of $\text{N-TO-D}(N)$ is $\mathcal{P}_N = \langle \mathcal{F}_N, A_N, \varrho_N \rangle$, where every transition $t \in T$ is translated into a condition-action rule $\xi_t \in \varrho_N$ and a dedicated action $\alpha_t \in A_N$, which respectively encode the enablement and firing semantics of t:

$$\xi_t = \bigwedge_{p_i^{in} \in \{p \mid F(p,t)=1\}} P_i^{in}(x_i) \mapsto \alpha_t(x_1, \ldots, x_{|\{p \mid F(p,t)=1\}|})$$

where $\alpha_t(x_1, \ldots, x_n)$ contains the following effects:

1. *(Lossy maintenance of tokens in input places)* For each $p_i^{in} \in P$ such that $F(p_i^{in}, t) = 1$:
$$P_i^{in}(y) \wedge y \neq x_i \rightsquigarrow P_i^{in}(f_i(y)) \in \text{EFFECT}(\alpha_t) \quad (1)$$
2. *(Lossy maintenance of tokens in other places)* For each $p_l \in P$ such that $F(p_l, t) = 0$:
$$P_l(y) \rightsquigarrow P_l(h_l(y)) \in \text{EFFECT}(\alpha_t) \quad (2)$$
3. *(Lossy token generation)* For each $p_j^{out} \in P$ such that $F(t, p_j^{out}) = 1$:
$$\mathsf{true} \rightsquigarrow \{P_j^{out}(g_j())\} \in \text{EFFECT}(\alpha_t) \quad (3)$$
4. *(Lossy token transfer)* For each $p_k^{tout} \in P$ such that $F(t, p_k^{out}) = p_k^{tin}$:
$$P_k^{tin}(y) \rightsquigarrow \{P_k^{tout}(h_k(y))\} \in \text{EFFECT}(\alpha_t) \quad (4)$$
5. No other effect belongs to $\text{EFFECT}(\alpha_t)$.

The intuition behind the translation is to mimic the firing of a transition by means of service calls. In the resulting DCDS, places become unary relations, and tokens become distinct identifiers from $\mathcal{C}$. The condition-action rule ξ_t checks whether each input place for t has a non-empty extension (i.e., contains at least one token) and, if so, non-deterministically selects one token from each of such places. Effects of type (1) and (2) maintain those tokens that are not affected by the firing, i.e., tokens present in non-input places, or tokens contained in input places but not selected by ξ_t. The maintenance is "lossy" because there is no guarantee that the service calls f_i will return different identifiers when called with different values. This notion of *lossiness* resembles that proposed by (Mayr 2003) for lossy counter machines and lossy Petri nets. Effects of type (3) are used to generate the tokens that t puts in its output places upon firing. Such generation is also lossy, because there is no guarantee that service calls g_j will return fresh identifiers, distinct from those already present in the output places. Effects of type (4) lossily deal with the transfer arcs of t, producing one token to be put in the transfer destination for each token present in the transfer source. Note that those places connected to a transition with a reset arc that does not form a transfer arc, do not lead to any effect in the translation. This reflects the "destructive" nature of DCDSs (data not explicitly copied are lost during the application of an action).

The following theorem states that, despite lossiness, the obtained DCDS preserves boundedness of the original net.

Theorem 1. *For every RT net N, N is bounded if and only if $\text{N-TO-D}(N)$ is state-bounded.*

This is proven in two steps. First we show that $\text{N-TO-D}(N)$ obeys to a sort of *monotonicity*. Given two database instances I_1 and I_2 over $\mathcal{R}$, we say that I_1 is *cardinality-contained* in I_2, written $I_1 \trianglelefteq I_2$ if for every relation $R \in \mathcal{R}$, $|R|_{I_1} \leq |R|_{I_2}$. Monotonicity is then defined as follows: for every two states s_1 and s_2 in Σ such that $db(s_1) \trianglelefteq db(s_2)$, and for each state s'_1 such that $s_1 \overset{\alpha_t}{\Longrightarrow} s'_1$, there exists s'_2 such that $s_2 \overset{\alpha_t}{\Longrightarrow} s'_2$ and $db(s'_1) \trianglelefteq db(s'_2)$. Monotonicity implies that, as long as state boundedness is concerned, for every state s in $\Upsilon_{\text{N-TO-D}(N)}$ it is sufficient to consider only its "maximal successors" $\text{MAX-SUCC}_{\alpha_t}(s) = \{s' \in \Sigma \mid s \overset{\alpha_t}{\Longrightarrow} s' \text{ and } \nexists s''.s \overset{\alpha_t}{\Longrightarrow} s'' \text{ and } s' \trianglelefteq s''\}$.

The second step consists in showing that the portion of $\Upsilon_{\text{N-TO-D}(N)}$ that just considers maximal successors faithfully reproduces $\text{RG}(N)$. To compare the states of $\Upsilon_{\text{N-TO-D}(N)}$ with those of $\text{RG}(N)$, we define the following *cardinality-equivalence* relation: given a marking $m \in M$ and a state $s \in \Sigma$, we say that m is cardinality-equivalent to s, written $m \approx s$, if, for each place $p_i \in P$, $m(p) = n$ if and only if $|P_i|_{db(s)} = n$. By definition, $m_0 \approx s_0$. It can then be shown, inductively, that, given $m \in M$ and $s \in \Sigma$ such that $m \approx s$, for every transition $t \in T$ (and corresponding $\alpha_t \in A_N$):

- $m[t\rangle$ if and only if α_t is executable in s;
- whenever $m[t\rangle$, given $m' \in M$ such that $m \xrightarrow{t} m'$, we have $m' \approx s'$ for every $s' \in \text{MAX-SUCC}_s(\alpha_t)$.

This implies the result, since $\text{RG}(N)$ has an unbounded run if and only if $\Upsilon_{\text{N-TO-D}(N)}$ has a state-unbounded run.

As a direct consequence, we obtain:

Corollary 2. *For every RT net N, N is structurally bounded if and only if $\text{N-TO-D}(N)$ is structurally state-bounded.*

3.3 Lossy Reset Transfer DCDSs

We now introduce a class of DCDSs that resembles those obtained from RT nets through the application of the N-TO-D translation function. For this reason, we call such a class *Lossy Reset Transfer (LRT)* DCDSs.

An *LRT DCDS* is a DCDS $\mathcal{S} = \langle \mathcal{D}, \mathcal{P} \rangle$, with $\mathcal{D} = \langle \mathcal{C}, \mathcal{R}, \mathcal{E}, I_0 \rangle$ and $\mathcal{P} = \langle \mathcal{F}, A, \varrho \rangle$, that obeys to the following requirements:

- $\mathcal{R} = \{P_1/1, \ldots, P_{|\mathcal{R}|}/1\}$ (only unary relations are used).
- $\mathcal{E} = \emptyset$.
- For each action $\alpha(\vec{x}) \in A$, ϱ contains a single rule of the form $Q(\vec{x}) \mapsto \alpha(\vec{x})$, where Q is a (non-self) cartesian

product of a set of unary relations:

$$Q(x_1, \ldots, x_n) = \bigwedge_{i \in \{1,\ldots,n\},\ P_i \neq P_j \text{ for } i \neq j} P_i(x_i)$$

The set of relations in Q is denoted by $\text{RELS}(Q)$.

- Every action $\alpha(\vec{x}) \in A$, with $Q(\vec{x}) \mapsto \alpha(\vec{x}) \in \varrho$, has the following shape:
  1. for each $P_i \in \text{RELS}(Q)$, α *must* contain a *lossy maintain-rest* effect of the form
  $$P_i(y) \wedge y \neq x_i \rightsquigarrow P_i(f_i(y)) \quad (5)$$
  2. for each $P_l \in \mathcal{R} \setminus \text{RELS}(Q)$, α *may* contain a *lossy maintain* effect of the form
  $$P_l(y) \rightsquigarrow P_l(h_l(y)) \quad (6)$$
  3. for each $P_j \in \mathcal{R} \setminus \text{RELS}(Q)$, α *may* contain *either* a *lossy create* effect of the form
  $$\mathsf{true} \rightsquigarrow P_j(g_j()) \quad (7)$$
  or a *lossy copy* effect of the form
  $$P'_j(y) \rightsquigarrow P_j(h_j(y)) \quad (8)$$
  for some $P'_j \in \mathcal{R} \setminus (\text{RELS}(Q) \cup P_j)$;
  4. no other effect belongs to α.

An LRT DCDS $\mathcal{S} = \langle \mathcal{D}, \mathcal{P} \rangle$ with $\mathcal{D} = \langle \mathcal{C}, \mathcal{R}, \emptyset, I_0 \rangle$ and $\mathcal{P} = \langle \mathcal{F}, A, \varrho \rangle$ is:

- A *Lossy Reset (LR) DCDS* if no action $\alpha \in A$ contains lossy-copy effects of the form (8); the "reset" nature comes from the fact that those relations that are not mentioned in the left-hand side of any effect in $\text{EFFECT}(\alpha)$ loose their current content when α is executed.
- A *Lossy Transfer (LT) DCDS* if, for every action $\alpha \in A$ with $Q(\vec{x}) \mapsto \alpha(\vec{x}) \in \varrho$, and every relation $P_i \in \mathcal{R} \setminus \text{RELS}(Q)$, P_i appears in the left-hand side of at least an effect of α (which must be either a lossy maintain effect of the form (6), or a lossy copy effect of the form (8)); in other words, every relation contributes to determine the content of the state obtained by the application of α.
- A *Lossy Petri (LP) DCDS* if, for every action $\alpha \in A$ with $Q(\vec{x}) \mapsto \alpha(\vec{x}) \in \varrho$, and every relation $P_i \in \mathcal{R} \setminus \text{RELS}(Q)$, P_i appears only in the left-hand side of a lossy maintain effect of the form (6) in α (and possibly in the right-hand side of a lossy create effect).

The following proposition highlights the connection induced by the N-TO-D translation function between the different classes of nets and DCDSs studied in this paper.

Proposition 3. *Given an RT/R/T/Petri net N,* $\text{N-TO-D}(N)$ *produces an LRT/LR/LT/LP DCDS.*

The proof of this proposition can be obtained by comparing the definitions for such different classes, and checking that N-TO-D preserves their properties in the translation.

We conclude this section by pointing out that LRT DCDSs are very weak in terms of their ability of querying and manipulating data. In fact, they only contain unary relations, which are queried without using any joins in the condition-action rules, and only by means of atomic queries in the effects. Furthermore, no negative components are used in such queries, except for a very limited use of inequalities (always employed to select all tuples of a relation except the one matching with one of the action parameters). Also, the content of relations is not guaranteed to be preserved when executing an action: copy and maintain effects always employ service calls to transfer data from one state to the other, which implies that the extension of a relation may change in content, and decrease in size. Finally, the overall size of the entire database instance may maximally increase only of a fixed amount of tuples, determined by the number of lossy create effects present in the applied action.

3.4 From LRT DCDSs to RT Nets

We define a translation function D-TO-N that, given an LRT DCDS $\mathcal{S} = \langle \mathcal{D}, \mathcal{P} \rangle$ with $\mathcal{D} = \langle \mathcal{C}, \mathcal{R}, \emptyset, I_0 \rangle$ and $\mathcal{P} = \langle \mathcal{F}, A, \varrho \rangle$, produces an RT net $\text{D-TO-N}(\mathcal{S}) = \langle P_\mathcal{S}, T_\mathcal{S}, F_\mathcal{S}, m_0^\mathcal{S} \rangle$ defined as follows:

- $p_i \in P_\mathcal{S}$ if and only if $P_i/1 \in \mathcal{R}$;
- $p_i^k \in m_0^\mathcal{S}$ if and only if $|P_i|_{I_0} = k$;
- $t_\alpha \in T$ if and only if $\alpha \in A$;
- As for pre-arcs, for each $p_i \in P_\mathcal{S}$ and each $t_\alpha \in T$:
  1. if, given $Q(\vec{x}) \mapsto \alpha(\vec{x})$ in ϱ, $P_i \in \text{RELS}(Q)$, then $F_\mathcal{S}(p_i, t_\alpha) = 1$;
  2. else if α contains an effect of the form $P_i(y) \rightsquigarrow P_i(h_i(y))$,[4] then $F_\mathcal{S}(p_i, t_\alpha) = 0$;
  3. else $F_\mathcal{S}(p_i, t_\alpha) = p_i$.
- As for post-arcs, for each $t_\alpha \in T$ and $p_i \in P_\mathcal{S}$:
  1. if α contains an effect of the form $\mathsf{true} \rightsquigarrow P_i(g_i())$, then $F(t_\alpha, p_i) = 1$;
  2. if α contains an effect of the form $P'_i(y) \rightsquigarrow P_i(h_i(y))$ with $P'_i \neq P_i$, then $F(t_\alpha, p_i) = p'_i$;
  3. $F(t_\alpha, p_i) = 0$ otherwise.

Intuitively, the translation works as follows. Every relation mentioned in the condition-action rule for α becomes an input place for t_α, and every relation targeted by a lossy create effect becomes an output place for t_α. Relations which are lossily maintained by α do not contribute as input for t_α, attesting that t will not consume tokens from them. Relations that do not fall in any of these two categories are consumed completely by t; this can happen either because their content is lossily copied, or because they do not appear in the left-hand side of any effect in α (and hence will loose their content when α is applied). Finally, lossy copy effects are translated into a transfer arc passing through t (notice that, in this case, the definition of LRT DCDSs does not allow the target relation to be also targeted by a lossy create effect).

Theorem 4. *The translation functions* N-TO-D *and* D-TO-N *are one the inverse of the other, i.e., (i) for every RT net N, $N = \text{D-TO-N}(\text{N-TO-D}(N))$; (ii) for every LRT DCDS $\mathcal{S}$, $\mathcal{S} = \text{N-TO-D}(\text{D-TO-N}(\mathcal{S}))$.*

The proof of this theorem is obtained by: *(i)* considering each component of an RT net, and showing that the same component is obtained by applying D-TO-N $\circ$ N-TO-D on it, *(ii)* considering each component of an LRT DCDS, and showing that the same component is obtained by applying N-TO-D $\circ$ D-TO-N on it.

Theorems 4 and 1, together with Proposition 3, imply:

[4] Note that the same relation P_i is used in both sides of the effect.

Corollary 5. *Given an LRT/LR/LT/LP DCDS $\mathcal{S}$,* D-TO-N($\mathcal{S}$) *produces an RT/R/T/Petri net.*

Theorem 6. *For every LRT DCDS $\mathcal{S}$, $\mathcal{S}$ is state-bounded if and only if* D-TO-N$\mathcal{S}$ *is bounded.*

As a direct consequence of Theorem 6, we then have:

Corollary 7. *For every LRT DCDS $\mathcal{S}$, $\mathcal{S}$ is structurally state-bounded if and only if* D-TO-N($\mathcal{S}$) *is structurally bounded.*

4 State-Boundedness is Difficult

We now exploit the connection between RT nets (and their subclasses) and LRT DCDSs (and their subclasses) to show that state-boundedness is intrinsically difficult to check for data-aware dynamic systems: either highly-undecidable[5] or intractable even for the low expressive systems expressible with LRT DCDSs. In particular, we have that: *(i)* checking boundedness of R nets reduces to checking state-boundedness of LR DCDSs (cf. Proposition 3 and Theorem 1); *(ii)* checking state-boundedness of LP DCDSs reduces to checking boundedness of Petri nets (cf. Corollary 5 and Theorem 6); *(iii)* checking state-boundedness of LT DCDSs reduces to checking boundedness of T nets (cf. Corollary 5 and Theorem 6). Similar reductions hold for structural state-boundedness, thanks to Proposition 3 and Corollaries 2, 5, and 7.

Since checking boundedness for R nets is Σ^1_1-complete (Dufourd, Finkel, and Schnoebelen 1998; Dufourd, Jancar, and Schnoebelen 1999), we thus get:

Theorem 8. *Checking state-boundedness is highly undecidable for LR (and hence LRT) DCDSs.*

Thanks to the fact that checking boundedness is EXPSPACE-complete for Petri nets (Esparza and Nielsen 1994), and decidable for T nets (Dufourd, Jancar, and Schnoebelen 1999), decidability is interestingly obtained for those LRT DCDSs in which all relations are used in the left-hand side of effects, i.e., all relations contribute to determine the new database instance obtained after the application of an action. The sub-class of LRT DCDSs that enjoy this property is that of LT (which includes LP) DCDSs:

Theorem 9. *Checking state-boundedness is* EXPSPACE*-complete for LP DCDSs.*

Theorem 10. *Checking state-boundedness is decidable and* EXPSPACE*-hard for LT DCDSs.*

Structural state-boundedness pushes the undecidability frontier even further, but can be efficiently checked for the very simple case of LP DCDSs. Specifically, since checking structural boundedness is Π^1_2-complete for R nets, Π^1_1-complete for T nets (Dufourd, Jancar, and Schnoebelen 1999), and decidable in PTIME for Petri nets, (Esparza and Nielsen 1994; Dufourd, Jancar, and Schnoebelen 1999) we get:

Theorem 11. *Checking structural state-boundedness is highly undecidable for LT and LR (and hence LRT) DCDSs.*

Theorem 12. *Checking structural state-boundedness is decidable in* PTIME *for LP DCDSs.*

[5]I.e., at the first level or above in the Analytical Hierarchy (Rogers 1967).

We conclude by observing that a line of reasoning analogus to that of DCDSs can be repeated for similar frameworks, e.g., ACMASs (Belardinelli, Lomuscio, and Patrizi 2012).

5 Sufficient State-Boundedness Conditions

In Section 3.1, we have proved that checking (structural) state-boundedness even for very limited DCDSs is already undecidable. We introduce now sufficient syntactic conditions that guarantee structural state-boundedness. In particular, we discuss different dimensions for relaxation of the GR^+-acyclicity condition originally introduced by Bagheri Hariri et al. (2013b), and based on them we develop our most general sufficient condition, called stratified-$\exists GR^{++}$-acyclicity.

5.1 GR^{++}-Acyclicity

The GR^+-acyclicity condition for structural state-boundedness (Bagheri Hariri et al. 2013b) is a syntactic restriction over the dataflow graph of a DCDS, in which nodes of the dataflow graph represent relation names that occur in the schema of the system, and edges represent the flow of the data between these relations. Here we introduce GR^{++}-acyclicity as a relaxation of GR^+-acyclicity in which the dataflow graph represents the system behavior at finer granularity by using as nodes positions of relations, instead of relations themselves.

We call *refined dataflow graph* of a set A of actions the directed edge-labeled graph $\langle N, G\rangle$ where: *(i)* $N \subseteq \mathcal{R} \times \mathbb{N}^+$ is a set of nodes such that for every R/n occurring in A, $\langle R, i\rangle \in N$ for every $i \in \{1, \ldots, n\}$; *(ii)* G is a 5-tuple $(R_1, \mathsf{id}, R_2, b, a)$, where R_1 and R_2 are two nodes in N, id is a (unique) edge identifier, b is a Boolean flag used to mark *special* edges, and a is flag used to denote the action of A to which the edge belongs. Formally, G is the minimal set such that, for each action α in A, each effect e in α of the form $q^+ \wedge Q^- \rightsquigarrow E$, each $R(r_1, \ldots, r_m)$ in q^+, each $i \in \{1, \ldots, m\}$, each $Q(t_1, \ldots, t_n)$ in E, and each $j \in \{1, \ldots, n\}$, we have that:

- if t_i is a free variable and $r_i = t_j$, then $(\langle R, i\rangle, \mathsf{id}, \langle Q, j\rangle, \mathsf{false}, \alpha) \in G$.
- if t_i is a service call $f(s_1, \ldots, s_l)$, then for each $k \in \{1, \ldots, l\}$, if $r_i = s_k$ then $(\langle R, i\rangle, \mathsf{id}, \langle Q, j\rangle, \mathsf{true}) \in G$.
- if t_i is a nullary service call $f()$, then $(\langle R, i\rangle, \mathsf{id}, \langle Q, j\rangle, \mathsf{true}) \in G$.

in which id is a fresh edge identifier.

Let π_1, π_2, and π_3 be paths in the dataflow graph D of A. We say that $\langle \pi_1, \pi_2, \pi_3\rangle$ is a *generate-recall triple* if

(i) $\pi_1\pi_2\pi_3$ forms a path in D,
(ii) π_1, π_3 are simple cycles, and
(iii) π_2 is a path containing a special edge, with $edges(\pi_2) \setminus edges(\pi_1) \neq \emptyset$.

The generate-recall triple $\langle \pi_1, \pi_2, \pi_3\rangle$ is called *non-accumulating* if there is an edge $e \in edges(\pi_2)$ that does not belong to the same action as any of the edges following e in $\pi_2\pi_3$. Finally, we say that A is GR^{++}*-acyclic* if all its generate-recall triples are non-accumulating.

We say a process layer $\mathcal{P} = \langle \mathcal{F}, A, \varrho\rangle$ is GR^{++}*-acyclic*, if A is GR^{++}-acyclic. A DCDS is GR^{++}-acyclic if its process layer is GR^{++}-acyclic. The GR^+-acyclicity definition by

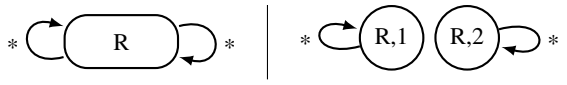

Figure 1: Dataflow and refined dataflow graphs of Example 1

Bagheri Hariri et al. (2013b) differs only in that the dataflow graph's nodes represent entire relations, not their positions (the dataflow graph by Bagheri Hariri et al. corresponds to collapsing all refined dataflow graph nodes modeling positions of relation R into a single node, for every R.)

Example 1. Consider a DCDS D with one action $\alpha = \{R(x,y) \rightsquigarrow \{R(f(x),\ h(y))\}$. It is easy to see that D is *(i)* structural state-bounded, *(ii)* not GR^{+}-acyclic, but *(iii)* GR^{++}-acyclic. For *(i)*, observe that the cardinality of R after executing α is at most the cardinality before execution (potentially strictly lower if the service calls behave non-injectively). For *(ii)*, consult the data flow graph on the left side of Figure 1. The simple cycle π_1 can be the left self-loop on node R, π_2 and π_3 can coincide with the right self-loop. For *(iii)*, consult the refined data flow graph on the right side of Figure 1. Notice now that this graph contains no generate-recall cycle, since in each connected component π_1 and π_2 must coincide. ■

Theorem 13. *GR^{++}-acyclicity is a strict relaxation of GR^{+}-acyclicity that guarantees structural state-boundedness.*

5.2 Safe-GR^{++}-Acyclicity

The main idea of this relaxation is to distinguish different types of special edges in the dataflow graph to define a more refined condition for structural state-boundedness. We borrowed the notion of affected positions, which are an overestimation of the positions in which a new value can be introduced, from Calì, Gottlob, and Kifer (2013), Meier, Schmidt, and Lausen (2009), to distinguish unbounded edges, which is an overestimation of the edges of the dataflow graph, in which unboundedly many different values can flow during the life of a DCDS.

More formally, we call *affected positions* of a set A of actions, denoted with $\text{AFF}(A)$, the smallest set of positions π occurring in A satisfying following conditions:

- If a service call appears in π, then $\pi \in \text{AFF}(A)$.
- If in the head of an effect a variable x appears in π, and occurrences of x in the body of this effect is only limited to the affected positions.

We use affected positions to determine an overestimation of unbounded edges of dataflow graph. Given an effect f, we say that an edge e from a position p in the body of e to a position in the head of e is (potentially) *unbounded* if all the positions in the body of e that using the same variable as p are affected positions. Otherwise, we call e *bounded*. For instance, consider a DCDS with one action as follows: $\{A(x) \wedge B(x) \wedge C(y) \rightsquigarrow A(f(x)), C(h(y))\}$. $\langle A,1\rangle$ and $\langle C,1\rangle$ are the only affected positions. The edges from the position $\langle A,1\rangle$ and $\langle B,1\rangle$ to $\langle A,1\rangle$ are bounded edges, since for each of them there is an unaffected position $\langle B,1\rangle$ in the body of the effect, while the special edge from $\langle C,1\rangle$ to $\langle C,1\rangle$ is an unbounded edge.

We call *safe-refined dataflow graph* of a set A of actions the directed edge-labeled graph $\langle N, G\rangle$ where: *(i)* $N \subseteq \mathcal{R} \times \mathbb{N}^{+}$ is a set of nodes such that for every R/n occurring in A, $\langle R,i\rangle \in N$ for every $i \in \{1,\ldots,n\}$; *(ii)* G is a 6-tuple $(R_1, \mathsf{id}, R_2, f_s, f_b, a)$, where R_1 and R_2 are two nodes in N, id is a (unique) edge identifier, f_s is a flag that specify if the edge is normal with "$-$", or special with "$*$", f_b is a flag that specify if an edge is bounded with "b", or unbounded with "u", and a is flag used to denote the action of A to which the edge belongs. Formally, G is the minimal set satisfying the following condition. For each action α in A, each effect e in α of the form $q^{+} \wedge Q^{-} \rightsquigarrow E$, each $R(r_1,\ldots,r_m)$ in q^{+}, each $i \in \{1,\ldots,m\}$ each $Q(t_1,\ldots,t_n)$ in E, and each $j \in \{1,\ldots,n\}$:

- If t_i is a free variable and $r_i = t_j$,
  - if for each position p in the body of e in which the variable r_i occurs, it holds that $p \in \text{AFF}(A)$, then $(\langle R,i\rangle, \mathsf{id}, \langle Q,j\rangle, \text{-}, u, a) \in G$;
  - otherwise, $(\langle R,i\rangle, \mathsf{id}, \langle Q,j\rangle, \text{-}, b, a) \in G$.
- If t_i is a service call $f(s_1,\ldots,s_l)$ with $l \geq 1$, then for each $k \in \{1,\ldots,l\}$, if $r_i = s_k$, then
  - If for each position p in the body of e in which the variable r_i happens it holds that $p \in \text{AFF}(A)$, then $(\langle R,i\rangle, \mathsf{id}, \langle Q,j\rangle, *, u, a) \in G$;
  - otherwise, $(\langle R,i\rangle, \mathsf{id}, \langle Q,j\rangle, *, b, a) \in G$.
- If t_i is a nullary service call $f()$, then
  - if for each position p in the body of e it holds that $p \in \text{AFF}(A)$ then $(\langle R,i\rangle, \mathsf{id}, \langle Q,j\rangle, *, u) \in G$;
  - otherwise, $(\langle R,i\rangle, \mathsf{id}, \langle Q,j\rangle, *, b) \in G$.

  in which id is a fresh edge identifier.

We define the notion of *generate-recall triple* for a safe-refined dataflow graph exactly as in the case of GR^{++}-acyclicity. Moreover, a generate-recall triple $\langle \pi_1, \pi_2, \pi_3\rangle$ is called *safe* if either there is an edge $e \in edges(\pi_2)$ that does not belong to the same action as any of the edges following e in $\pi_2\pi_3$, or π_3 contains a bounded edge. Finally, we say that A is *safe-GR^{++}-acyclic* if all its generate-recall triples are safe.

Example 2. Consider a DCDS D with one action

$$\alpha = \begin{cases} A(x) \rightsquigarrow \{A(f(x))\} \\ B(x) \rightsquigarrow \{B(x)\} \\ A(x) \rightsquigarrow \{R(x,f(x))\} \\ R(x,y) \wedge B(x) \rightsquigarrow \{R(y,x)\} \end{cases}$$

D is *(i)* structural state-bounded, *(ii)* not GR^{++}-acyclic, but *(iii)* safe-GR^{++}-acyclic.

Given a state I of a DCDS, let's denote with $|R_i|_I$ the number of different values that occurs in I in the position i of the relation R. Consider the states I and I' of D, in which I' is the result of the execution of α over I.

For *(i)* observe that $|A_1|_{I'} \leq |A_1|_I$, $|B_1|_{I'} = |B_1|_I$, $|R_2|_{I'} \leq |A_1|_I + |B_1|_I$, and $|R_1|_{I'} \leq (|A_1|_I + |R_2|_I) \leq (2.|A_1|_I + |B_1|_I)$. Given the fact that the cardinality of $\langle A,1\rangle$ and $\langle B,1\rangle$ is not increasing, and the cardinality of all the positions is linear in the cardinality of these two positions, the size of the resulting instance by application of α cannot

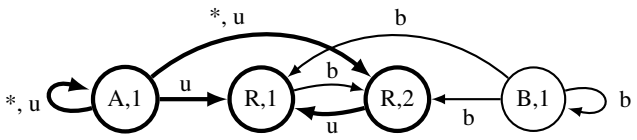

Figure 2: Safe-refined dataflow graph of Example 2. Affected positions and unbounded edges are shown with thicker lines

increase unboundedly. For *(ii)* consult the refined dataflow graph of D given in Figure 2, ignoring the labels for boundedness of edges. The path π_1 can be the self loop in $\langle A, 1\rangle$, π_2 can be the edge from $\langle A, 1\rangle$ to $\langle R, 1\rangle$, and π_3 can be the simple cycle between $\langle R, 1\rangle$ and $\langle R, 1\rangle$. For *(iii)*, consult the safe-refined dataflow graph of Figure 2. $\langle A, 1\rangle$ and $\langle R_2\rangle$ are affected positions because of occurrences of the service call $f(x)$ in them. Moreover, because of the third effect, $\langle R, 1\rangle$ is also an affected position, but $\langle B, 1\rangle$ is not an affected position. Consequently all the outgoing edges from $\langle B, 1\rangle$ are bounded edges. Moreover, because of the occurrences of $\langle B_1\rangle$ with the same variable as the $\langle R, 1\rangle$ in the body of the fourth effect, the outgoing edge from $\langle R, 1\rangle$ to $\langle R, 2\rangle$ is also a bounded edge. Notice now that this graph contains no generate-recall cycle $\pi_1\pi_2\pi_3$ such that all the edges of the recall cycle are unbounded edges. ■

Theorem 14. *Safe-GR^{++}-acyclicity is a strict relaxation of GR^{++}-acyclicity that guarantees structural state-boundedness.*

5.3 Stratified-GR^{++}-Acyclicity

The syntactic restrictions that we have studied until now are defined over the structure of the effects of the actions, and ignore the conditions under which the actions can be executed, i.e., the process of the system. Here, we exploit process to single out larger classes of structural state-bounded DCDSs. Getting insight from stratified relaxation of weak-acyclicity in data exchange (Deutsch, Nash, and Remmel 2008), we specify the potential order of execution of actions of a system, through what we call the control-flow graph of the system, and use this graph to determine maximal set of actions that can violate structural state-boundedness. Remember that actions of DCDSs are not inflationary, and the next state is only determined by applying the effects of the action over the current state. Consequently, by looking to the head of the effects of an action α, we can find a superset of the actions that can be fired after α. We use this idea to relax safe-GR^{++}-acyclicity.

Given an action α and a set of condition-action rules ρ, the set of requirements for firing of α wrt ρ is a set of set of relation names defined as follows: $\text{INPUT}(\rho, \alpha) = \{\{\text{RELATIONS}(Q^+)\} \mid (Q^+ \wedge Q \mapsto \alpha) \in \rho\}$, in which Q^+ is a conjunctive query, and $\text{RELATIONS}(Q)$ is the set of relation names occurring in Q. We denote with $\text{OUTPUT}(\alpha)$ the set of relation names occurring in the head of effects of α. Given a set of condition-action rules ϱ, and two actions α and β, we say that β can (potentially) be fired after α wrt ϱ, written $\alpha <_\varrho \beta$ (or simply $\alpha < \beta$), if there exists a set of relation names $S \in \text{INPUT}(\varrho, \beta)$ such that $S \subseteq \text{OUTPUT}(\alpha)$.

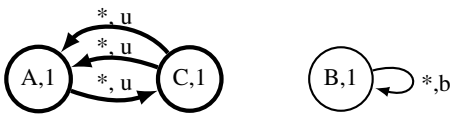

Figure 3: Safe-refined dataflow graph of Example 3. Affected positions and unbounded edges are shown with thicker lines

Given a set of condition-action rules ϱ and a set of actions A, the *controlflow graph* of A is the directed edge-labeled graph $\langle A, E\rangle$ in which for two actions $\alpha, \beta \in \Sigma$ we have that $(\alpha, \beta) \in E$ iff $\alpha < \beta$. We say a DCDS with the set of actions A is *stratified-GR^{++}-acyclic* if for every set of actions S that correspond to a maximal strongly connected component in the controlflow graph of A, the restriction of A to S is safe-GR^{++}-acyclic.

Example 3. Consider a DCDS D with two actions $\alpha(x) = \{A(x) \wedge B(y) \rightsquigarrow \{C(x), B(y)\}$ and $\beta(x, y) = \{C(x) \wedge C(y) \rightsquigarrow \{A(g(x)), A(h(y))\}$ and the set of condition-action rules $\{A(x) \wedge B(x) \mapsto \alpha(x), C(x) \wedge C(y) \mapsto \beta(x, y)\}$. The refined dataflow graph of D is shown in Figure 3. It is easy to see that D is *(i)* structural state-bounded, *(ii)* not safe-GR^{++}-acyclic, but *(iii)* stratified-GR^{++}-acyclic.

For *(i)*, observe that after execution of action α it is only possible to execute action β since the resulting state will not have any atom with the relation name A, which is needed for execution of α. Moreover, after executing β, none of the actions can be fired, since the resulting state will not have any atom with the relation name B, which is needed for execution of α, and not any atom with the relation name of C which is needed for execution of β. For *(ii)*, consult the safe-refined dataflow graph of Figure 3. As a witness of the generate-recall cycle, it is possible to select π_1 as the cycle generated by the top edge from $\langle C, 1\rangle$ and $\langle A, 1\rangle$ and the edge from $\langle A, 1\rangle$ to $\langle C, 1\rangle$, π_2 as the second edge from $\langle C, 1\rangle$ to $\langle A, 1\rangle$, and π_3 as the cycle generated by the edge from $\langle A, 1\rangle$ to $\langle C, 1\rangle$ and the second edge from $\langle C, 1\rangle$ to $\langle A, 1\rangle$.

For *(iii)*, $\text{INPUT}(\varrho, \alpha) = \{\{A, B\}\}$, $\text{INPUT}(\varrho, \beta) = \{\{C\}\}$, $\text{OUTPUT}(\alpha) = \{B, C\}$, $\text{OUTPUT}(\beta) = \{A\}$. Consequently, $\alpha \not< \alpha$, $\alpha < \beta$, $\beta \not< \alpha$, and $\beta \not< \beta$. The controlflow graph has only one edge from α to β. Since there is no strongly connected component in the controlflow graph, D trivially satisfies the condition of stratified-GR^{++}-acyclicity. ■

Theorem 15. *Stratified-GR^{++}-acyclicity is a strict relaxation of safe-GR^{++}-acyclicity that guarantees structural state-boundedness.*

5.4 $\exists$- Acyclicity Relaxations

All the syntactic restrictions presented so far are based on finding cycles in the corresponding dataflow graphs, as part of generate-recall pairs. The graph edges are constructed conservatively, to reflect possible flow of data between relations of the data layer. In this section, we observe that edge construction can be over-conservative, and we show a technique to safely consider fewer edges. This is clearly beneficial, as removing edges reduces the opportunity for forming cycles.

The technique is based on a counterintuitive observation regarding overestimations of an original DCDS D. These are rewritings O of D whose effects generate a superset of the data generated by the effects of D. It turns out that it is possible for the data flow graph of overestimate O to have a subset of the edges of the data flow graph of D. Since structural state-boundedness of O guarantees state-boundedness of D, checking the data flow graph of O leads to a relaxed syntactic restriction for state-boundedness.

One situation in which overestimation of the system results in smaller dataflow graphs is when a nullary service call occurs in heads of the DCDS. In the definition of GR^{++}-acyclicity in Section 5.1, for each nullary service call in the head of an effect we add a special edge from all the positions of the body of the effect to the position in which the service call occurs. Consider an effect $e : A(x) \wedge B(y) \rightsquigarrow C(f())$. In the definition of GR^{++}-acyclicity there are special edges from $\langle A, 1\rangle$ and $\langle B, 1\rangle$ to $\langle C, 1\rangle$ in the dataflow graph. However, since we are looking for sufficient conditions for state-boundedness, we can overestimate the result of e by replacing the effect e with $e_1 : A(x) \wedge B(y) \rightsquigarrow C(f(x))$ or $e_2 : A(x) \wedge B(y) \rightsquigarrow C(f(y))$. Notice although the resulting system is an overestimation of the original system, the resulting dataflow graph has less edges, and consequently, it is more likely to satisfy the condition of GR^{++}-acyclicity.

A similar situation holds for repeated positions with the same variables in the body of the effect. Lets assume to have an effect $f : A(x) \wedge B(x) \rightsquigarrow C(x)$. It is possible to over estimate f with $f1 : A(x) \wedge \exists y B(y) \rightsquigarrow C(x)$ or $f2 : \exists y A(y) \wedge B(x) \rightsquigarrow C(x)$. The resulting dataflow graphs will have less edges, and consequently, it is more likely to satisfy the condition of GR^{++}-acyclicity.

More formally, given a DCDS D, $\text{OVEREST}(D)$ is a set of DCDSs obtained from D by applying the following rules for each of the possible options:

- Replace the nullary service calls in the head of the effects with a unary service call using as variable, one of the variables of the body of the effect. Notice that for each choice of variables for unary service calls, there will be one DCDS in $\text{OVEREST}(D)$.
- Among multiple occurrences of one variable in different positions of the body of an effect, keep one of them, and rename and existentially quantify the others. Also notice that for each possible selection option, there will be a DCDS in $\text{OVEREST}(D)$.

We say that D is $\exists GR^{++}$-acyclic, if there exists a DCDS $D' \in \text{OVEREST}(D)$, such that D' is GR^{++}-acyclic.

Example 4. Consider a DCDS D with one actions $\alpha = \{A(x) \wedge B(x) \wedge B(y) \rightsquigarrow \{A(f()), B(g())\}$. The dataflow graph of D is depicted in Figure 4. It is easy to see that D is *(i)* state-bounded, and *(ii)* not stratified-GR^{++}-acyclic, but *(iii)* $\exists GR^{++}$-acyclic. For *(i)*, observe that $|A_1|_{I'} \leq |A_1|_I$, and $|B_1|_{I'} \leq |B_1|_I$. For *(ii)*, consult the safe-refined dataflow graph of Figure 4. As a witness of the generate-recall cycle consider π_1 as the self loop of $\langle A, 1\rangle$, π_2 as the edge from $\langle A, 1\rangle$ to $\langle B, 1\rangle$, and π_3 as the self loop of $\langle B, 1\rangle$.

For *(iii)*, considering the two options for selecting a position among the positions with the same variable in body of the only effect of α, and four options for overestimating

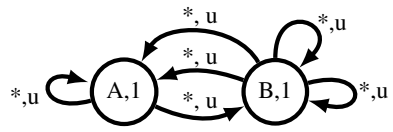

Figure 4: Safe-refined dataflow graph of Example 4

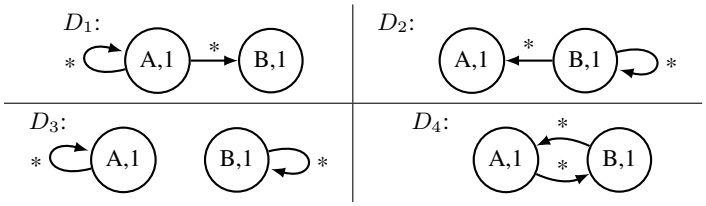

Figure 5: Refined dataflow graphs regarding $\exists GR^{++}$-acyclicity of Example 4

the two nullary service calls in the head of the effect of α to unary service calls using the variables x and y of the body, $\text{OVEREST}(D)$ contains eight different overestimations. Here we represent four of these overestimations $D_1, \ldots, D_4$, each of them with one action, namely, $\alpha_1, \ldots, \alpha_4$ as follows:

$$\alpha_1 : \{A(x) \wedge \exists z\ B(z) \wedge B(y) \rightsquigarrow \{A(f(x), B(g(x))\}\}$$
$$\alpha_2 : \{\exists z\ A(z) \wedge B(x) \wedge B(y) \rightsquigarrow \{A(f(x), B(g(x))\}\}$$
$$\alpha_3 : \{A(x) \wedge \exists z\ B(z) \wedge B(y) \rightsquigarrow \{A(f(x), B(g(y))\}\}$$
$$\alpha_4 : \{A(x) \wedge \exists z\ B(z) \wedge B(y) \rightsquigarrow \{A(f(y), B(g(x))\}\}$$

For *(iii)*, consult the refined dataflow graphs of $D_1, \ldots, D_4$ in Figure 5. For $\exists GR^{++}$-acyclicity, it is enough to have one of the overestimations GR^{++}-acyclic. In this example, all four represented overestimations are GR^{++}-acyclic. ■

Theorem 16. *$\exists GR^{++}$-acyclicity is a strict relaxation of GR^{++}-acyclicity that guarantees state-boundedness.*

A Hierarchy of Acyclicity Classes. The idea for $\exists GR^{++}$-acyclicity applies to generate existential relaxations of safe-GR^{++}-acyclicity and stratified-GR^{++}-acyclicity, called safe-$\exists GR^{++}$-acyclicity and stratified-$\exists GR^{++}$-acyclicity. Figure 6 summarizes our results. Note that stratified-$\exists GR^{++}$-acyclicity is the most relaxed condition, and GR^{+} is the most over-conservative. Moreover, we can prove that safe-GR^{++}-acyclicity and $\exists GR^{++}$-acyclicity are incomparable.

All acyclicity variants we have introduced are purely syntactic notions. The non-existential ones can be checked in coNP since the various versions of dataflow graphs have size polynomial in the size of the process layer specification, and, if there is a violation of acyclicity, then we can show that there is a polynomial-sized one. For existential relaxations, complexity jumps to Σ_2^p, due to the need of guessing the member of $\text{OVEREST}(D)$ to which the coNP check applies.

6 Conclusion

State-boundedness has recently gained a central place in verification of data-aware dynamic systems. This motivated us to study whether there are interesting decidable classes of such systems for which state-boundedness is decidable. Thanks to

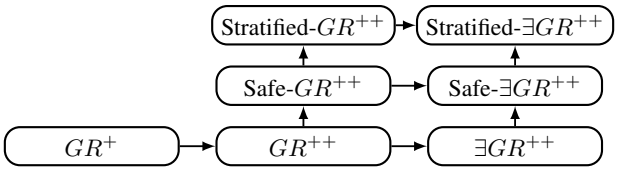

Figure 6: Syntactic restrictions for structural state-boundedness. Arrows show strict containment of classes. Unconnected classes are incomparable.

novel connections with Petri nets, we answer the question in the negative, but at the same time paving the way towards an entire field dedicated to studying sufficient, checkable conditions for state-boundedness. Inspired from sufficient conditions for chase termination in database theory, we show that there are many non-trivial classes of DCDSs that guarantee state-boundedness. The flourishing literature on fine-grained syntactic conditions for chase termination, not considered in this work, points to promising future research.

Abstract

The situation calculus is a popular formalism for reasoning about actions and change. Since the language is first-order, reasoning in the situation calculus is undecidable in general. An important question then is how to weaken reasoning in a principled way to guarantee decidability. Existing approaches either drastically limit the representation of the action theory or neglect important aspects such as sensing. In this paper we propose a model of limited belief for the epistemic situation calculus, which allows very expressive knowledge bases and handles both physical and sensing actions. The model builds on an existing approach to limited belief in the static case. We show that the resulting form of limited reasoning is sound with respect to the original epistemic situation calculus and eventually complete for a large class of formulas. Moreover, reasoning is decidable.

Introduction

The situation calculus (McCarthy 1963; Reiter 2001) is a popular formalism for reasoning about action and change. Since the language is first-order, one of the advantages of the situation calculus is its high degree of expressiveness. However, this comes at a price: reasoning in the situation calculus is undecidable in general.

There are various ways of addressing this issue in a principled way. One would be to drastically limit the expressiveness, either by moving to a propositional action language such as the language $\mathcal{A}$ (Gelfond and Lifschitz 1993) or its descendants, or by integrating actions into description logics (Baader *et al.* 2005). Another would be to stay within the situation calculus but limit its representational or inferential capabilities (or both) without giving up its first-order nature. In (Gu and Soutchanski 2007), the authors use the two-variable fragment of first-order logic, which is known to be decidable, as the base logic of the situation calculus. In (De Giacomo *et al.* 2012; 2013), decidability is achieved by bounding the extension of fluent predicates by some constant. Going beyond two variables or boundedness requires further restrictions on the inference mechanism to retain decidability. The approach by Liu and Levesque (2005) restricts the representation of what holds in the current situation to literals. Such knowledge bases can then be queried efficiently using a sound but incomplete evaluation-based reasoner proposed in (Levesque 1998). When actions have only local effects, the result of an action can be represented by progressing the current knowledge base to a new set of literals. In (Claßen and Lakemeyer 2009), the restriction to literals is relaxed by allowing disjunctions in the representation of the initial situation. Queries about what holds after actions have been performed are evaluated by first regressing them to a query about the initial situation and then appealing to a logic of limited belief for static knowledge bases with disjunctions developed by Liu et al. (2004). Here a major limitation is that sensing actions cannot be dealt with.

The last two approaches have in common that they separate the reasoning task into two parts: one which addresses the dynamics of actions using progression and regression, respectively, and another which deals with querying a static knowledge base using existing techniques. A downside of this separation is that certain desirable features seem to get lost. For example, it is not at all clear how to handle sensing actions in the case of (Claßen and Lakemeyer 2009).

In order to avoid such limitations, we propose a new model of limited belief, which avoids the above separation by incorporating actions directly into the model. The starting point is the model of limited belief for the static case proposed in (Lakemeyer and Levesque 2013), which itself is based on (Liu et al. 2004). The general idea behind logics of limited belief is to capture, in a semantically perspicuous way, weaker forms of logical entailment. Other examples of such approaches are (Levesque 1984b; Konolige 1986; Vardi 1986; Fagin and Halpern 1988; Fagin *et al.* 1990; Lakemeyer 1996; Cadoli and Schaerf 1992; Delgrande 1995).

In the case of (Liu et al. 2004; Lakemeyer and Levesque 2013), the semantic primitive is a *setup*, a possibly infinite set of ground clauses closed under unit propagation. Roughly, the clauses in a setup can be viewed as those which the agent believes explicitly. Setups are used to give meaning to a sequence of modalities $\boldsymbol{B}_k$, for $k \geq 0$, where $\boldsymbol{B}_k\phi$ should be read as "ϕ is believed at level k." For example, given a clause c, $\boldsymbol{B}_0 c$ is satisfied by a setup s just in case

*Gerhard Lakemeyer is also affiliated with the Dept. of Computer Science at the University of Toronto.

there is a clause in s contained in c. In other words, at level 0, belief essentially reduces to retrieval wrt. s. At level 1, the agent believes everything that is believed at level 0 and, in addition, the agent is able to reason by cases allowing to split a single clause in s. At belief level 2, the number of possible case splits increases to 2, and so on.

In order to extend this framework to a dynamic setting, we borrow from a modal variant of the epistemic situation calculus called $\mathcal{ES}$ (Lakemeyer and Levesque 2011), which features formulas of the form $[n]\alpha$ meaning that α holds after action n. Setups are then allowed to not only mention literals l but also extended literals of the form $[n_1]\cdots[n_m]l$. The new setups are thus able to talk about what is true initially and after any number of actions have been performed. As we will see, this allows us to model Reiter's basic action theories (Reiter 2001) as infinite setups. Limited belief will be defined in a way analogous to what we sketched in the previous paragraph.[1]

We then specify a reasoning service in terms of valid sentences of the form $\boldsymbol{B}_0 KB \supset [n_1]\cdots[n_m]\boldsymbol{B}_k\phi$, which may be read as "if *KB* is explicitly believed initially, then after actions n_1 to n_m ϕ is believed at level k." Here ϕ itself may mention actions and *KB* represents a basic action theory in the sense of Reiter. We will show that this reasoning service is sound wrt. the situation calculus variant $\mathcal{ES}$. We also obtain an eventual completeness result for a large class of queries in the following sense: If $KB \supset \phi$ is valid in $\mathcal{ES}$, then there is a k such that $\boldsymbol{B}_0 KB \supset \boldsymbol{B}_k\phi$ is valid in the new logic. Moreover, and perhaps most importantly, we obtain a decidability result for so-called bounded queries.

The rest of the paper is organized as follows. In the next section we briefly review the epistemic situation calculus $\mathcal{ES}$. We then introduce our new logic $\mathcal{ESL}$, which is like $\mathcal{ES}$ except that the classical belief operator $\boldsymbol{K}$ is replaced by its limited counterparts $\boldsymbol{B}_k$. We then define our reasoning service and show soundness and eventual completeness. After that we turn to decidability and then conclude.

The Logic $\mathcal{ES}$

The language of $\mathcal{ES}$ is a modal first-order dialect with equality. It comes equipped with a countably infinite set of *standard names*, which can be thought of as special constants that satisfy the unique name assumption and an infinitary version of domain closure. In this sense, the standard names can be identified with the domain of discourse. As we will see, this greatly simplifies the semantic definitions below like interpreting quantification substitutionally (existing criticism of substitutional quantification notwithstanding (Kripke 1976)).

First-order variables and standard names come in two sorts, *action* (like *repair* and *bestAction*) and *object* (like *block5* and *location*). We let $\mathcal{N}$ denote the set of all standard names and $\mathcal{Z}$ denote the set of all sequences of standard names for actions, including $\langle\,\rangle$, the empty sequence.

A term is either a variable or a standard name. The *well-formed formulas* of the language form the least set such that

1. If $t_1, \ldots, t_k$ are terms, and P is a k-ary predicate symbol then $P(t_1, \ldots, t_k)$ is an (atomic) formula;
2. If t_1 and t_2 are terms, then $(t_1 = t_2)$ is a formula;
3. If t is an action term and α is a formula, then $[t]\alpha$ is a formula;
4. If α and β are formulas, and v is a first-order variable, then the following are also formulas: $(\alpha \vee \beta)$, $\neg\alpha$, $\exists v.\,\alpha$, $\Box\alpha$, $\boldsymbol{K}\alpha$.

We read $[n]\alpha$ as "α holds after action n", and $\Box\alpha$ as "α holds after any sequence of actions." We will freely use $\wedge, \supset, \equiv$, and $\forall$ as the usual abbreviations. There are two distinguished predicates *SF* and *Poss*: $Poss(n)$ says that action n can be executed, and $SF(n)$ says that action n returns a binary sensing result of 1 or 0.

Given a sequence of actions $z = \langle z_1, z_2, \ldots, z_n\rangle$ and a formula α, we usually write $[z]\alpha$ instead of $[z_1][z_2]\cdots[z_n]\alpha$. When z is the empty sequence, then $[z]\alpha = \alpha$. For action sequences z and z' we also write $z \cdot z'$ to mean the action sequence consisting of z followed by z'. We write $z \sqsubseteq z'$ when z is a prefix of z'. For a set of action sequences Z, we write $z \sqsubseteq Z$ to mean that there is some $z' \in Z$ such that $z \sqsubseteq z'$.

We call a formula without free variables a *sentence*. By a *primitive sentence* we mean a formula of the form $P(n_1, \ldots, n_m)$ where P is a predicate symbol and all of the n_i are standard names. For simplicity all predicates are considered to be fluent, that is, they may vary as a result of actions and their value may be unknown. It is convenient to distinguish between certain types of formulas using the following terminology:

- a formula with no $\Box$ operators is called *bounded*;
- a formula with no $\Box$ or $[t]$ operators is called *static;*
- a formula with no $\boldsymbol{K}$ operators is called *objective;*
- a formula with no fluent, $\Box$, or $[t]$ operators outside the scope of a $\boldsymbol{K}$ is called *subjective;*
- a formula with no $\boldsymbol{K}$, $\Box$, $[t]$, *Poss*, or *SF* is called a *fluent* formula;

Intuitively, to determine whether or not a sentence α is true after a sequence of actions z has been performed, we need to specify two things: a world w and an epistemic state e. We write $e, w, z \models \alpha$. A world determines truth values for the primitive sentences after any sequence of actions. An epistemic state is defined by a set of worlds, as in possible-world semantics. More precisely:

- a world $w \in W$ is any function from the primitive sentences and $\mathcal{Z}$ to $\{0, 1\}$.
- an epistemic state $e \subseteq W$ is any set of worlds.

To interpret what is known after a sequence of actions possibly including sensing has taken place, we define $w' \simeq_z w$ (read: w' and w agree on the sensing throughout action sequence z) inductively by the following:

1. $w' \simeq_{\langle\,\rangle} w$ for all w';
2. $w' \simeq_{z\cdot n} w$ iff
   $w' \simeq_z w$ and $w'[SF(n), z] = w[SF(n), z]$.

[1] A preliminary version of our model was developed by Capes (2010).

Putting all these together, here is the semantic definition of truth. Given $e \subseteq W$ and $w \in W$, we define $e, w \models \alpha$ (read: α is true) as $e, w, \langle\,\rangle \models \alpha$, where for any $z \in \mathcal{Z}$:

1. $e, w, z \models P(n_1, \ldots, n_m)$ iff $w[P(n_1, \ldots, n_m), z] = 1$, where $P(n_1, \ldots, n_m)$ is a primitive sentence;
2. $e, w, z \models (n_1 = n_2)$ iff n_1 and n_2 are identical standard names;
3. $e, w, z \models (\alpha \vee \beta)$ iff $e, w, z \models \alpha$ or $e, w, z \models \beta$;
4. $e, w, z \models \neg\alpha$ iff $e, w, z \not\models \alpha$;
5. $e, w, z \models \exists v.\, \alpha$ iff $e, w, z \models \alpha^x_n$, for some standard name n (of the same sort as v);
6. $e, w, z \models [n]\alpha$ iff $e, w, z \cdot n \models \alpha$;
7. $e, w, z \models \Box\alpha$ iff $e, w, z \cdot z' \models \alpha$, for every $z' \in \mathcal{Z}$;
8. $e, w, z \models \boldsymbol{K}\alpha$ iff $e, w', z \models \alpha$, for every $w' \in e$ such that $w' \simeq_z w$.

When α is *objective* (has no $\boldsymbol{K}$ operators), we can leave out the e and write $w \models \alpha$. When Σ is a set of sentences and α is a sentence, we write $\Sigma \models \alpha$ (read: Σ logically entails α) to mean that for every e and w, if $e, w \models \alpha'$ for every $\alpha' \in \Sigma$, then $e, w \models \alpha$. Finally, we write $\models \alpha$ (read: α is valid) to mean $\{\} \models \alpha$.

We will not go into details of the logical properties of $\mathcal{ES}$ except to note that $\boldsymbol{K}$ behaves like an ordinary *K45* modal operator (Chellas 1980), after any number of actions.

Basic Action Theories

While $\mathcal{ES}$ in general is less expressive than the classical situation calculus, we showed in (Lakemeyer and Levesque 2011) that it suffices to fully capture Reiter's *basic action theories (BATs)*.

Definition 1 *Given a set of fluents $\mathcal{F}$, a set $\Sigma \subseteq \mathcal{ES}$ of sentences is called a basic action theory over $\mathcal{F}$ iff $\Sigma = \Sigma_0 \cup \Sigma_{\text{pre}} \cup \Sigma_{\text{post}} \cup \Sigma_{\text{sense}}$ where Σ mentions only fluents in $\mathcal{F}$ and*

1. *Σ_0 is any set of fluent sentences;*
2. *Σ_{pre} is a singleton sentence of the form $\Box$Poss$(a) \equiv \pi$, where π is a fluent formula;*[2]
3. *Σ_{post} is a set of sentences of the form $\Box[a]F(\vec{v}) \equiv \gamma_F$, one for each relational fluent F, where γ_F is a fluent formula.*[3]
4. *Σ_{sense} is a sentence (parallel to the one for Poss) of the form $\Box$SF$(a) \equiv \varphi$, where φ is a fluent formula.*

Σ_0 is intended to express what is true initially; Σ_{pre} characterizes the preconditions of actions in a single axiom; Σ_{post} contains the *successor state axioms*, one per fluent, which incorporate Reiter's solution to the frame problem (Reiter 2001); following (Scherl and Levesque 2003), Σ_{sense} expresses the sensing outcomes of every action. (In case an action does not return a meaningful sensing results, the value of *SF* can be defined to be vacuously true.)

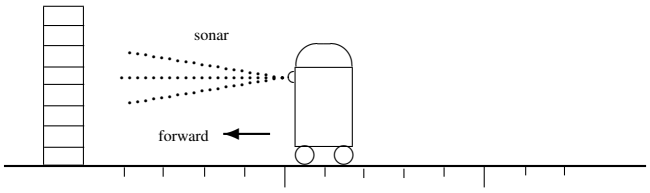

Figure 1: A simple robot

To illustrate BATs, let us consider the example depicted in Figure 1. Here a robot has two actions: *forward* moves it one unit forward towards the wall, and *sonar* is a sensing action, which returns 1 if the robot is close to the wall. Locations are denoted by propositional fluents d_i, which may be read as "the robot is located i units from the wall."[4]

$$\Box\,\textit{Poss}(a) \equiv a = \textit{forward} \wedge \neg d_0 \vee a = \textit{sonar} \wedge \text{TRUE}.$$

In other words, *sonar* is always possible, and *forward* is executable only when the robot is not already at the wall. Next, we define the sensing results for the actions:

$$\Box\,\textit{SF}(a) \equiv a = \textit{forward} \wedge \text{TRUE} \vee a = \textit{sonar} \wedge (d_0 \vee d_1).$$

While *forward* always returns *true* as a sensing result, $\textit{SF}(\textit{sonar})$ is 1 in case the robot is either at location d_0 or d_1. Finally, here are the successor state axioms for the d_i:

$$\Box\,[a]d_i \equiv a = \textit{forward} \wedge d_{i+1} \vee a \neq \textit{forward} \wedge d_i \quad \text{for } i > 0.$$

$$\Box\,[a]d_0 \equiv a = \textit{forward} \wedge d_1 \vee d_0$$

In other words, after *forward*, d_i becomes true if d_{i+1} was true before, and false otherwise, except in the case of d_0, which remains true after *forward* was executed in d_1. After *sonar* the value of d_i does not change.

For a given basic action theory Σ, projection queries, which are bounded sentences, are of particular importance, as they are a basic ingredient of action languages such as Golog (Levesque et al. 1997), among other things.

Let Σ consist of the above axioms together with $(d_2 \vee d_3), \neg d_1$, and $\neg d_0$. Then it follows from $\boldsymbol{K}\Sigma$ that the robot believes that it is initially either 2 or 3 units away from the wall. Suppose the robot is actually 2 units away from the wall. Abbreviating *forward* as f and *sonar* as s, respectively, let $S = \textit{SF}(f) \wedge [f]\textit{SF}(s)$ represent the actual sensing values obtained when executing f and s after f. We write *Close* instead of $(d_0 \vee d_1)$. Then we have:

[2] We assume that $\Box$ has lower syntactic precedence than the logical connectives, so that $\Box\textit{Poss}(a) \equiv \pi$ stands for $\forall a.\Box(\textit{Poss}(a) \equiv \pi)$.

[3] The $[t]$ construct has higher precedence than the logical connectives. So $\Box[a]F(\vec{x}) \equiv \gamma_F$ abbreviates $\forall a.\Box([a]F(\vec{x})) \equiv \gamma_F$.

[4] This way of handling distances is needed because we are not assuming any sort of built-in arithmetic in $\mathcal{ESL}$.

1. $\models \boldsymbol{K}\Sigma \supset \boldsymbol{K}\neg \mathit{Close}$;
2. $\not\models S \wedge \boldsymbol{K}\Sigma \supset [f]\boldsymbol{K}\mathit{Close}$;
3. $\models S \wedge \boldsymbol{K}\Sigma \supset [f][s]\boldsymbol{K}\mathit{Close}$;
4. $\models S \wedge \boldsymbol{K}\Sigma \supset \boldsymbol{K}[f][f]\mathit{Close}$;

In other words: initially the robot knows that it is not close to the wall (1); it does not know that it is close after executing a forward action (2); it knows that it is close after a forward and sensing the distance to the wall (3); it knows that it will be close if it were to perform two forward actions (4).

Since $\mathcal{ES}$ is a full first-order language, answering projection queries is clearly undecidable, even in the case without any actions at all. So let us now consider a variant of $\mathcal{ES}$ with a limited model of belief as the basis for deciding projection queries.

The Logic $\mathcal{ESL}$

The language of $\mathcal{ESL}$ is that of $\mathcal{ES}$ except that the operator $\boldsymbol{K}$ is replaced by operators $\boldsymbol{B}_k$ for $k = 0, 1, 2, \ldots$ For the purposes of this paper, we also assume that the $\boldsymbol{B}_k$ do not occur nested. The definitions of bounded, static, objective, subjective, and fluent formulas carry over in the obvious way, with $\boldsymbol{B}_k$ replacing $\boldsymbol{K}$.

As extended forms of literals and clauses play an important role in the semantics, we introduce them here together with some additional terminology. An *extended literal* is a sequence of actions (possibly empty) followed by a literal, where a literal is either an atomic formula not mentioning $=$ or its negation. $\neg P(n)$ and $[m_1][m_2]P(n)$ are examples of extended literals. The complement of an extended literal l, denoted as $\bar{l}$, is obtained by complementing the literal it contains. For example, the complement of $[m_1][m_2]P(n)$ is $[m_1][m_2]\neg P(n)$. An *extended clause* is a disjunction of extended literals. Often an extended clause is identified with the set of extended literals it contains. In the following we will often refer to extended clauses simply as clauses.

The empty clause is denoted as $[]$. A unit clause is a clause with a single extended literal. A primitive clause is a clause whose atomic formulas are primitive sentences, and similar for primitive literals. When z is a sequence of actions and c a clause we write $[z]c$ to mean c with every extended literal l replaced by $[z]l$.

A *setup* is a (possibly infinite) set of primitive clauses. For any setup s, the closure of s under unit propagation, which we denote as $\mathsf{UP}(s)$, is defined as the least set s' which contains s, and if unit clause $l \in s'$ and $\{\bar{l}\} \cup c \in s'$, then $c \in s'$. $\mathsf{VP}(s)$ is defined as the set $\{c \mid c \text{ is a primitive clause and there exists a } c' \in \mathsf{UP}(s) \text{ such that } c' \subseteq c\}$.

Similar to $\mathcal{ES}$ the semantics of $\mathcal{ESL}$ is defined wrt. a world, an agent's epistemic state, and a sequence of actions. While worlds and action sequences are the same as in $\mathcal{ES}$, the epistemic state is now characterized by a setup. Intuitively, the clauses in a setup determine what the agent believes explicitly, or at level 0. Beliefs at higher levels are then obtained by reasoning by cases.

Given a world w, a setup s, and an action sequence z, the truth of a sentence α, written as $s, w, z \models \alpha$, is inductively defined as follows:

1. $s, w, z \models P(n_1, \ldots, n_m)$ iff $w[P(n_1, \ldots, n_m), z] = 1$, where $P(n_1, \ldots, n_m)$ is a primitive formula;
2. $s, w, z \models (n_1 = n_2)$ iff n_1 and n_2 are identical;
3. $s, w, z \models (\alpha \vee \beta)$ iff $s, w, z \models \alpha$ or $s, w, z \models \beta$;
4. $s, w, z \models \neg\alpha$ iff $s, w, z \not\models \alpha$;
5. $s, w, z \models \exists x.\, \alpha$ iff $s, w, z \models \alpha^x_n$, for some standard name n (of the same sort as x);
6. $s, w, z \models [n]\alpha$ iff $s \cup \{[z] \pm \mathit{SF}(n)\}, w, z \cdot n \models \alpha$;[5]
7. $s, w, z \models \Box\alpha$ iff $s, w, z \models [z']\alpha$, for all $z' \in \mathcal{Z}$;
8. $s, w, z \models \boldsymbol{B}_k\alpha$ iff $s, z, k \models \alpha$.

Note that Rules 1–5 are essentially identical to those of $\mathcal{ES}$. Rule 6 differs in that we explicitly remember the sensing result of the action in s. Roughly, this has the same effect as the compatibility relation $\simeq_z$ of $\mathcal{ES}$ when it comes to interpreting belief. Rule 7 is again essentially the same as in $\mathcal{ES}$. Let us now turn to the semantics of limited belief (Rule 8). Let α be objective. $s, z, k \models \alpha$ is the least relation such that

9. $s, z, k \models \alpha$ if $[] \in \mathsf{UP}(s)$;
10. $s, z, k \models c$ if $k = 0$, c is a clause and $[z]c \in \mathsf{VP}(s)$;
11. $s, z, k \models \alpha$ if $k > 0$ and there is an extended primitive literal l such that $s \cup \{l\}, z, k-1 \models \alpha$ and $s \cup \{\bar{l}\}, z, k-1 \models \alpha$;
12. $s, z, k \models (n = m)$ if n, m are identical std. names; $s, z, k \models \neg(n = m)$ if n, m are distinct std. names;
13. $s, z, k \models \neg\neg\alpha$ if $s, z, k \models \alpha$;
14. $s, z, k \models (\alpha \vee \beta)$ if $s, z, k \models \alpha$ or $s, z, k \models \beta$; $s, z, k \models \neg(\alpha \vee \beta)$ if $s, z, k \models \neg\alpha$ and $s, z, k \models \neg\beta$;
15. $s, z, k \models \exists x.\alpha$ if $s, z, k \models \alpha^x_n$ for some n; $s, z, k \models \neg\exists x.\alpha$ if $s, z, k \models \neg\alpha^x_n$ for all n;
16. $s, z, k \models [n]\alpha$ if $s \cup \{[z]\mathit{SF}(n)\}, z \cdot n, k \models \alpha$ and $s \cup \{[z]\neg\mathit{SF}(n)\}, z \cdot n, k \models \alpha$; $s, z, k \models \neg[n]\alpha$ if $s \cup \{[z]\mathit{SF}(n)\}, z \cdot n, k \models \neg\alpha$ and $s \cup \{[z]\neg\mathit{SF}(n)\}, z \cdot n, k \models \neg\alpha$;
17. $s, z, k \models \Box\alpha$ if $s, z, k \models [z']\alpha$ for all $z' \in \mathcal{Z}$; $s, z, k \models \neg\Box\alpha$ if $s, z, k \models [z']\neg\alpha$ for some $z' \in \mathcal{Z}$.

Rules 9–15 are similar to those proposed for limited belief in the static case (Lakemeyer and Levesque 2013). Rule 9 says that whenever the empty clause can be derived by unit propagation everything is believed. Rule 10, which we will also refer to as the subsumption rule, says that a clause c is believed at level 0 after z just in case $[z]c$ is subsumed by a clause in $\mathsf{UP}(s)$. Rule 11, which we will also refer to as the split rule, says that α is believed at level $k > 0$ if the belief holds at level $k-1$ after splitting on an extended literal.[6] Rule 12 deals with equality in a classical way, independent of any setup. In other words, we assume perfect reasoning

[5] Here $\pm\mathit{SF}(n)$ stands for $\mathit{SF}(n)$ if $w[\mathit{SF}(n), z] = 1$ and $\neg\mathit{SF}(n)$ if $w[\mathit{SF}(n), z] = 0$, respectively.

[6] In (Lakemeyer and Levesque 2013) we considered splitting a clause in s instead. As we will see below, splitting an arbitrary literal has certain advantages.

when it comes to equality. Rules 13–15 make sure that certain "obvious" beliefs are obtained. For example, to believe $(\alpha \vee \beta)$ at level k it suffices to believe either α or β. Rule 16 considers the case of believing that α (or its negation) holds after an action n. Note that in thinking about what will hold after action n, the agent has as yet no access to the sensing information that will result from performing this action. Therefore it needs to entertain both possibilities ($SF(n)$ and $\neg SF(n)$) when evaluating whether α is believed after n. Finally, $\Box$ is handled in the obvious way by considering all action sequences. Note that Rules 7 and 17 are well-founded when including the number of $\Box$ operators occurring in α in the measure for α.[7]

When a formula α is objective, we sometimes write $w, z \models \alpha$ instead of $s, w, z \models \alpha$. For subjective α, we write $s, z \models \alpha$. If, in addition, z is empty, we simply write $w \models \alpha$ and $s \models \alpha$, respectively.

To conclude the semantic definition, we say that a set of sentences Σ logically entails a sentence α (written $\Sigma \models \alpha$) if for every setup s and world w, if $s, w, \langle\,\rangle \models \alpha'$ for every $\alpha' \in \Sigma$, then $s, w, \langle\,\rangle \models \alpha$. Finally, α is valid (written $\models \alpha$) if $\{\} \models \alpha$. (So far we have used $\models$ for entailment in both $\mathcal{ES}$ and $\mathcal{ESL}$. In the following, we will write $\models_{\mathcal{ES}}$ when referring to entailment in $\mathcal{ES}$.)

Some Properties

Here we will not go into a detailed discussion of the properties of $\mathcal{ESL}$ except to note the following. The logic of limited belief presented in (Lakemeyer and Levesque 2013) is very similar to $\mathcal{ESL}$ when restricted to formulas without nested beliefs. This is because, in the case of static formulas, the semantics of both logics is the same except for the split rule. The same applies to a slight variant of the logic presented in (Liu et al. 2004), and the properties discussed there for static formulas generally carry over in a straightforward way to the dynamic case. For example, a simple induction proof establishes that for any k

$\models \Box(\boldsymbol{B}_k \neg\neg\alpha \equiv \boldsymbol{B}_k\alpha)$
$\models \Box(\boldsymbol{B}_k(\alpha \wedge \beta) \equiv \boldsymbol{B}_k\alpha \wedge \boldsymbol{B}_k\beta)$
$\models \Box(\boldsymbol{B}_k \forall x.\alpha \equiv \forall x.\boldsymbol{B}_k\alpha)$

While most of the equivalence preserving transformations of formulas such as removing double negations are preserved at all belief levels, there are exceptions. For example,

$$\boldsymbol{B}_k(p \wedge (q \vee r)) \supset \boldsymbol{B}_k((p \wedge q) \vee (p \wedge r))$$

is not valid. See (Liu et al. 2004) for a detailed discussion of why this is so.

Intuitively, one would expect belief to be monotonic in the sense that the beliefs held at a certain setup and level of belief continue to hold when moving to larger setups or increasing the level of belief. We now show that this is indeed the case.

Theorem 1 *Let s and s' be setups such that $s \subseteq s'$. Then for any z, k, and objective ϕ, if $s, z, k \models \phi$ then $s', z, k \models \phi$.*

[7] We remark that there are equivalent versions of Rule 7 and 17, where the sequence z' is only mentioned on the left-hand side of the rules, but at the expense of a more complicated definition.

Proof: The proof is by induction on k and the structure of ϕ. Let $k = 0$. The only interesting case is when ϕ is a clause c. It is easy to show that $\mathsf{VP}(s) \subseteq \mathsf{VP}(s')$ given that $s \subseteq s'$. Hence, if $[z]c \in \mathsf{VP}(s)$ then $[z]c \in \mathsf{VP}(s')$. Note also that, in the case of actions (Rule 16+17), the same *SF*-formulas are added to s and s' so that the subset relation between the augmented setups continues to hold.

Suppose the lemma holds for some k and let $s, z, k+1 \models \phi$. Again, the proof is by induction on the structure of ϕ. Here the only interesting case is the split rule. So suppose, there is some extended literal l such that $s \cup \{l\}, z, k \models \phi$ and $s \cup \{\bar{l}\}, z, k \models \phi$. In both cases we can apply the induction hypothesis for k and obtain $s', z, k+1 \models \phi$. ∎

Corollary 1 *If $\mathsf{VP}(s) \subseteq \mathsf{VP}(s')$ then $s, z, k \models \phi$ implies $s', z, k \models \phi$.*

Theorem 2 *If $s, z, k \models \phi$ then $s, z, k+1 \models \phi$.*

Proof: Let $s, z, k \models \phi$ and let l be any extended literal. Then, by Theorem 1, $s \cup \{l\}, z, k \models \phi$ and $s \cup \{\bar{l}\}, z, k \models \phi$. Hence, by the split rule, $s, z, k+1 \models \phi$. ∎

As an immediate corollary we obtain

Corollary 2 $\models \Box(\boldsymbol{B}_k\phi \supset \boldsymbol{B}_{k+1}\phi)$.

Eventual completeness

When considering sentences e that only mention $=$, limited belief behaves exactly like $\boldsymbol{K}$, even at level 0. A simple induction shows that $\models_{\mathcal{ES}} \Box(\boldsymbol{K}e \equiv e)$ and $\models \Box(\boldsymbol{B}_0 e \equiv e)$, that is, e is believed just in case e is true, after any number of actions. In general, of course, $\boldsymbol{B}_k$ is much weaker than $\boldsymbol{K}$, especially when k is small. For example, while $\boldsymbol{K}(p \vee \neg p)$ is valid, $\boldsymbol{B}_0(p \vee \neg p)$ is not. For example, if s is the empty setup, then $s, \langle\,\rangle \not\models \boldsymbol{B}_0(p \vee \neg p)$ because neither Rule 10 nor Rule 14 applies. On the other hand, $\boldsymbol{B}_1(p \vee \neg p)$ is valid, since we can apply the split rule using p. This is not accidental. We will now show that for any objective valid bounded propositional formula ϕ of $\mathcal{ESL}$ we can always find a k such $\boldsymbol{B}_k\phi$ is valid. By a propositional formula we mean a formula which does not contain quantifiers and which does not mention $=$.

We begin with a useful lemma that shows the connection between worlds and their corresponding setups for arbitrary objective formulas.

Definition 2 *Given a world w let*

$$s(w) = \{l \mid l \text{ is an extended literal and } w \models l\}.$$

In other words, $s(w)$ is the setup consisting of all extended literals true at w. Note that $[z]l \in s(w)$ iff $w, z \models l$ for any literal l.

Lemma 1 *For any objective ϕ and sequence of actions z, $s(w), z, k \models \phi$ iff $w, z \models \phi$ for all k.*

Proof: We first prove the lemma for $k = 0$ by induction on the structure of ϕ. For a clause c we have $s(w), z, 0 \models c$ iff $[z]l \in s(w)$ for some $l \in c$ (by the subsumption rule) iff $w, z \models l$ for some $l \in c$ (by the construction of $s(w)$) iff $w, z \models c$. The lemma clearly holds for $(n = m)$ and $\neg(n =$

m) and also (by induction) for $\neg\neg\phi$, $(\phi \wedge \psi)$, $\neg(\phi \wedge \psi)$, $\forall x.\phi$, and $\neg\forall x.\phi$.

$s(w), z, 0 \models [n]\phi$ iff $s(w) \cup \{[z]SF(n)\}, z \cdot n, 0 \models \phi$ and $s(w) \cup \{[z]\neg SF(n)\}, z \cdot n, 0 \models \phi$ iff $s(w), z \cdot n, 0 \models \phi$ (because $s(w)$ already contains either $[z]SF(n)$ or $[z]\neg SF(n)$ and hence either does not change by adding the extended literal or it becomes inconsistent so that Rule 9 applies) iff $w, z \cdot n \models \phi$ (by induction) iff $w, z \models [n]\phi$. (The case for $\neg[n]\phi$ is similar.) $s(w), z, 0 \models \Box\phi$ iff $s(w) \cup \sigma, z, 0 \models [z']\phi$ for all z' iff $s(w), z \cdot z', 0 \models \phi$ for all z' (since, similar to the case of a single action, adding all combinations of sensing results for z' to $s(w)$ leads either to inconsistency or leaves $s(w)$ as is) iff $w, z \cdot z' \models \phi$ for all z' iff $w, z \models \Box\phi$.

We now show that $s(w), z, k \models \phi$ iff $s(w), z, k+1 \models \phi$, from which the lemma follows. The only-if direction follows from Lemma 2. For the if direction, suppose $s(w), z, k+1 \models \phi$. The proof is by induction on the structure of ϕ. For a clause c and since $k + 1 > 0$, the only applicable rule is the split rule. Hence there is an extended literal l such that $s(w) \cup \{l\}, z, k \models \phi$ and $s(w) \cup \{\bar{l}\}, z, k \models \phi$. Since $s(w)$ is a complete set of literals, either l or $\bar{l}$ is in $s(w)$. Suppose $l \in s(w)$. Then $s(w) \cup \{l\} = s(w)$ and, hence, $s(w), z, k \models \phi$. The other case is symmetric. The case of $=$-expression is obvious. For the induction step, if any of the rules (12)–(17) apply, then the induction hypothesis applies immediately. In case of the split rule the argument is the same as above. ∎

For the rest of this subsection, we only consider propositional bounded formulas. The following definition characterizes the positive extended literals contained in a formula, or PEL(ϕ) for short.

Definition 3 *Let ϕ be bounded and objective. Then PEL(ϕ) is defined inductively as follows:*

PEL(p) = $\{p\}$ when p is a primitive sentence;
PEL($\neg\phi$) = PEL(ϕ);
PEL($\phi \vee \psi$) = PEL(ϕ) $\cup$ PEL(ψ);
PEL($[n]\phi$) = $\{[n \cdot z]p \mid [z]p \in$ PEL(ϕ)$\}$.

For example, if $\phi = [n](p \vee [m](\neg q \vee [l]r))$ then PEL(ϕ) = $\{[n]p, [n \cdot m]q, [n \cdot m \cdot l]r\}$. Note that PEL ignores negations. Let PEL(ϕ)$_z$ = $\{[z \cdot z']p \mid [z']p \in$ PEL(ϕ)$\}$ for any action sequence z.

Definition 4 (Worlds compatible with a setup) *Let s be a setup. Then*

$$C(s) = \{w \mid w \text{ is a world and } w \models c \text{ for all } c \in s\}$$

Lemma 2 *Let $A = \{p_1, \ldots, p_n\}$ be a set of positive extended literals and $L = \{l_1, \ldots, l_n\}$ with $l_i = p_i$ or $l_i = \overline{p}_i$. Let s be a setup such that $L \subseteq s$. Then for all sequences of actions z, all ϕ with PEL$_z(\phi) \subseteq A$, and all $w \in C(s)$, $w, z \models \phi$ iff $s, z, 0 \models \phi$.*

Proof: First note that in case s is inconsistent the lemma holds vacuously, since there are no compatible worlds in this case. Now suppose s is consistent. Then s does not contain $\bar{l}$ for any $l \in L$ as s already contains l.

The proof is by induction on the structure of ϕ. For a clause c suppose $w, z \models c$. Then $w, z \models l$ for some extended literal $l \in c$. By assumption, either $[z]l \in A$ or $[z]\bar{l} \in A$. Since w is compatible with s and, in particular, with L, $[z]l \in L$ and hence $[z]l \in s$ by assumption. Therefore, by the subsumption rule, $s, z, 0 \models c$.

Conversely, let $s, z, 0 \models c$. Then $[z]c \in \mathsf{VP}(s)$ by subsumption. Since $L \subseteq s$ and since s is consistent, there must be some extended literal $l \in c$ such that $[z]l \in s$ and $[z]l \in L$. Thus $w, z \models l$ follows and, hence, $w, z \models c$.

The cases for $\neg\neg\phi$, $(\phi \vee \psi)$, and $\neg(\phi \vee \psi)$ follow trivially by induction. Let $w, z \models [n]\phi$. Then $w, z \cdot n \models \phi$ and, by induction, $s, z \cdot n, 0 \models \phi$. (Note that PEL$_z([n]\phi)$ = PEL$_{z \cdot n}(\phi)$. By monotonicity, $s \cup \{[z]SF(n)\}, z \cdot n, 0 \models \phi$ and $s \cup \{[z]\neg SF(n)\}, z \cdot n, 0 \models \phi$. Hence, $s, z, 0 \models [n]\phi$. Conversely, let $s, z, 0 \models [n]\phi$. Then $s \cup \{[z]SF(n)\}, z \cdot n, 0 \models \phi$ and $s \cup \{[z]\neg SF(n)\}, z \cdot n, 0 \models \phi$. Suppose $w, z \models SF(n)$ (the other case is symmetric). Then $w \in$ C$(s \cup \{[z]SF(n)\})$. Hence, by induction, $w, z \cdot n \models \phi$ and, therefore $w, z \models [n]\phi$. ∎

We are now ready to prove our eventual-completeness result. The interesting part is that any valid propositional, bounded ϕ is believed at some level k. Roughly, this is because we can always split on every extended literal contained in ϕ so that the resulting setups are essentially complete valuations of all the extended literals mentioned.

Theorem 3 *For any propositional, bounded, objective ϕ, $\models \phi$ iff $\models \boldsymbol{B}_k\phi$ for some k.*

Proof: For the if direction, suppose $\models \boldsymbol{B}_k\phi$ for some k and consider any world w. Then $s(w), \langle\,\rangle, k \models \phi$ and, by Lemma 1, $w, \langle\,\rangle \models \phi$.

Conversely, let $\models \phi$. Let n be the size of PEL(ϕ), and for any setup s, let $\nu(s)$ be the number of elements p of PEL(ϕ) such that either p or $\overline{p}$ appears in s. We will first show that for any s and $k = n - \nu(s)$, $s \models \boldsymbol{B}_k\phi$. The proof is by induction on k.

For $k = 0$ we need to show that $s, \langle\,\rangle, 0 \models \phi$. If $[] \in \mathsf{UP}(s)$ then clearly $s, \langle\,\rangle, 0 \models \phi$ because of Rule 9. Otherwise, since $\nu(s) = n$, we have that for every atom p in ϕ, exactly one of p or $\overline{p}$ is in s. Let $L = \{l_1, \ldots, l_n\}$ be the set of all such literals. Let $w \in$ C(L). Since $w \models \phi$ by assumption, $L \models \boldsymbol{B}_0\phi$ holds by Lemma 2. Since $L \subseteq s$, by Theorem 1, $s \models \boldsymbol{B}_0\phi$.

Suppose for all s with $k = n - \nu(s)$ and $0 \leq k < n$, $s \models \boldsymbol{B}_k\phi$. Now consider a setup s' with $n - \nu(s') = k + 1$. Let p be an atom occurring in ϕ such that neither p nor $\overline{p}$ is in s'. Such p must exist since $n \neq \nu(s')$ by assumption. Since $n - \nu(s' \cup \{p\}) = n - \nu(s' \cup \{\overline{p}\}) = k$, by induction, $s' \cup \{p\} \models \boldsymbol{B}_k\phi$ and $s' \cup \{\neg p\} \models \boldsymbol{B}_k\phi$. Since ϕ is objective, it follows that $s' \cup \{p\}, \langle\,\rangle, k \models \phi$ and $s' \cup \{\neg p\}, \langle\,\rangle, k \models \phi$. Hence, using the split rule, we obtain, $s', \langle\,\rangle, k+1 \models \phi$, that is, $s' \models \boldsymbol{B}_{k+1}\phi$.

To complete the proof of the only-if direction, let s be any setup and let $k = n$. By the above argument, $s \models \boldsymbol{B}_{k'}\phi$ for $k' = n - \nu(s)$. Since $0 \leq k' \leq n$, $s \models \boldsymbol{B}_k\phi$ (using $\models \boldsymbol{B}_{k'}\phi \supset \boldsymbol{B}_{k'+1}\phi$ if needed). ∎

We remark that this significantly strengthens an earlier result by Liu et al. (2004), who showed that eventual

completeness in the static case obtains only when querying knowledge bases and only when the query belongs to a restricted class of formulas in a normal form defined in (Levesque 1998). The reason for our stronger result is our modified split rule. While Liu et al. restricted splitting to clauses in the setup, we allow splitting arbitrary literals, which is strictly more general. In the next section we will revisit the issue of eventual completeness also in the context of querying knowledge bases.

A Reasoning Service Based on $\mathcal{ESL}$

We now turn to the use of the logic as a specification of a reasoning service for an agent with limited beliefs. In particular, we phrase it in terms of the valid sentences of the following form:

$$\boldsymbol{B}_0\phi \supset [z]\boldsymbol{B}_k\psi, \tag{1}$$

where ϕ typically encodes a basic action theory of the kind introduced earlier, and ψ is a bounded formula, that is, it may contain actions but not $\Box$. We will refer to sentences (1) as *belief implications*, and they can be read as "if ϕ is explicitly believed initially then after actions z have occurred ψ is believed at level k." Belief implications specify a reasoning service in the sense that determining beliefs at level k after some actions requires computing whether the corresponding belief implication is valid.

We begin our investigations by showing that belief implications are sound with respect to the original epistemic situation calculus $\mathcal{ES}$.

Theorem 4 *If* $\models \boldsymbol{B}_0\alpha \supset [z]\boldsymbol{B}_k\beta$ *then* $\models_{\mathcal{ES}} \boldsymbol{K}\alpha \supset [z]\boldsymbol{K}\beta$.

Proof: Here we prove it for the case of a single action n. Generalizing it to an arbitrary z is straightforward. Suppose $\models \boldsymbol{B}_0\alpha \supset [n]\boldsymbol{B}_k\beta$ and let $e, w \models \boldsymbol{K}\alpha$. Then $w' \models \alpha$ for all $w' \in e$. Then $s(w'), \langle\,\rangle, 0 \models \alpha$ by Lemma 1. Let $w' \in e$ and suppose $w' \simeq_n w$. Thus $s(w'), w \models \boldsymbol{B}_0\alpha$. By assumption, $s(w') \cup \{\pm SF(n)\}, w, \langle n\rangle \models \boldsymbol{B}_k\beta$ and, therefore, $s(w') \cup \{\pm SF(n)\}, \langle n\rangle, k \models \beta$. Since $w' \simeq_z w$ we have $s(w') \cup \{\pm SF(n)\} = s(w')$ and hence, by Lemma 1, $w', \langle n\rangle \models \beta$. As this holds for all $w' \in e$ such that $w' \simeq_n w$, $e, w \models [n]\boldsymbol{K}\beta$ follows. ∎

Liu et al. (2004) considered so-called proper$^+$ knowledge bases, for which they showed that reasoning under limited belief is decidable in the static case. We will now extend this idea to knowledge bases representing basic action theories. In the following we let e range over *ewffs*, which are quantifier-free fluent formulas that mention only $=$ and no other predicate symbols. Let θ be a mapping from variables to standard names (of the appropriate sort). Then we write $e\theta$ to mean e with each variable substituted by the standard name according to θ. For a formula α we write $\forall\alpha$ to denote its universal closure.

Definition 5 (proper$^+$ Knowledge Bases) *Let e be an ewff and c an extended clause. Then we call a formula of the form $\forall(e \supset c)$ a $\forall$-clause and a formula of the form $\Box\forall(e \supset c)$ a $\Box$-clause. A KB is called proper$^+$ if it is a finite set of $\forall$- and $\Box$-clauses.*

Given a proper$^+$ KB, we let gnd(KB) be the infinite setup which is the union of $\{c\theta \mid \forall(e \supset c) \in KB \text{ and } \models e\theta\}$ and $\{[z]c\theta \mid \Box\forall(e \supset c) \in KB, \models e\theta, \text{ and } z \in \mathcal{Z}\}$.

In the following we will not consider proper$^+$ *KB*s in their full generality but only those which are the translation of a basic action theory as defined earlier. We call such *KB*s *proper$^+$ BATs*. It will also be necessary to consider proper$^+$ BATs augmented with a finite set of extended literals. We call such *KB*s augmented proper$^+$ BATs.

Note that a proper$^+$ BAT has two kinds of $\Box$-formulas: Those $\Box\forall(e \supset c)$ which are the result of the translation of a successor state axiom are such that c mentions a single extended literal of the form $[a]l$, where l is a literal and a is an action variable. All other $\Box\forall(e \supset c)$ like the ones resulting from the translation of the *SF*-axiom are such that c mentions only literals and no actions, that is, c is static.

As an example, let us consider the BAT for our robot example. It is easy to translate the original axioms into a proper$^+$ KB. Here we consider only the translations of the sensing axiom and the successor state axiom for d_i with $i > 0$. The *SF*-axiom can be represented by the following five $\Box$-clauses:

$\Box\forall(a \neq \mathit{forward} \supset (\neg SF(a) \vee d_0 \vee d_1))$;
$\Box\forall(a \neq \mathit{forward} \wedge a \neq \mathit{sonar} \supset \neg SF(a))$;
$\Box\forall(a = \mathit{forward} \supset SF(a))$;
$\Box\forall(a = \mathit{sonar} \supset (\neg d_0 \vee SF(a)))$;
$\Box\forall(a = \mathit{sonar} \supset (\neg d_1 \vee SF(a)))$.

The successor state axiom for d_i with $i > 0$ is captured by these $\Box$-clauses:

$\Box\forall(a = \mathit{forward} \supset (\neg d_{i+1} \vee [a]d_i))$;
$\Box\forall(a \neq \mathit{forward} \supset (\neg d_i \vee [a]d_i))$;
$\Box\forall(a \neq \mathit{forward} \supset ([a]\neg d_i \vee d_i))$;
$\Box\forall(a = \mathit{forward} \supset ([a]\neg d_i \vee d_{i+1}))$;

When considering belief implications, the following result is very useful as it reduces belief implications for proper$^+$ *KB*s to truth in the setup gnd(*KB*).

Theorem 5 $\models \boldsymbol{B}_0 KB \supset \boldsymbol{B}_k\phi$ *iff* $gnd(KB) \models \boldsymbol{B}_k\phi$.

Proof: For the only-if direction, let $\models \boldsymbol{B}_0 KB \supset \boldsymbol{B}_k\phi$. It suffices to show that gnd(*KB*) $\models \boldsymbol{B}_0 KB$. It is easy to see that this is the case. For consider $\Box\forall(e \supset c) \in KB$. We need to show that gnd(*KB*), $z, 0 \models (\neg e\theta \vee c\theta)$ for any z and substitution θ. Note that gnd(*KB*), $\langle\,\rangle, 0 \models [z]e\theta$ iff $\models e\theta$. If $\not\models e\theta$, then the claim holds by Rule 14. Otherwise, the subsumption rule applies. (The case of a $\forall$-clause is proved the same way except that $z = \langle\,\rangle$.)

For the if direction, suppose that gnd(*KB*) $\models \boldsymbol{B}_k\phi$. Let $s \models \boldsymbol{B}_0 KB$. Then $\mathsf{VP}(\text{gnd}(KB)) \subseteq \mathsf{VP}(s)$. By Corollary 1, $s \models \boldsymbol{B}_k\phi$. ∎

Corollary 3
$\models \boldsymbol{B}_0 KB \supset [n]\boldsymbol{B}_k\phi$ *iff* $gnd(KB) \cup \{SF(n)\}, n, k \models \phi$ *and* $gnd(KB) \cup \{\neg SF(n)\}, n, k \models \phi$.

Let *KB* be the proper$^+$ BAT of our robot example, including clauses $(d_2 \vee d_3)$, $\neg d_1$, and $\neg d_0$ for the initial situation. As before, suppose the robot is 2 units away from the wall and let $S = SF(f) \wedge [f]SF(s)$. Then

1. $\models \boldsymbol{B}_0 KB \supset \boldsymbol{B}_0(\neg Close)$;
2. $\not\models S \wedge \boldsymbol{B}_0 KB \supset [f]\boldsymbol{B}_0(d_1 \vee d_2)$;
3. $\models S \wedge \boldsymbol{B}_0 KB \supset [f]\boldsymbol{B}_1(d_1 \vee d_2)$;
4. $\models S \wedge \boldsymbol{B}_0 KB \supset [f][s]\boldsymbol{B}_1 Close$;

The robot believes that it is not close initially at level 0 by subsumption, using the clauses $\neg d_0$ and $\neg d_1$ from gnd(*KB*); after *forward*, it believes that it is at d_1 or d_2 only at level 1, because it needs to split a literal, for example, d_2, and then use unit propagation on the $(\neg d_i \vee [a]d_i)$ for $i = 2$ and $i = 3$; After a *forward* and then sensing the distance to the wall, we can show that the robot believes at level 1 that it is close using the following argument: since the *KB* is augmented by $[f]SF(s)$, $[f](d_0 \vee d_1)$ obtains by unit propagation from $[f](\neg SF(s) \vee d_0 \vee d_1)) \in$ gnd(*KB*). Then splitting $[f]d_0$ and using $[f](\neg d_i \vee [s]d_i)$ the result obtains.

Decidability

We will now turn to the problem of deciding belief implications for proper$^+$ BATs and strictly bounded queries, which are bounded objective formulas not mentioning any action variables. In other words, all actions mentioned in such queries are standard names, as in the examples above.

We will mostly consider belief implications of the form $\boldsymbol{B}_0 KB \supset \boldsymbol{B}_k\phi$. Once we have established decidability for those, the extension to $\boldsymbol{B}_0 KB \supset [z]\boldsymbol{B}_k\phi$-formulas will be straightforward.

The following definition shows how to extract the action sequences mentioned in such queries in a way very similar to PEL (Definition 3).

Definition 6 *Let ϕ be strictly bounded and objective. Then AS(ϕ) is defined inductively as follows:*

$AS(p) = \{\langle\rangle\}$ *when p is an atomic formula;*
$AS((t = t')) = \{\langle\rangle\}$;
$AS(\neg\phi) = AS(\phi)$;
$AS(\phi \vee \psi) = AS(\phi) \cup AS(\psi)$;
$AS(\exists x.\phi) = AS(\phi)$;
$AS([n]\phi) = \{n \cdot z \mid z \in AS(\phi)\}$.

Let $AS_z(\phi) = \{z \cdot z' \mid z' \in AS(\phi)\}$, where z is any action sequence.

The next result shows that, when considering a strictly bounded query ϕ, we only need to consider those instances of $\Box$-formulas in the *KB* which mention action sequences that are subsequences of those in AS(ϕ). We begin by defining such instantiated *KB*s:

Definition 7 *Let KB be proper$^+$ and Z a set of action sequences. The Z-instantiation $KB{\downarrow_Z}$ is then defined as the union of the following sets:*

- $\{[z]\forall(e \supset c) \mid z \sqsubseteq Z, \Box\forall(e \supset c) \in KB, \text{ and } c \text{ static}\}$
- $\{[z]\forall(e \supset c_n^a) \mid z{\cdot}n \sqsubseteq Z, \Box\forall(e \supset c) \in KB, \ c \text{ not static}\}$
- $\{\forall(e \supset c) \mid \forall(e \supset c) \in KB\}$

Theorem 6 *Let KB be a proper$^+$ BAT, ϕ a strictly bounded objective formula, and $Z = AS(\phi)$. Then $\models \boldsymbol{B}_0 KB \supset \boldsymbol{B}_k\phi$ iff $\models \boldsymbol{B}_0 KB{\downarrow_Z} \supset \boldsymbol{B}_k\phi$.*

The proof is not hard. It involves showing that instances of $\Box$-clauses that are not subsequences of action sequences in AS(ϕ) are irrelevant in establishing beliefs about formulas whose action sequences are included in AS(ϕ). We remark that the analogous theorem holds in $\mathcal{ES}$ as well, that is, $\models \boldsymbol{K}KB \supset \boldsymbol{K}\phi$ iff $\models \boldsymbol{K}KB{\downarrow_Z} \supset \boldsymbol{K}\phi$. It is crucial, though, that *KB* is a proper$^+$ BAT, that is, the $\Box$-clauses in *KB* correspond to the dynamic part of a basic action theories. Otherwise, it is easy to construct a counterexample: for instance, there is a basic action theory *KB* such that $\models \boldsymbol{B}_0 KB \supset \boldsymbol{B}_0[n_1]F$ and $\models \boldsymbol{B}_0 KB \supset \boldsymbol{B}_0[n_1][n_2]F$, yet $\models \boldsymbol{B}_0 KB \supset \boldsymbol{B}_0[n_1][n_2][n_3]\neg F$. Then adding $\Box F$ to *KB* would lead to an inconsistency by unit propagation at level 0, that is, $[] \in \mathsf{UP}(\text{gnd}(KB \cup \{\Box F\}))$, and we obtain that $\boldsymbol{B}_0(KB \cup \{\Box F\}) \supset \boldsymbol{B}_0 p$ is valid for any atomic proposition p. The problem is that we would need to instantiate $KB \cup \{\Box F\}$ using all subsequences of $n_1 \cdot n_2 \cdot n_3$ to discover this, yet AS(p) = {}.

Given Theorem 6, we can restrict our attention to AS(ϕ)-instantiated proper$^+$*KB*s for any given query ϕ. In order to arrive at a decision procedure for belief implications we need two more things: restrict the set of literals to choose from when splitting and, most importantly, restrict the possible substitutions of standard names to consider to a finite set. To achieve the former we let

$$\text{PEL}(KB, \phi, Z) = \{[z]p \mid p \text{ is an atom in } KB \text{ or } \phi, z \sqsubseteq Z\}.$$

The idea is that only literals that mention atoms from the *KB* or the query together with their respective action sequences need to be considered. To limit substitutions of standard names, we follow (Liu et al. 2004) and define a sufficiently large but finite set of standard names for a given *KB* and query ϕ:

For any $m \geq 0$ let H_m^+ be the set of standard names mentioned in *KB* and ϕ plus m new standard names of type object. Let n be the maximum number of (object) variables appearing in a $\forall$-clause appearing in *KB*. Then $\text{gnd}(KB)|_{H_n^+}$ denotes gnd(*KB*) with substitutions θ restricted to names in H_n^+. Similarly, $\text{PEL}(KB, \phi, Z)|_{H_n^+}$ denotes the set of extended literals in $\text{PEL}(KB, \phi, Z)$ with all variables replaced by names in H_n^+.

With these abbreviations in hand, we now define a computable function V, which, as will be shown below, returns 1 just in case $\text{gnd}(KB), z, k \models \phi$, that is, V decides belief implications.

Definition 8 *Let ϕ be a strictly bounded objective sentence, z an action sequence, KB an AS(ϕ)$_z$-instantiated augmented BAT, and $k \geq 0$.*

$$V[KB, \phi, z, k] = \begin{cases} 1 & \text{if any of the following} \\ & \text{conditions (1)–(12) holds} \\ 0 & \text{otherwise} \end{cases}$$

1. $[] \in \mathsf{UP}(gnd(KB)|H_n^+)$;
2. $k = 0$, *ϕ is a clause c, and there exists a* $c' \in \mathsf{UP}(gnd(KB)|H_n^+)$ *such that* $c' \subseteq [z]c$;
3. $k > 0$ *and*
   for some extended literal $l \in PEL(KB, \phi, AS(\phi)_z)|_{H_n^+}$,
   $V[KB \cup \{l\}, \phi, z, k-1] = 1$ *and* $V[KB \cup \{\bar{l}\}, \phi, z, k-1] = 1$

4. $\phi = (n = m)$, *and* n, m *are the same standard names;*
5. $\phi = \neg(n = m)$, *and* n, m *are distinct standard names;*
6. $\phi = \neg\neg\psi$, *and* $V[KB, \psi, z, k] = 1$*;*
7. $\phi = (\psi \vee \chi)$, $V[KB, \psi, z, k] = 1$ *or* $V[KB, \chi, z, k] = 1$*;*
8. $\phi = \neg(\psi \vee \chi)$, $V[KB, \neg\psi, z, k] = 1$ *and* $V[KB, \neg\chi, z, k] = 1$*;*
9. $\phi = \exists x.\psi$, *and* $V[KB, \psi^x_n, z, k] = 1$ *for some* $n \in H^+_1$*;*
10. $\phi = \neg\exists x.\psi$, *and* $V[KB, \neg\psi^x_n, z, k] = 1$ *for all* $n \in H^+_1$*;*
11. $\phi = [n]\psi$, $V[KB \cup \{[z]SF(n)\}, \psi, z \cdot n, k] = 1$ *and* $V[KB \cup \{[z]\neg SF(n)\}, \psi, z \cdot n, k] = 1$*;*
12. $\phi = \neg[n]\psi$, $V[KB \cup \{[z]SF(n)\}, \neg\psi, z \cdot n, k] = 1$ *and* $V[KB \cup \{[z]\neg SF(n)\}, \neg\psi, z \cdot n, k] = 1$.

We will now show that the above restrictions, that is, considering only a finite number of substitution instances of the *KB* and the query, and only finitely many split literals, are indeed sufficient to correctly compute belief implications. As in (Liu et al. 2004), the main idea is that names not mentioned in the *KB* or the query are, in a sense, indistinguishable and hence interchangeable. The following definition of a bijection over names makes this precise:

Let * be a bijection over the set of names (preserving sorts). For any formula α, let α^* be α with every name n replaced by n^*. We extend this notion to sets of formulas, including setups, and substitutions θ in the obvious way. The following properties of * are easy to prove:

Lemma 3

- $\models [z]e$ *iff* $\models [z^*]e^*$ *iff* $\models e^*$*;*
- $c \in \mathsf{UP}(s)$ *iff* $c^* \in \mathsf{UP}(s^*)$*;*
- $s, z, k \models \phi$ *iff* $s^*, z^*, k \models \phi^*$*;*
- *gnd*$(KB)^* =$ *gnd*(KB^*).

Lemma 4 *Let* $m_1, \ldots, m_n$ *be the names in* H^+_n *that do not occur in KB and* ϕ*. Let* $c \in \mathsf{UP}($*gnd*$(KB))$ *contain names* $m'_1, \ldots, m'_l$ $(l \leq n)$ *not mentioned in* H^+_n*. Let* * *be the bijection which swaps* m_i *and* m'_i *for all* $1 \leq i \leq l$ *and is the identity otherwise. Then* $c^* \in \mathsf{UP}($*gnd*$(KB)|_{H^+_n})$.

The proof essentially follows the same argument as Lemma 4 in (Liu et al. 2004). Note that any $c \in \mathsf{UP}(\text{gnd}(KB))$ mentions at most n names not in H^+_n. Also note that the lemma covers the special case that, if $[] \in \mathsf{UP}(\text{gnd}(KB))$ then $[] \in \mathsf{UP}(\text{gnd}(KB)|_{H^+_n})$.

Lemma 5 *Let* ϕ *be a strictly bounded objective formula with a single object variable* x*. Let* n, m *be object names not occurring in KB or* ϕ*.*
Then *gnd*$(KB), z, k \models \phi^x_n$ *iff* *gnd*$(KB), z, k \models \phi^x_m$.

The lemma is easily proved using Lemma 3. Note that this justifies that restricting substitutions of names for quantified variables (Rule 9+10) to elements of H^+_1 is correct.

Lemma 6
Suppose that *gnd*$(KB), z, k \models \phi$ *by splitting an extended primitive literal* l*. Then* *gnd*$(KB), z, k \models \phi$ *by splitting an extended primitive literal* l *in PEL*$(KB, \phi, AS(\phi)_z)|_{H^+_n}$.

Proof: Clearly, only elements of $\text{PEL}(KB, \phi, \text{AS}(\phi)_z)$ are relevant when choosing a literal for splitting. The fact that only substitution instances from H^+_n are needed can again be shown using Lemma 3. ∎

Finally, we are able to show that the beliefs of a proper knowledge base at any level can be decided by V:

Theorem 7 *gnd*$(KB), z, k \models \phi$ *iff* $V[KB, \phi, z, k] = 1$.

Proof: Given Lemma 4–6, the proof is a simple induction on k and the structure of ϕ. ∎

Given Theorem 5, we immediately obtain:

Corollary 4 *The validity problem for sentences of the form* $\boldsymbol{B}_0 KB \supset \boldsymbol{B}_k\phi$*, where KB is a proper*$^+$ *BAT,* ϕ *a strictly bounded objective sentence, and* $k \geq 0$*, is decidable.*

The result can easily be extended to the case of beliefs after a sequence of actions. For simplicity, consider a single action n. Then $\boldsymbol{B}_0 KB \supset [n]\boldsymbol{B}_k\phi$ iff $\text{gnd}(KB) \cup \{SF(n)\}, n, k \models \phi$ and $\text{gnd}(KB) \cup \{\neg SF(n)\}, n, k \models \phi$ (Corollary 3). In both cases, we obtain decidability because Theorem 7 applies.

Corollary 5 *The validity problem for sentences of the form* $\boldsymbol{B}_0 KB \supset [z]\boldsymbol{B}_k\phi$ *is decidable.*

Given the result on eventual completeness in the propositional case (Theorem 3), it is not hard to obtain a similar result for belief implications when the query is propositional.

Theorem 8 *Let KB be a proper*$^+$ *BAT and* ϕ *a propositional strictly bounded objective sentence. Then* $\models KB \supset \phi$ *iff* $\models \boldsymbol{B}_0 KB \supset \boldsymbol{B}_k\phi$ *for some* k.

Proof: (Sketch) Note that $\models \boldsymbol{B}_0 KB \supset \boldsymbol{B}_k\phi$ iff $\text{gnd}(KB{\downarrow_Z})|_{H^+_n} \models \boldsymbol{B}_k\phi$ for $Z = \text{AS}(\phi)$ (by Theorem 6,7). Moreover, $\text{gnd}(KB{\downarrow_Z})|_{H^+_n}$ is finite. By an argument very similar to the proof of Theorem 3 one can show that, provided $\models KB \supset \phi$, $\text{gnd}(KB \downarrow_Z)|_{H^+_n} \models \boldsymbol{B}_k\phi$ holds where k is the size of $\text{PEL}(\text{gnd}(KB{\downarrow_Z})|_{H^+_n}, \phi, Z)$. ∎
We can even generalize the theorem to universal queries of the form $\forall\vec{x}.\phi$ where ϕ mentions no quantifiers. Here we only consider the case of a single universal quantifier:

Corollary 6
$\models KB \supset \forall x.\phi$ *iff* $\models \boldsymbol{B}_0 KB \supset \boldsymbol{B}_k \forall x.\phi$ *for some* k.

Proof: $\models \boldsymbol{B}_0 KB \supset \boldsymbol{B}_k \forall x\phi$ iff $\models \boldsymbol{B}_0 KB \supset \forall x.\boldsymbol{B}_k\phi$ iff $\models \boldsymbol{B}_0 KB \supset \boldsymbol{B}_k\phi^x_n$ for all n mentioned in *KB* and ϕ plus one new name (using Lemma 5). Now apply the theorem for each such n and choose k to be the largest among all of them. ∎

Conclusions

In this paper we extended ideas of limited belief, which were first explored by Liu et al. (2004) for static knowledge bases, to the dynamic case. By modifying the split rule considered by Liu et al. we were able to substantially extend results on eventual completeness. Moreover, for proper$^+$ knowledge bases which encode Reiter-style basic action theories and strictly bounded queries we showed decidability.

In (Lakemeyer and Levesque 2013), we considered decidable reasoning with nested beliefs and unknown individuals, but only in the static case. We believe that these results carry over to the dynamic setting without much difficulty.

Furthermore, it is not hard to generalize our results to bounded queries that may contain action variables. For example, we could then ask whether $\exists a_1 \exists a_2 [a_1][a_2]\phi$ is believed at some level k. Hence, with bounded queries we are able to express a form of bounded planning problems. Allowing $\Box$ within a query is much more problematic, as $\Box\phi$ expresses a state constraint about ϕ holding after any sequence of actions. Handling $\Box$ as part of a query is problematic for reasons similar to those that make it essential that proper$^+$ *KB*s are restricted to those representing basic action theories. In fact, we conjecture that answering queries involving $\Box$ is undecidable even for limited belief.

Finally, a possible extension we would like to consider in the future is to allow for action functions like *pickup*(x). These are clearly desirable when constructing a basic action theory for a given domain. The main question will be how to achieve this without losing decidability.

A First-Order Semantics for Golog and ConGolog under a Second-Order Induction Axiom for Situations

Fangzhen Lin

Abstract

Golog and ConGolog are languages defined in the situation calculus for cognitive robotics. Given a Golog program δ, its semantics is defined by a macro $Do(\delta, s, s')$ that expands to a logical sentence that captures the conditions under which performing δ in s can terminate in s'. A similar macro is defined for ConGolog programs. In general, the logical sentences that these macros expand to are second-order, and in the case of ConGolog, may involve quantification over programs. In this paper, we show that by making use of the foundational axioms in the situation calculus, in particular, the second-order closure axiom about the space of situations, these macro expressions can actually be defined using first-order sentences.

Introduction

Golog (Levesque et al. 1997) and ConGolog (De Giacomo, Lespérance, and Levesque 2000) are Algol-like programming languages defined in the situation calculus (McCarthy 1968; Reiter 2001). They are intended for high-level control of agents, including both physical robots and virtual agents (Reiter 2001; Burgard et al. 1999; Funge 2000; Lespérance, Levesque, and Ruman 1997; McIlraith and Son 2002). They include non-determinism, and in the case of ConGolog, concurrency.

The semantics of Golog programs is axiomatized in logic by macro expansions (Levesque et al. 1997): given a Golog program δ and two situation terms s and s', the macro expression $Do(\delta, s, s')$ is used to denote that s' is a terminating situation of performing δ in s. There may be more than one possible terminating situation as the program may be indeterminate. In general, the macro expression $Do(\delta, s, s')$ expands into a second-order sentence because δ may have loops. In the case of ConGolog programs, which are extensions of Golog programs with some concurrency operators, De Giacomo, Lespérance and Levesque (2000) introduced a one-step transition predicate $Trans(\delta, s, \delta', s')$ (performing δ in s for one step may end up in situation s' with δ' as the remaining program to be performed) and a final predicate $Final(\delta, s)$ (program δ terminates in s). The Do macros are then defined using these predicates, and in general expand to sentences that are not only second-order, but also involve quantification over programs.

The second-order formulas that are needed in Golog and ConGolog macro expansions are fundamentally the same as the ones for defining transitive closures. One of the foundational axioms of the situation calculus is a second-order one that defines the space of situations as the transitive closure of $do(a, s)$ starting at the initial situation S_0. In this paper, we show that this second-order foundational axiom can be used to capture loops and recursions so that for Golog and ConGolog programs, the macro expression $Do(\delta, s, s')$ can in fact be defined using first-order sentences.

The situation calculus

We first briefly review the situation calculus used for Golog and ConGolog. For more details, see (Reiter 2001; Lin 2007). The language of the situation calculus is a many-sorted one with sorts $action$ for actions, $situation$ for situations, and other domain dependent ones. There is a constant S_0 of sort $situation$, and a function $do : action \times situation \rightarrow situation$.

The foundational axioms say that the set of situations consists exactly of those that can be constructed from S_0 using function $do(a, s)$ (we assume that variables in displayed formulas are universally quantified from outside):

$$S_0 \neq do(a, s), \tag{1}$$

$$do(a_1, s_1) = do(a_2, s_2) \supset a_1 = a_2 \wedge s_1 = s_2, \tag{2}$$

$$\forall P.[P(S_0) \wedge \forall a, s(P(s) \supset P(do(a, s)))] \supset \forall s P(s), \tag{3}$$

The first two axioms are unique names axioms, and the third one a second-order induction axiom. Given a sequence $[a_1, ..., a_n]$ of actions, we use $do([a_1, ..., a_n], s)$ to denote the situation resulting from doing the sequence of actions in s: $do(a_n, ..., do(a_1, s)...)$. Using this notation, we can understand the foundational axioms as saying that s is a situation iff there is a sequence α of actions such that $s = do(\alpha, S_0)$.

With these axioms, one can define other relations inductively on situations (Reiter 1993; Lin and Reiter 1994). The following axioms define a partial order $\leq$ on situations:

$$\neg s < S_0,$$
$$s < do(a, s') \equiv s = s' \vee s < s',$$
$$s \leq s' \equiv s < s' \vee s = s'.$$

Again in terms of sequences of actions, we can see that $s \leq s'$ iff there is a sequence α of actions such that $s' = do(\alpha, s)$.

In the following, we denote by Σ the set of foundational axioms as well as the above axioms for $<$.

Golog

In this section, we briefly review the definitions of Golog programs and their semantics as defined in (Levesque et al. 1997). Golog programs are complex actions and procedures. Complex actions are defined inductively as follows:

$$\begin{array}{rcl}\delta & ::= & A \mid \varphi? \mid \delta;\delta \mid \\ & & (\delta \mid \delta) \mid (\pi x)\delta \mid \delta^*\end{array}$$

where A is a primitive action, φ is a pseudo-situation calculus formula with all situation arguments suppressed. In (Levesque et al. 1997), the semantics of a complex action δ is defined by a macro $Do(\delta, s, s')$ that expands to a situation calculus formula that says that s' is a terminating situation of performing δ in s. Formally, this macro expansion is defined inductively as follows:

$$\begin{array}{l}Do(A, s, s') \stackrel{def}{=} Poss(A, s) \wedge s' = do(A, s),\\ Do(\varphi?, s, s') \stackrel{def}{=} s' = s \wedge \varphi[s],\\ Do(\delta_1;\delta_2, s, s') \stackrel{def}{=} \exists s''.Do(\delta_1, s, s'') \wedge Do(\delta_2, s'', s'),\\ Do(\delta_1 \mid \delta_2, s, s') \stackrel{def}{=} Do(\delta_1, s, s') \vee Do(\delta_2, s, s'),\\ Do((\pi x)\delta(x), s, s') \stackrel{def}{=} \exists x.Do(\delta(x), s, s'),\\ Do(\delta^*, s, s') \stackrel{def}{=} \forall P.[\forall s_1 P(s_1, s_1) \wedge\\ \quad \forall s_1, s_2, s_3(Do(\delta, s_1, s_2) \wedge P(s_2, s_3) \supset P(s_1, s_3))]\\ \qquad \supset P(s, s'),\end{array}$$

where A is a primitive action, $Poss(A, s)$ the action precondition predicate, and $\varphi[s]$ the result of restoring s as the situation argument to the fluents in φ.

As we mentioned, the macro $Do(\delta, s, s')$ expands into a formula that is in general second-order. With nested iterations, the formula can get rather complicated. Consider the following complex action $g = (\pi x)(A(x) \mid (\pi x)B(x)^*)^*$. Let $g_1 = (A(x) \mid (\pi x)B(x)^*)^*$, $g_2 = A(x) \mid (\pi x)B(x)^*$, $g_3 = (\pi x)B(x)^*$, and $g_4 = B(x)^*$. Then

$$\begin{array}{l}Do(g, s, s') \stackrel{def}{=} \exists x.Do(g_1, s, s'),\\ Do(g_1, s, s') \stackrel{def}{=} \forall P.\{\forall s_1 P(s_1, s_1) \wedge\\ \quad \forall s_1, s_2, s_3(P(s_1, s_2) \wedge Do(g_2, s_2, s_3) \supset P(s_1, s_3))\}\\ \qquad \supset P(s, s'),\\ Do(g_2, s, s') \stackrel{def}{=} Do(A(x), s, s') \vee Do(g_3, s, s'),\\ Do(A(x), s, s') \stackrel{def}{=} Poss(A(x), s) \wedge s' = do(A(x), s),\\ Do(g_3, s, s') \stackrel{def}{=} \exists x.Do(g_4, s, s'),\\ Do(g_4, s, s') \stackrel{def}{=} \forall P.\{\forall s_1 P(s_1, s_1) \wedge\\ \quad \forall s_1, s_2, s_3(P(s_1, s_2) \wedge Do(B(x), s_2, s_3) \supset P(s_1, s_3))\}\\ \qquad \supset P(s, s'),\\ Do(B(x), s, s') \stackrel{def}{=} Poss(B(x), s) \wedge s' = do(B(x), s).\end{array}$$

As one can see, when fully expanded, $Do(g, s, s')$ is a second-order sentence with nested second-order quantification.

Golog Do macro - a first-order definition

We now show that given that we already have a second-order induction axiom for situations, the macros can actually be defined in first-order terms.

Obviously, the question is how to expand $Do(\delta^*, s, s')$. The second-order sentence in the previous section defines it to be the transitive closure of $Do(\delta, s, s')$. If we introduce a new predicate denoting this transitive closure, then it can be defined inductively just like $<$:

$$Do(\delta^*, s, s') \stackrel{def}{=} P_\delta(\vec{x}, s, s'), \quad (4)$$

$$\begin{array}{l}P_\delta(\vec{x}, s, s') \equiv s = s' \vee\\ \quad \exists s''.s < s'' \leq s' \wedge Do(\delta, s, s'') \wedge P_\delta(\vec{x}, s'', s'),\end{array} \quad (5)$$

where P_δ a new predicate, and $\vec{x}$ the tuple of free variables in δ. Notice that $P_\delta(\vec{x}, s, s')$ is recursive on $P_\delta(\vec{x}, s'', s')$ for s'' such that $s < s'' \leq s'$, making it well-defined according to the "distance" between s and s'.

Our proposal is then to replace the macro definition of $Do(\delta^*, s, s')$ in the previous section by (4) and add the axiom (5) whenever the macro is expanded (see Theorem 1 below).

As an example, consider again the complex action g given above. We have

$$\begin{array}{l}Do(g, s, s') \stackrel{def}{=} \exists x.Do(g_1, s, s'),\\ Do(g_1, s, s') \stackrel{def}{=} P_{g_2}(x, s, s'),\\ P_{g_2}(x, s, s') \equiv s = s' \vee\\ \quad \exists s''.s < s'' \leq s' \wedge Do(g_2, s, s'') \wedge P_{g_2}(x, s'', s'),\\ Do(g_2, s, s') \stackrel{def}{=} Do(A(x), s, s') \vee Do(g_3, s, s'),\\ Do(A(x), s, s') \stackrel{def}{=} Poss(A(x), s) \wedge s' = do(A(x), s),\\ Do(g_3, s, s') \stackrel{def}{=} \exists x.Do(g_4, s, s'),\\ Do(g_4, s, s') \stackrel{def}{=} P_{B(x)}(x, s, s'),\\ P_{B(x)}(x, s, s') \equiv s = s' \vee\\ \quad \exists s''.s < s'' \leq s' \wedge Do(B(x), s, s'') \wedge P_{B(x)}(x, s'', s'),\\ Do(B(x), s, s') \stackrel{def}{=} Poss(B(x), s) \wedge s' = do(B(x), s).\end{array}$$

Thus the axioms about the two extra predicates are

$$\begin{array}{l}P_{g_2}(x, s, s') \equiv s = s' \vee\\ \quad \exists s''\{s < s'' \leq s' \wedge P_{g_2}(x, s'', s') \wedge\\ \quad [Poss(A(x), s) \wedge s'' = do(A(x), s)] \vee \exists x.P_{B(x)}(x, s, s'')\},\\ P_{B(x)}(x, s, s') \equiv s = s' \vee\\ \quad \exists s''.s < s'' \leq s' \wedge P_{B(x)}(x, s'', s') \wedge\\ \quad [Poss(B(x), s) \wedge s'' = do(B(x), s)].\end{array}$$

To illustrate how to reason with these axioms, suppose there are two objects a and b, and that $Poss(A(a), S_0)$ and $Poss(B(b), do(A(a), S_0))$ hold. We show that

$$Do(g, S_0, do(B(b), do(A(a), S_0)))$$

holds. It is easy to see that this follows from

$$\exists x.P_{g_2}(x, S_0, S_2),$$

where $S_2 = do(B(b), S_1)$ and $S_1 = do(A(a), S_0)$. This follows from

$$Poss(A(a), S_0) \wedge P_{g_2}(a, S_1, S_2).$$

The first conjunct is assumed to be true. The second conjunct follows from

$$\exists x.P_{B(x)}(x, S_1, S_2).$$

This is proved by showing $P_{B(x)}(b, S_1, S_2)$, which follows from

$$Do(B(b), S_1, S_2),$$

which is true because $Poss(B(b), S_1)$ is assumed to be true.

Now suppose that there is another primitive action $C(x)$. Furthermore, assume the unique names axioms for actions, $C(x) \neq A(y) \neq B(z)$. Then we can show that $Do(g, S_0, do(C(a), S_0))$ does not hold:

$$\neg Do(g, S_0, S_3),$$

where $S_3 = do(C(a), S_0)$, follows from

$$\forall x.\neg P_{g_2}(x, S_0, S_3),$$

which is equivalent to

$$\forall x \forall s.\neg\{S_0 < s \leq S_3 \wedge P_{g_2}(x, s, S_3) \wedge$$
$$[Poss(A(x), S_0) \wedge s = do(A(x), S_0)] \vee \exists x.P_{B(x)}(x, S_0, s)\}$$

which is equivalent to

$$\forall x \forall s.S_0 < s \leq S_3 \supset$$
$$[\neg[Poss(A(x), S_0) \wedge s = do(A(x), S_0)] \wedge$$
$$\neg\exists x.P_{B(x)}(x, S_0, s)]\}.$$

Because S_3 is the only s that can make $S_0 < s \leq S_3$ true, thus the above assertion is equivalent to

$$\forall x.\neg[Poss(A(x), S_0) \wedge S_3 = do(A(x), S_0)] \wedge$$
$$\neg\exists x.P_{B(x)}(x, S_0, S_3).$$

But $S_3 \neq do(A(x), S_0)$ for any x, thus the above assertion is equivalent to

$$\forall x.\neg P_{B(x)}(x, S_0, S_3),$$

which is equivalent to

$$\forall x.\neg[Poss(B(x), S_0) \wedge S_3 = do(B(x), S_0)],$$

which is equivalent to

$$\forall x.S_3 \neq do(B(x), S_0),$$

which is always true as $S_3 = do(C(a), S_0)$.

The following result is not hard to prove.

Theorem 1 *Let $Do1(\delta, s, s')$ be the macro operator defined in (Levesque et al. 1997) (given in the previous section), and $Do2(\delta, s, s')$ the modification to $Do1$ as described above. For any Golog complex action δ, we have that*

$$\Sigma \cup T_\delta \models \forall \vec{x}, s, s'.Do1(\delta, s, s') \equiv Do2(\delta, s, s'),$$

where $\vec{x}$ is the tuple of free variables in δ, and T_δ is the set of axioms about P_{δ_1} for any δ_1 such that δ_1^* occurs in δ.

Notice that for a program like

$$\delta = [A(a)]^*; [(\pi x)A(x)]^*; (\pi x)A(x)^*,$$

T_δ would contain axioms about $P_{A(a)}(s, s')$, $P_{(\pi x)A(x)}(s, s')$, and $P_{A(x)}(x, s, s')$.

Procedures

Golog programs can have recursively defined procedures in the following form (Levesque et al. 1997):

proc $P_1(\vec{v}_1)\delta_1$ **endProc** ; ...; **proc** $P_n(\vec{v}_n)\delta_n$ **endProc** ; δ_0.

Here P_i, $1 \leq i \leq n$, are procedures, and δ_0 is the main program. The procedure bodies and the main program δ_i, $0 \leq i \leq n$, are complex actions, extended by procedure calls. In the main program δ_0, a procedure call $P_i(\vec{t}_i)$ is treated like an action:

$$Do(P_i(\vec{t}_i), s, s') \stackrel{def}{=} P_i(\vec{t}_i[s], s, s'),$$

where $P_i(\vec{v}_i, s, s')$ is a new predicate for the procedure P_i, and $\vec{t}_i[s]$, like $\varphi[s]$, is the tuple of terms obtained by restoring s as the situation arguments in the functional fluents occurring in $\vec{t}_i$. As discussed in (Levesque et al. 1997), this amounts to call by value. These new predicates are defined by second-order sentences in (Levesque et al. 1997) to capture least fixed-point semantics of recursive procedures. Here we axiomatize these predicates using first-order axioms, with the help of some additional new predicates: For each $P_i(\vec{v}_i, s, s')$, we introduce a new one with the same name but with one more situation argument $P_i(\vec{v}_i, s, s', s'')$. Intuitively, the extra argument s'' records the number of times that the procedures have been activated. More precisely, $P_i(\vec{v}_i, s, s', s'')$ holds if in the initial situation s, the procedure P_i can return and yields the new situation s' with at most $|s''|$ number of activations for all procedures, where $|s''|$ is the number of actions in the sequence α such that $s'' = do(\alpha, S_0)$. Thus we have the following axioms:

$$P_i(\vec{v}_i, s, s') \equiv \exists s''.P_i(\vec{v}_i, s, s', s''), \quad (6)$$
$$\neg P_i(\vec{v}_i, s, s', S_0), \quad (7)$$
$$P_i(\vec{v}_i, s, s', do(a, s'')) \equiv Do(\delta_i[s''], s, s'), \quad (8)$$
$$Do(P_i(\vec{t}_i, s''), s, s') \stackrel{def}{=} P_i(\vec{t}_i[s], s, s', s''), \quad (9)$$

where $\delta_i[s'']$ is the result of replacing every procedure call of the form $P_j(\vec{t}_j)$ in δ_i by the call $P_j(\vec{t}_j, s'')$.

Consider the following program in the blocks world from (Levesque et al. 1997) ($maketower(n)$ makes a tower of n blocks; $tower(x, m)$ is true if there is a tower of m blocks whose top one is x; $stack(x, n)$ places n blocks on the tower whose top one is x; $unstack(x, n)$ removes n blocks from the tower whose top is x):

proc $maketower(n)$
  $(\pi x, m)[tower(x, m)?;$
  if $m \leq n$ **then** $stack(x, n - m)$
    else $unstack(x, m - n)$
  endIf]
endProc;

proc $stack(x, n)$
  $n = 0? \mid (\pi y)[put(y, x); stack(y, n - 1)]$
endProc;

proc $unstack(x, n)$

$n = 0? \mid (\pi y)[on(x, y)?; movetotable(x);$
$unstack(y, n-1)]$

endProc;

$maketower(7); \neg(\exists x) on(x, A)?$

We have the following axioms for $maketower(n, s, s')$, $stack(x, n, s, s')$, and $unstack(x, n, s, s')$:

$maketower(n, s, s') \equiv \exists s_1.maketower(n, s, s', s_1),$
$stack(x, n, s, s') \equiv \exists s_1.stack(x, n, s, s', s_1),$
$unstack(x, n, s, s') \equiv \exists s_1.unstack(x, n, s, s', s_1),$
$\neg maketower(n, s, s', S_0),$
$maketower(n, s, s', do(a, s_1)) \equiv \exists x, m.[tower(x, m, s) \wedge$
$m \leq n \supset stack(x, n-m, s, s', s_1) \wedge$
$m > n \supset unstack(x, m-n, s, s', s_1)],$
$\neg stack(x, n, s, s', S_0),$
$stack(x, n, s, s', do(a, s_1)) \equiv (n = 0 \wedge s = s') \vee$
$\exists y, s''.s'' = do(put(y, x), s) \wedge stack(y, n-1, s'', s', s_1),$
$\neg unstack(x, n, s, s', S_0),$
$unstack(x, n, s, s', do(a, s_1)) \equiv (n = 0 \wedge s = s') \vee$
$[\exists y, s''.on(x, y, s) \wedge s'' = do(movetotable(x), s) \wedge$
$unstack(y, n-1, s'', s', s_1)].$

To see how our approach handles cycles, consider the following cyclic procedure:

proc P $\{P\}$ **endProc**
P

Clearly, the call P would never terminate. Our axioms for P are:

$P(s, s') \equiv \exists s_1.P(s, s', s_1),$
$\neg P(s, s', S_0),$
$P(s, s', do(a, s_1)) \equiv P(s, s', s_1)$

By induction using the foundational axioms, it is easy to see that these axioms entail $\forall s, s', s_1.\neg P(s, s', s_1)$, thus $\forall s, s'.\neg P(s, s')$.

Again the following result is not hard to see.

Theorem 2 *Given a Golog program below*

proc $P_1(\vec{v}_1)\delta_1$ **endProc** ; ...; **proc** $P_n(\vec{v}_n)\delta_n$ **endProc** ; δ_0

we have that

$$\Sigma \cup T_{\delta_0} \models \forall \vec{x}, s, s'.Do1(\delta_0, s, s') \equiv Do2(\delta_0, s, s'),$$

where $\vec{x}$ is the tuple of free variables in δ, $Do1(\delta_0, s, s')$ and $Do2(\delta_0, s, s')$ the macro operators defined in (Levesque et al. 1997) and this paper, respectively, and T_{δ_0} the set of axioms about the new predicates introduced in defining $Do2$, including those for P_δ for each δ such that δ^* occurs in some δ_i, $0 \leq i \leq n$, and (6) - (9) for each P_i.

Concurrent processes

ConGolog (De Giacomo, Lespérance, and Levesque 2000) extends Golog by adding some concurrency operators that allows two programs to be executed concurrently. Instead of the Do macro, the main construct is a transition predicate $Trans(\delta, s, \delta', s')$ which says one way to do δ in s is to perform a primitive or a testing action that will lead to situation s' with δ' as the remaining program to be executed. For example, $Trans(a; b, s, b, do(a, s))$ holds because performing the sequence $a; b$ in s will result in performing a, which leads to $do(a, s)$ with b as the remaining program to do.

In (De Giacomo, Lespérance, and Levesque 2000), the axiomatization of $Trans$ requires programs be reified and quantified over. For instance, the axiom for sequence is

$$Trans(\delta_1; \delta_2, s, \delta', s') \equiv$$
$$\exists \gamma.\delta' = (\gamma; \delta_2) \wedge Trans(\delta_1, s, \gamma, s') \vee$$
$$Final(\delta_1, s) \wedge Trans(\delta_2, s, \delta', s'),$$

where $Final(\delta, s)$ is a predicate which says that δ has finished in s.

Using $Trans$, and by quantifying over programs, Do is then defined as

$$Do(\delta, s, s') \stackrel{def}{=} \exists \delta'.Trans^*(\delta, s, \delta', s') \wedge Final(\delta', s'),$$

where $Trans^*$ is the transitive closure of $Trans$.

Here we show that even for concurrent processes, the Do macro can be defined using first-order axioms only, and without having to reify and quantify over programs.

Consider concurrent execution by interleaving $\delta_1 \parallel \delta_2$. Executing this program in s can result in s' if there is a sequence of primitive actions, some from δ_1 and the rest from δ_2, that can be executed in s to yield s'. For example, there are six possible ways to interleave $(P?; A)$ and $(B; A)$, resulting in the following four possible sequences of primitive and test actions:

$$(P?; A; B; A), (P?; B; A; A), (B; A; P?; A), (B; P?; A; A).$$

If we ignore the test actions, as they do not result in changes of situations, we then get two possible sequences of primitive actions: $[A, B, A]$ and $[B, A, A]$. Notice that these are *possible* interleavings. Not all of them may come to fruit. For example, $P?$ may not be true initially, thus cannot be performed as the first action.

If we are told that $[A, B, A]$ is the actual sequence of actions performed, then we know that the first action A must come from the process $(P?; A)$, and the last from $(B; A)$. However, if $[B, A, A]$ is the actual sequence, then for the two A's in the sequence, we do not know from which process each of them come.

To keep track of which action comes from which process in a sequence of primitive actions, we introduce two special primitive actions Y (for yes), and N (for no). Situations consisting of only these two actions are called "schedules':

$sch(S_0),$
$sch(do(a, s)) \equiv sch(s) \wedge (a = Y \vee a = N).$

For example, the schedule $do(Y, do(N, do(Y, do(Y, S_0))))$ $(do([Y, Y, N, Y], S_0))$ tells a process to first execute two actions, then wait for the other process to execute one action,

then execute one more action. Referring back to our earlier example, if we know that $[B, A, A]$ is the actual sequence, then for process $(P?; A)$, there can be only two possible schedules: $do([N, Y, N], S_0)$ or $do([N, N, Y], S_0)$. The first implies that the first A in the sequence $[B; A; A]$ comes from the process, and the second that the second A in the sequence comes from it. Notice that our "schedule situations" only tell when to execute primitive actions while ignore test actions. For process $(P?; A)$ to be successfully executed, we know that P must be tested and succeeded sometime before A is executed, but we do not care exactly when it was actually tested.

These special schedule situations will be used to model possible interleavings. Before we proceed, we first introduce some useful operators about situations:

- We say that two situations are of equal length, written $el(s, s')$, if the number of actions in s is the same as that in s':

$$el(S_0, S_0),$$
$$\neg el(do(a, s), S_0),$$
$$el(do(a, s), do(b, s')) \equiv el(s, s').$$

- We say one schedule s_1 is earlier than s_2, written $earlier(s_1, s_2)$, if at least one action is scheduled earlier in s_1:

$$earlier(s_1, s_2) \equiv \exists s_3.do(Y, s_3) \leq s_1 \wedge do(N, s_3) \leq s_2.$$

- A schedule can be split into two: $split(s, s_1, s_2)$ holds if for any action, it is scheduled to be performed in s iff it is scheduled to be performed either in s_1 or s_2, but not both:

$$split(S_0, S_0, S_0),$$
$$split(do(N, s), s_1, s_2) \equiv \exists s_3, s_4.split(s, s_3, s_4) \wedge$$
$$s_1 = do(N, s_3) \wedge s_2 = do(N, s_4),$$
$$split(do(Y, s), s_1, s_2) \equiv \exists s_3, s_4.split(s, s_3, s_4) \wedge$$
$$[(s_1 = do(Y, s_3) \wedge s_2 = do(N, s_4)) \vee$$
$$(s_1 = do(N, s_3) \wedge s_2 = do(Y, s_4))].$$

  It is easy to see that splitting preserves the length of the schedule:

$$sch(s) \wedge split(s, s_1, s_2) \supset el(s, s_1) \wedge el(s, s_2).$$

- We have two special schedules: $Full(s, s')$ if the schedule from s to s' is full (all "Y"), and $Empty(s, s')$ if the schedule from s to s' is empty (all "N"):

$$Full(s, s') \equiv \forall a, s_1(s < do(a, s_1) \leq s' \supset a = Y),$$
$$Empty(s, s') \equiv \forall a, s_1(s < do(a, s_1) \leq s' \supset a = N).$$

  Notice that $Full(s, s)$ and $Empty(s, s)$ are always true.

ConGolog has three main concurrency operators: $\delta_1 \parallel \delta_2$ (execute δ_1 and δ_2 concurrently by interleaving), $\delta_1 \gg \delta_2$ (interleaving δ_1 and δ_2 with priority to δ_1), and $\delta^{\parallel}$ (interleave δ any number of times).

The prioritized concurrency $\delta_1 \gg \delta_2$ needs special attention. Consider

$$((A; fail?) \mid B) \gg C.$$

Suppose that initially both A and C are executable, but B is not. Suppose further that if C is executed, then B becomes executable. According to the semantics in (De Giacomo, Lespérance, and Levesque 2000), the above program cannot be executed as $((A; fail?) \mid B)$ has priority, so its first action, which is A, is executed. But once A is executed, it is at a dead end. In this view, if a process has priority, then its first executable action is performed, regardless whether executing that action can lead to a successful execution of this process. However, if we insist on only executing actions that can lead to termination, then the process with lower priority, C, would be executed first as the process with higher priority cannot be executed. After C is performed, B from the other process can then be executed.

Which interpretation is more appropriate depends on the applications. We'll axiomatize both. In our framework, it is easier to axiomatize the latter, so we do it first.

Using schedule situations, we extend the Do macro to concurrency as follows: $Do(\delta, s, s')$ if with a full schedule, executing δ in s can lead to s':

$$Do(\delta, s, s') \stackrel{def}{=} \exists s_1.Full(S_0, s_1) \wedge el(s', s_1) \wedge Do(\delta, s, s', s_1), \tag{10}$$

where $Do(\delta, s, s', s_1)$ is a new macro meaning that executing the sequence of actions from s to s' according to schedule s_1 is a valid way to execute δ in s:

$$Do(A, s, s', s_1) \stackrel{def}{=} \exists s_2, s_3, s''.s < do(A, s'') \leq s' \wedge$$
$$s_2 < do(Y, s_3) \leq s_1 \wedge el(s, s_2) \wedge el(s'', s_3) \wedge$$
$$Empty(s_2, s_3) \wedge Empty(do(Y, s_3), s_1) \wedge Poss(A, s''),$$

$$Do(\varphi?, s, s', s_1) \stackrel{def}{=} \exists s_2, s''.s \leq s'' \leq s' \wedge$$
$$s_2 \leq s_1 \wedge el(s, s_2) \wedge Empty(s_2, s_1) \wedge \varphi[s''],$$

$$Do(\delta_1; \delta_2, s, s', s_1) \stackrel{def}{=} \exists s''.s_2.s_2 \leq s_1 \wedge el(s_2, s'') \wedge$$
$$Do(\delta_1, s, s'', s_2) \wedge Do(\delta_2, s'', s', s_1),$$

$$Do(\delta_1 \mid \delta_2, s, s', s_1) \stackrel{def}{=}$$
$$Do(\delta_1, s, s', s_1) \vee Do(\delta_2, s, s', s_1),$$

$$Do((\pi x)\delta(x), s, s', s_1) \stackrel{def}{=} \exists x.Do(\delta(x), s, s', s_1),$$

$$Do(\delta(\vec{x})^*, s, s', s_1) \stackrel{def}{=} P_\delta(\vec{x}, s, s', s_1),$$
$$P_\delta(\vec{x}, s, s', s_1) \equiv s = s' \vee$$
$$\exists s''.s_2.s < s'' \leq s' \wedge s_2 \leq s_1 \wedge el(s_2, s'') \wedge$$
$$Do(\delta, s, s'', s_2) \wedge P_\delta(\vec{x}, s'', s', s_1),$$

$$Do(\delta_1 \parallel \delta_2, s, s', s_1) \stackrel{def}{=} \exists s_2, s_3.split(s_1, s_2, s_3) \wedge$$
$$Do(\delta_1, s, s', s_2) \wedge Do(\delta_2, s, s', s_3),$$

$$Do(\delta_1 \gg \delta_2, s, s', s_1) \stackrel{def}{=} \exists s_2, s_3\{split(s_1, s_2, s_3) \wedge$$
$$Do(\delta_1, s, s', s_2) \wedge Do(\delta_2, s, s', s_3) \wedge$$
$$\neg\exists s_4, s_5, s_6, s''[split(s_1, s_4, s_5) \wedge earlier(s_4, s_2) \wedge$$
$$s_6 < s_4 \wedge s_6 < s_2 \wedge el(s_6, s) \wedge Do(\delta_1, s, s'', s_4)]\},$$

$$Do(\delta(\vec{x})^{\parallel}, s, s', s_1) \stackrel{def}{=} s = s' \vee P_\delta^{\parallel}(\vec{x}, s, s', s_1),$$
$$\exists s_2(s_2 \leq s_1 \wedge el(s, s_2) \wedge Empty(s_2, s_1)) \supset$$
$$P_\delta^{\parallel}(\vec{x}, s, s', s_1),$$

$$\neg\exists s_2(s_2 \leq s_1 \wedge el(s, s_2) \wedge Empty(s_2, s_1)) \supset$$
$$[P_\delta^{\|}(\vec{x}, s, s', s_1) \equiv$$
$$\exists s_2, s_3.split(s_1, s_2, s_3) \wedge s_1 \neq s_2 \wedge P_\delta^{\|}(\vec{x}, s, s', s_2) \wedge$$
$$Do(\delta(\vec{x}), s, s', s_3)].$$

Notice that for $Do(\delta, s, s', s_1)$ to make sense, the length of the terminating situation s' should be the same as the length of the schedule s_1, and only the segment of the schedule from s to s' is relevant. Thus, for example,

$$Do(\delta, do(a, S_0), do(b, do(a, S_0)), do(Y, do(N, S_0)))$$

holds iff

$$Do(\delta, do(a, S_0), do(b, do(a, S_0)), do(Y, do(Y, S_0)))$$

holds as the two schedules are the same as far as the last action is concerned. We explain the first two definitions in more details below:

- For a primitive action A, $Do(A, s, s', s_1)$ holds if the schedule s_1 has exactly one occurrence of "Y", and at that point, the corresponding action in s' is A. Reformatted in terms of sequences of actions, the definition says that $Do(A, s, s', s_1)$ holds if for some sequences of actions α, γ, β_i, and γ_i, $i = 1, 2$, we have:
$$s = do(\alpha, S_0),$$
$$s' = do(\beta_1, do(A, do(\beta_2, s))),$$
$$s_1 = do(\gamma_1, do(Y, do(\gamma_2, do(\gamma, S_0)))),$$
$$|\alpha| = |\gamma|,$$
$$|\beta_i| = |\gamma_i|, i = 1, 2,$$
$$a \in \gamma_i \supset a = N, i = 1, 2.$$

- For a test action, $Do(\varphi?, s, s', s_1)$ holds if the schedule s_1 is empty, and φ is true somewhere between s and s'. Again, it is easier to understand in terms of sequences of actions. The definition says that $Do(\varphi, s, s', s_1)$ holds if for some sequences of actions α, β, and γ, we have:
$$\exists s''.s \leq s'' \leq s' \wedge \varphi[s''],$$
$$s = do(\alpha, S_0),$$
$$s_1 = do(\gamma, do(\beta, S_0)),$$
$$|\alpha| = |\beta|,$$
$$a \in \gamma \supset a = N.$$

As an example, consider again the following prioritized concurrent program:

$$\delta = ((A; fail?) \mid B) \gg C,$$

where A, B, and C are primitive actions, and $fail$ is a fluent that is never true. Suppose that $Poss(A, S_0)$, $\neg Poss(B, S_0)$, $Poss(C, S_0)$, and $Poss(B, do(C, S_0))$. We show that

$$Do(\delta, S_0, do(B, do(C, S_0))).$$

We need to prove

$$Do(\delta, S_0, do(B, do(C, S_0)), do(Y, do(Y, S_0))).$$

Let $\delta_1 = (A; fail?) \mid B$. The above assertion follows from the following three assertions:

$$Do(\delta_1, S_0, do(B, do(C, S_0)), do(Y, do(N, S_0))), \quad (11)$$
$$Do(C, S_0, do(B, do(C, S_0)), do(N, do(Y, S_0))), \quad (12)$$
$$\neg\exists s_1, s_2, s.split(do(Y, do(Y, S_0)), s_1, s_2) \wedge$$
$$earlier(s_1, do(Y, do(N, S_0))) \wedge Do(\delta_1, S_0, s, s_1). \quad (13)$$

The first assertion (11) follows from

$$Do(B, S_0, do(B, do(C, S_0)), do(Y, do(N, S_0))),$$

which follows from the following facts:

$$el(S_0, S_0),$$
$$el(do(C, S_0), do(N, S_0)),$$
$$Empty(S_0, do(N, S_0)),$$
$$Empty(do(Y, do(N, S_0)), do(Y, do(N, S_0))),$$
$$Poss(B, do(C, S_0)).$$

The second assertion (12) follows easily from the following facts:

$$el(S_0, S_0),$$
$$Empty(S_0, S_0),$$
$$Empty(do(Y, S_0), do(N, do(Y, S_0))),$$
$$Poss(C, S_0).$$

For the last assertion (13), notice first that for

$$split(do(Y, do(Y, S_0)), s_1, s_2) \wedge earlier(s_1, do(Y, do(N, S_0)))$$

to be true, s_1 must be either $do(Y, do(Y, S_0))$ or $do(N, do(Y, S_0))$. But in either case, there is no s such that $Do(\delta_1, S_0, s, s_1)$ can be true.

Notice that under ConGolog's semantics (De Giacomo, Lespérance, and Levesque 2000), there is no s such that $Do(\delta, S_0, s)$ can be true. This shows that our treatment of the prioritized concurrency operator $\gg$ is different from the one in ConGolog (De Giacomo, Lespérance, and Levesque 2000). If we ignore operator $\gg$, then our semantics is equivalent to the one in (De Giacomo, Lespérance, and Levesque 2000). Before we prove this, we first prove some formal properties about our axiomatization.

We mentioned that in $Do(\delta, s, s', s_1)$, only the part of the schedule between s and s' matters. We now make this precise.

We say that two situations s_1 and s_2 are the same between s and s', written $eq(s_1, s_2, s, s')$, if there are sequences $\alpha_1, \alpha_2, \alpha_3, \alpha_4$ of actions such that

- $s' = do(\alpha_1, s)$,
- $s_1 = do(\alpha_3, do(\alpha_2, s_3))$ and $s_2 = do(\alpha_4, do(\alpha_2, s_4))$,
- $|\alpha_1| = |\alpha_2|$,
- s_3, s_4, and s are of equal length.

In terms of situation calculus formulas, we have

$$eq(s_1, s_2, s, s') \stackrel{def}{=}$$
$$\exists s_3, s_4, s_5, s_6.s_3 \leq s_1 \wedge s_4 \leq s_2 \wedge el(s_3, s) \wedge el(s_4, s) \wedge$$
$$s_5 \leq s_1 \wedge s_6 \leq s_2 \wedge el(s_5, s') \wedge el(s_6, s') \wedge$$
$$\forall a, s_7, s_8.[s_3 \leq s_7 < s_5 \wedge s_4 \leq s_8 < s_6 \wedge el(s_7, s_8) \supset$$
$$do(a, s_7) \leq s_5 \equiv do(a, s_8) \leq s_6]$$

Lemma 1 *Under our axiomatization, we have that for any δ, s, s', s_1, s_2, if s', s_1, and s_2 are all of equal length, and the schedules s_1 and s_2 are the same between s and s', then $Do(\delta, s, s', s_1)$ iff $Do(\delta, s, s', s_2)$:*

$$s \leq s' \wedge el(s', s_1) \wedge el(s', s_2) \wedge eq(s_1, s_2, s, s') \supset Do(\delta, s, s', s_1) \equiv Do(\delta, s, s', s_2).$$

We mentioned that our formalization of prioritized concurrency $\gg$ is different from that in (De Giacomo, Lespérance, and Levesque 2000). We now show that when a program does not have this operator, and does not have the special nil action used in (De Giacomo, Lespérance, and Levesque 2000), then our axiomatization agrees with that in (De Giacomo, Lespérance, and Levesque 2000).

Theorem 3 *Let δ be a ConGolog complex action without the prioritized concurrency operator $\gg$, and without the special action nil. Let $Do1$ and $Do2$ be the macro operators defined in (De Giacomo, Lespérance, and Levesque 2000) and here in this paper, respectively. We have*

$$\Sigma \cup T_1 \cup T_2 \models \forall \vec{x}, s, s'.Do1(\delta, s, s') \equiv Do2(\delta, s, s'),$$

where $\vec{x}$ is the tuple of the free variables in δ, T_1 the set of axioms about $Trans$, $Trans^*$, and $Final$, and T_2 the set of axioms in this paper about sch, el, split, Full, Empty, P_{δ_1} for each δ_1 such that δ_1^* is in δ, and $P^{\|}_{\delta_1}$ for each δ_1 such that $\delta_1^{\|}$ is in δ.

This theorem is proved using the following lemma

Lemma 2 *Let δ be a ConGolog complex action without $\gg$ and nil. Let $s \leq s'$ be two situations, and $s_2 \leq s_1$ two schedules such that $el(s_2, s)$ and $el(s_1, s')$. Then $Do(\delta, s, s', s_1)$ iff for some sequence $s \leq S_1 \leq S_1' \leq S_2 \leq S_2' \leq \cdots \leq S_n \leq S_n' \leq s'$ of situation terms, and a sequence $\delta = \delta_1, ..., \delta_{n+1}$ of ConGolog complex actions, we have that*

- $Trans(\delta_i, S_i, \delta_{i+1}, S_i')$, $1 \leq i \leq n$;
- $Final(\delta_{n+1}, S_n')$;
- *the sequence $S_1 \leq S_1' \leq S_2 \leq S_2' \leq \cdots \leq S_n \leq S_n'$ conforms with the schedule s_1 starting from s_2: for any s_3, $s_2 < do(Y, s_3) \leq s_1$ iff there is an i such that $el(s_3, S_i)$ and $S_i < S_i'$.*

We have already seen an example program that mentions $\gg$ for which our semantics differs from the one in (De Giacomo, Lespérance, and Levesque 2000). We now proceed to show that our approach can also handle the $\gg$ operator as defined in (De Giacomo, Lespérance, and Levesque 2000). To do this, we introduce a new predicate $PDo(\delta, s, s', s_1)$ (partially do the program), meaning that δ has been carried out from s to s' according schedule s_1. The new definition of $Do(\delta_1 \gg \delta_2, s, s', s_1)$ is as below:

$$\begin{aligned}
&Do(\delta_1 \gg \delta_2, s, s', s_1) \stackrel{def}{=} \exists s_2, s_3\{split(s_1, s_2, s_3) \wedge \\
&\quad Do(\delta_1, s, s', s_2) \wedge Do(\delta_2, s, s', s_3) \wedge \\
&\quad \neg\exists s_4, s_5, s_6, s''[split(s_1, s_4, s_5) \wedge \\
&\quad earlier(s_4, s_2) \wedge do(Y, s_6) \leq s_4 \wedge do(N, s_6) \leq s_2 \wedge \\
&\quad s < s'' \leq s' \wedge el(do(Y, s_6), s'') \wedge \\
&\quad PDo(\delta_1, s, s'', do(Y, s_6))]\}.
\end{aligned}$$

The new predicate PDo is defined as follows. It is the same as Do on primitive actions, test actions, choices, and concurrencies, with Do replaced by PDo:

$$\begin{aligned}
&PDo(A, s, s', s_1) \equiv \exists s_2, s_3, s''.el(s, s_2) \wedge \\
&\quad \{Empty(s_2, s_1) \vee \\
&\quad [s < do(A, s'') \leq s' \wedge s_2 < do(Y, s_3) \leq s_1 \wedge \\
&\quad el(s'', s_3) \wedge Empty(s_2, s_3) \wedge Empty(do(Y, s_3), s_1) \wedge \\
&\quad Poss(A, s'')]\}, \\
&PDo(\varphi?, s, s', s_1) \equiv \exists s_2.s_2 \leq s_1 \wedge el(s, s_2) \wedge \\
&\quad Empty(s_2, s_1), \\
&PDo(\delta_1 \mid \delta_2, s, s', s_1) \equiv \\
&\quad PDo(\delta_1, s, s', s_1) \vee PDo(\delta_2, s, s', s_1), \\
&PDo((\pi x)\delta(x), s, s', s_1) \equiv \exists x.PDo(\delta(x), s, s', s_1), \\
&PDo(\delta_1 \parallel \delta_2, s, s', s_1) \equiv \exists s_2, s_3.split(s_1, s_2, s_3) \wedge \\
&\quad PDo(\delta_1, s, s', s_2) \wedge PDo(\delta_2, s, s', s_3), \\
&PDo(\delta_1 \gg \delta_2, s, s', s_1) \equiv \exists s_2, s_3\{split(s_1, s_2, s_3) \wedge \\
&\quad PDo(\delta_1, s, s', s_2) \wedge PDo(\delta_2, s, s', s_3) \wedge \\
&\quad \neg\exists s_4, s_5, s_6, s''[split(s_1, s_4, s_5) \wedge \\
&\quad earlier(s_4, s_2) \wedge do(Y, s_6) \leq s_4 \wedge do(N, s_6) \leq s_2 \wedge \\
&\quad s < s'' \leq s' \wedge el(do(Y, s_6), s'') \wedge \\
&\quad PDo(\delta_1, s, s'', do(Y, s_6))]\}.
\end{aligned}$$

Partially executing a sequence $\delta_1; \delta_2$ means either partially executing δ_1 or partially executing δ_2 after δ_1 is executed:

$$\begin{aligned}
&PDo(\delta_1; \delta_2, s, s', s_1) \equiv PDo(\delta_1, s, s', s_1) \vee \exists s'', s_2[\\
&\quad s_2 \leq s_1 \wedge Do(\delta_1, s, s'', s_2) \wedge PDo(\delta_2, s'', s', s_1)].
\end{aligned}$$

Similarly for iterations:

$$\begin{aligned}
&PDo(\delta^*, s, s', s_1) \equiv PDo(\delta, s, s', s_1) \vee \\
&\quad \exists s'', s_2.s_2 \leq s_1 \wedge Do(\delta, s, s'', s_2) \wedge PDo(\delta, s'', s', s_1), \\
&PDo(\delta^{\|}, s, s', s_1) \equiv PDo(\delta, s, s', s_1) \vee \\
&\quad \exists s_2, s_3.[split(s_1, s_2, s_3) \wedge s_3 \neq s_1 \wedge \\
&\quad PDo(\delta, s, s', s_2) \wedge PDo(\delta^{\|}, s, s', s_3)].
\end{aligned}$$

Notice that the last axiom will not lead to a cyclic definition as splitting s_1 into s_2 and s_3, with $s_3 \neq s_1$, will eventually lead to s_3 being an empty schedule.

Related work

If we consider generally the problem of formalizing semantics of programs, there is a huge literature about this in computer science. In particular, Golog and its original semantics was strongly influenced by dynamic logic (Harel 1979). The unique feature of Golog is that actions are specified axiomatically by successor state axioms, and the Do macro axiomatizes legal execution paths in the situation calculus.

Baier, Fritz and McIlraith (2007) proposed to translate a Golog program to a basic action theory. Later, Fritz, Baier and McIlraith (2008) extended it to ConGolog. Their motivation was to use Golog and ConGolog to encode domain specific control information in planning. Given a basic action theory D, and a goal G, instead of asking if there is an

executable sequence of actions that can achieve G: whether

$$D \models \exists s.Executable(s) \wedge G[s]$$

holds, they proposed to encode the domain specific control information about D as a ConGolog program δ, and ask if there is a sequence of actions that is a legal execution of δ and can achieve G: whether

$$D \models \exists s.Do(\delta, S_0, s) \wedge G[s].$$

To implement this, they translated D and δ to a new basic action theory D' in a new language, and showed that there is a mapping τ from sequences of actions (situations) in the language of D' to sequences of actions (situations) in the language of D such that $D' \models Executable(S) \wedge G[S]$ iff $D \models Do(\delta, S_0, \tau(S)) \wedge G[\tau(S)]$. Thus, the semantics of δ is captured by D'. While the axioms in D' are also first-order, they use natural numbers. In comparison, our axiomatization uses the same language of the original situation calculus. An interesting question is whether our first-order reformulation of Golog and ConGolog semantics could make the translation from D and δ to D' simpler.

While we consider Golog and ConGolog programs, Gabaldon (2003; 2004) considered "programs" written in temporal logic formulas, and their translation into first-order situation calculus.

Conclusions

We have shown that by using the foundational axioms in the situation calculus, it is possible to give a first-order semantics to Golog and ConGolog programs. In the case of Golog, this is achieved by introducing a new predicate when an iteration is encountered. In the case of ConGolog, this is done by using so-called scheduling situations. The overall message is that once we have second-order induction on the situations, other inductive structures and fixed-points can be defined in first-order terms. We hope the simpler first-order semantics will lead to more effective ways of doing program verification and synthesis in Golog and ConGolog.

Appendix: Proofs

Proof of Theorem 1

Let δ be a complex action, M a model of $\Sigma \cup T_\delta$, and σ a variable assignment for $\vec{x}$, s, and s'. We need to show that

$$M, \sigma \models Do1(\delta, s, s') \equiv Do2(\delta, s, s').$$

This is done by induction on the structure of δ. Notice that $Do1$ and $Do2$ are identical except on iterations, so we need only to prove the inductive step for this construct. We know that

$$M, \sigma \models Do1(\delta^*, s, s')$$

iff there is a sequence of $S_0, .., S_n$, $0 \leq n$, of situation terms, such that under σ, $s = S_0$, $S_n = s'$, and for any $0 \leq i < n$,

$$M, \sigma \models Do1(\delta, S_i, S_{i+1}).$$

On the other hand,

$$M, \sigma \models Do2(\delta^*, s, s')$$

iff

$$M, \sigma \models P_\delta(\vec{x}, s, s').$$

Since M is a model of T_δ, by induction on s', it can be seen that the above holds iff there is a sequence of $S_0, .., S_n$, $0 \leq n$, of situation terms, such that $s = S_0$, $S_n = s'$, and for any $0 \leq i < n$,

$$M, \sigma \models Do2(\delta, S_i, S_{i+1}).$$

Thus the desired result holds by the inductive assumption that

$$M, \sigma \models Do2(\delta, S, S') \equiv Do1(\delta, S, S')$$

for any situation terms S and S'.

Proof of Theorem 2 (Sketch)

Inductively for any complex action δ extended with P_i, $1 \leq i \leq n$, define $Do1^k$ as follows:

$$P_i^0(\vec{v}_i, s, s') \equiv false,$$
$$P_i^k(\vec{v}_i, s, s') \equiv Do1^{k-1}(\delta_i, s, s'),$$
$$Do1^k(\delta, s, s') \stackrel{def}{=} Do1(\delta(\vec{P}/\vec{P^k}), s, s'),$$

where $\delta(\vec{P}/\vec{P^k})$ is the result of replacing each occurrence of $P_i(\vec{t})$ in δ by $P_i^k(\vec{t})$, for every $1 \leq i \leq n$. The second order definition of $Do1(\delta_0, s, s')$ in (Levesque et al. 1997) captures the least fixed points for P_i, meaning that $Do1(\delta_0, s, s')$ iff for some k, $Do1^k(\delta_0, s, s')$. From this, the result of the theorem follows.

Proof of Lemma 1

Suppose $el(s', s_1)$, $el(s', s_2)$, and $eq(s_1, s_2, s, s')$ hold. This means that s_1 and s_2 are the same after s, not just between s and s', as s' is really the end of s_1 and s_2. Suppose $Do(\delta, s, s', s_1)$. We prove by induction on δ that $Do(\delta, s, s', s_2)$ holds as well. The base cases for primitive actions and test actions are straightforward by noting that s_1 and s_2 are the same after s. Inductively, we have the following cases:

- $\delta = \delta_1; \delta_2$. From $Do(\delta, s, s', s_1)$, we have that for some s'' and s_3, $s_3 \leq s_1$, $el(s_2, s'')$, and

  $$Do(\delta_1, s, s'', s_3) \wedge Do(\delta_2, s'', s', s_1).$$

  hold. Now let $s_4 \leq s_2$ and $el(s_4, s_3)$. By inductive assumptions, we have

  $$Do(\delta_1, s, s'', s_4) \wedge Do(\delta_2, s'', s', s_2),$$

  which implies $Do(\delta, s, s', s_2)$.
- The cases for $\delta_1 \mid \delta_2$ and $(\pi x)\delta_1(x)$ are trivial.

- $\delta = \delta_1(\vec{x})^*$. From $Do(\delta, s, s', s_1)$, we have $P_{\delta_1}(\vec{x}, s, s', s_1)$. We show by induction on s that $P_{\delta_1}(\vec{x}, s, s', s_2)$ holds as well. The base case $s = s'$ is trivial. Inductively, assume $s < s'$ and the result holds for all s'' such that $s < s'' \leq s'$. From $P_{\delta_1}(\vec{x}, s, s', s_1)$, we have that for some s'' and s_3:

$$s < s'' \leq s' \wedge s_3 \leq s_1 \wedge el(s_3, s'') \wedge Do(\delta_1, s, s'', s_3) \wedge P_{\delta_1}(\vec{x}, s'', s', s_1).$$

By inductive assumption, we have

$$s < s'' \leq s' \wedge s_3 \leq s_1 \wedge el(s_3, s'') \wedge Do(\delta_1, s, s'', s_3) \wedge P_{\delta_1}(\vec{x}, s'', s', s_2).$$

Now let $s_4 \leq s_2$ be such that $el(s_4, s_3)$, by inductive assumption on δ_1, we have

$$s < s'' \leq s' \wedge s_4 \leq s_2 \wedge el(s_4, s'') \wedge Do(\delta_1, s, s'', s_4) \wedge P_{\delta_1}(\vec{x}, s'', s', s_2).$$

Thus $P_{\delta_1}(\vec{x}, s, s', s_2)$.

- $\delta = \delta_1 \parallel \delta_2$. From $Do(\delta, s, s', s_1)$, we have for some s_3, s_4 such that $split(s_1, s_3, s_4)$,

$$Do(\delta_1, s, s', s_3) \wedge Do(\delta_2, s, s', s_4).$$

Since s_1 and s_2 are the same after s, we can split s_2 the same way after s: $split(s_2, s_5, s_6)$ so that s_3 and s_5, and s_4 and s_6, respectively, are the same after s. By inductive assumption, we then have

$$Do(\delta_1, s, s', s_5) \wedge Do(\delta_2, s, s', s_6).$$

Thus $Do(\delta, s, s', s_2)$.

- The case for $\delta_1 \gg \delta_2$ is similar to the previous case.
- $\delta = \delta_1(\vec{x})^{\parallel}$. The case for $s = s'$ is trivial. Suppose $s < s'$. From $Do(\delta_1(\vec{x})^{\parallel}, s, s', s_1)$, we have $P^{\parallel}_{\delta_1}(\vec{x}, s, s', s_1)$. We show by induction on the number of "Y" actions in s_1 that $P^{\parallel}_{\delta_1}(\vec{x}, s, s', s_2)$ holds as well. If s_1 is all empty, then s_2 is all empty starting from s:

$$\exists s_3(s_3 \leq s_2 \wedge el(s, s_3) \wedge Empty(s_3, s_2)). \quad (14)$$

By our axiom about $P^{\parallel}$, $P^{\parallel}_{\delta_1}(\vec{x}, s, s', s_2)$ holds. Inductively, there are two cases. Case 1: s_1 is all empty starting from s. Then s_2 is all empty starting from s as well. Case 2: s_1 is not all empty starting from s. Then for some s_3 and s_4 such that $split(s_1, s_3, s_4) \wedge s_1 \neq s_3$, we have

$$P^{\parallel}_{\delta_1}(\vec{x}, s, s', s_3) \wedge Do(\delta_1(\vec{x}), s, s', s_4).$$

We can split s_2 in the same way: $split(s_2, s_5, s_6)$ so that $s_2 \neq s_5$, and s_5 and s_3, and s_6 and s_4, respectively, are the same after s. Now the number of "Y" actions in s_3 must be less than that in s_1. Thus by inductive assumptions,

$$P^{\parallel}_{\delta_1}(\vec{x}, s, s', s_5) \wedge Do(\delta_1(\vec{x}), s, s', s_6).$$

Thus $P^{\parallel}_{\delta_1}(\vec{x}, s, s', s_2)$.

This completes the inductive step, thus the proof of the lemma.

Proof of Lemma 2 (Sketch)

Let $s \leq s'$ be two situations, and $s_2 \leq s_1$ two schedules such that $el(s_2, s)$ and $el(s_1, s')$. We prove by induction on δ. There are two base cases, primitive actions and test actions. If $\delta = A$ is a primitive action, then $Do(\delta, s, s', s_1)$ iff for some s_3 and s'',

$$s < do(A, s'') \leq s' \wedge s_2 < do(Y, s_3) \leq s_1 \wedge el(s'', s_3) \wedge Empty(s_2, s_3) \wedge Empty(do(Y, s_3), s_1) \wedge Poss(A, s'')$$

iff for some s_3 and s'', the following are true

- $s \leq s'' < do(A, s'') \leq s'$,
- $Trans(A, s'', nil, do(A, s'')) \wedge Final(nil, do(A, s''))$,
- the sequence $s'' < do(A, s'')$ conforms with the schedule s_1 starting from s_2: it has exactly one "Y" which occurs at the position marked by s''.

Noting that $Trans(A, S, \delta', S')$ holds iff $\delta' = nil$, $S' = do(A, S)$, and $Poss(A, S)$, this proves the lemma for the case.

The case for $\delta = \varphi?$ is almost identical, noting that $Trans(\varphi?, S, \delta', S')$ iff $\varphi[S]$, $S' = S$, and $\delta' = nil$.

Inductively, there are several cases. Suppose $\delta = \delta^1; \delta^2$. Then $Do(\delta^1; \delta^2, s, s', s_1)$ iff for some s_3, s''

$$s_3 \leq s_1 \wedge el(s_3, s'') \wedge Do(\delta^1, s, s'', s_3) \wedge Do(\delta^2, s'', s', s_1).$$

The result then follows from the inductive assumptions on $Do(\delta^1, s, s'', s_3)$ and $Do(\delta^2, s'', s', s_1)$, and the definition of $Trans$ from (De Giacomo, Lespérance, and Levesque 2000). If $\delta = \delta^1 \parallel \delta^2$, then $Do(\delta^1 \parallel \delta^2, s, s', s_1)$ iff for some s_3 and s_4,

$$split(s_1, s_3, s_4) \wedge Do(\delta^1, s, s', s_3) \wedge Do(\delta^2, s, s', s_4).$$

Notice that $split(s_1, s_3, s_4)$ implies that $el(s_1, s_3)$ and $el(s_1, s_4)$. Thus the inductive assumption can apply to $Do(\delta^1, s, s', s_3)$ and $Do(\delta^2, s, s', s_4)$, from which the result follows. The other cases are similar.

Proof of Theorem 3

$Do2(\delta, s, s')$ iff $Do2(\delta, s, s', s_1)$, where s_1 is a full schedule such that $el(s', s_1)$, iff (by Lemma 2) for some sequence $s \leq S_1 \leq S'_1 \leq S_2 \leq S'_2 \leq \cdots \leq S_n \leq S'_n \leq s'$ of situation terms, and a sequence $\delta = \delta_1, ..., \delta_{n+1}$ of ConGolog complex actions, we have that

- $Trans(\delta_i, S_i, \delta_{i+1}, S'_i)$, $1 \leq i \leq n$;
- $Final(\delta_{n+1}, S'_n)$;
- the sequence $S_1 \leq S'_1 \leq S_2 \leq S'_2 \leq \cdots \leq S_n \leq S'_n$ conforms with the the full schedule s_1 starting from s_2, where $s_2 \leq s_1$ and $el(s, s_2)$: for any s_3 such that $s_2 \leq s_3 < s_1$, there is an i such that $el(s_3, S_i)$ and $S_i < S'_i$.

Given that s and s_2 have the same length, and s' and s_1 have the same length, the last condition implies that $S'_i = S_{i+1}$ for every $1 \leq i < n$, $s = S_1$, and $S'_n = s'$. Thus the above condition holds iff $Do1(\delta, s, s')$.

Model Checking Unbounded Artifact-Centric Systems

Alessio Lomuscio and Jakub Michaliszyn
Department of Computing, Imperial College London, UK

Abstract

Artifact-centric systems are a recent paradigm for representing and implementing business processes. We present further results on the verification problem of artifact-centric systems specified by means of FO-CTL specifications. While the general problem is known to be undecidable, results in the literature prove decidability for artifact systems with infinite domains under boundedness and conditions such as uniformity. We here follow a different approach and investigate the general case with infinite domains. We show decidability of the model checking problem for the class of artifact-centric systems whose database schemas consist of a single unary relation, and we show that that the problem is undecidable if artifact systems are defined by using one binary relation or two unary relations.

1 Introduction

Artifact-centric systems (ACS) have been put forward as a framework for reasoning about and implementing data-aware business processes (Alonso et al. 2004; Hull 2008; Hull et al. 2011). Artifacts are constructs consisting of *data* and *lifecycles*. The data component is given by means of a relational database, i.e., a set of finite relations with fixed *schema*. The lifecycles describe how the artifacts may interact and evolve over time.

ACS can be programmed via the Guard-Stage-Milestone (GSM) language (Hull et al. 2011). The iHub (Heath III et al. 2013) is a production and execution suite for ACS implemented in GSM. Both GSM and the iHub are designed to help stakeholders encode business interactions intuitively and efficiently.

A problem that naturally arises is whether ACS are correct against specifications. GSMC, a model checking tool for GSM systems, has recently been put forward (Gonzalez, Griesmayer, and Lomuscio 2012) to assess this problem.

While GSMC has shown considerable promise, verifying GSM programs via model checking remains highly problematic. Classical techniques based on model checking (Clarke, Grumberg, and Peled 1999) are typically insufficient as they normally tackle finite-state systems. Yet artifacts exhibit infinitely many different possible configurations. It is therefore important to establish at a fundamental level under what conditions an artifact-system can actually be verified.

The verification problem for ACS specified by quantified temporal specifications is known to be undecidable (Deutsch et al. 2009; Hariri et al. 2011; Belardinelli, Lomuscio, and Patrizi 2011) and considerable research has gone into the exploration of decidable fragments.

Contribution. In this paper we explore novel boundaries in the decidability conditions for the model checking problem of ACS against quantified, temporal specifications. While much of the recent work has focused on the identification of relational properties on the generated models for complete and decidable abstraction procedures, an alternative avenue of investigation consists in considering classes of specifications for the artifacts' transitions. To this end, we here define the logic CARL which we use to model the artifacts' lifecycles. By using CARL to model the artifacts' evolutions, we can express Boolean combinations of the basic relational properties: "**c**heck that the relation is empty, "**a**dd one arbitrary element to the relation", "**r**emove one arbitrary element", and "**l**eave the relation unchanged". We show that model checking ACS described via CARL against reachability specifications is undecidable thereby providing further insights on the difficulty of verifying data-aware systems.

We then focus on restricting the database schema appearing in the ACS. We show that the model checking problem remains undecidable if the schema contain either one relation of arity greater than one, or at least two arbitrary relations. Our undecidability proofs involve the encoding of two-counter machines (Minsky 1967).

Finally, we show that the model checking problem is decidable if we consider only artifacts whose schema consists of a single unary relation and sentence-atomic temporal specifications. We prove this result in three steps. Firstly, we study the expressive power of first-order logic over unary relations using Ehrenfeucht-Fraisse games. Then, we show how to transform an ACS and a specification into an infinite Kripke structure and a CTL specification. Finally, we prove that the resulting infinite Kripke structure can be encoded as a pushdown system. We then define a CTL* specification that the pushdown system satisfies if and only if the ACS satisfies the original FO-CTL specification. Since the former problem is decidable (Bozzelli 2007), we conclude that the latter is decidable as well.

Related Work. Previous research on verifying artifact-centric systems has focused on abstraction techniques where semantical conditions such as "uniformity" and "weak acyclicity" are shown to guarantee decidability under the assumption that systems are bounded, i.e., either the states or the runs do not contain more than a given number of predicates (Belardinelli, Lomuscio, and Patrizi 2012b; Hariri et al. 2013). Differently from these approaches, the investigation here presented makes no assumption on the boundedness of the artifact-systems to be studied.

Model checking artifact-centric systems against a quantified version of LTL was studied in (Deutsch et al. 2009). It was shown that the problem is generally undecidable, but becomes decidable if one considers *guarded artifact systems* and *guarded specifications*, a form of quantification where no variables appear free in a temporal context. A PSPACE model checking algorithm for fixed-arity schemas is also shown in (Deutsch et al. 2009). While the results presented are positive, compared to the classes of artifacts studied here, the expressivity of the fragment studied is limited.

More recently (Hariri et al. 2013) presented results on the model checking problem against specifications given in the first-order extension of the μ-calculus. The problem is undecidable in this setting; however, it is shown that by adding additional restrictions, including forbidding fresh, unbounded data along a run, the problem is decidable. Also in that line, and differently from this paper, systems are assumed to be bounded and sufficient conditions based on acyclicity for boundedness are established.

While all results above focus on complete procedures, in recent work (Belardinelli and Lomuscio 2013) partial model checking procedures against the universal fragment of FO-CTL have been explored. Differently from (Belardinelli, Lomuscio, and Patrizi 2012b) these are given for bounded but possibly non-uniform artifact-centric systems. Conversely, the results established in this paper concern unbounded, but uniform systems.

Scheme of the paper. In Section 2 we provide the background on ACS and relevant concepts, and we define the model checking problem. We observe that the problem is generally undecidable. In Section 3 we investigate the implications of restricting the database schemas and the expressive power of the language used to model the artifacts' lifecycles. We show that under various restrictions the problem remains undecidable. In Section 4 we characterise a scenario in which the model checking problem is decidable and explore its complexity. Taken together the results in the two sections show that the conditions we identify can be interpreted as being maximal for decidability. We conclude in Section 5.

2 Verifying Artifact Systems

Artifacts are operational models of *business process* (Cohn and Hull 2009). Each artifact is composed by two parts: a *data model*, which captures a fragment of the structure of the information relevant to the process, and a *lifecycle model*, which is a specification of their evolution. In this paper we follow the formalisation proposed in (Hariri et al. 2011) and define artifact systems by means of a (relational) database and a set of artifact transitions, which account for the artifact data models and the artifact lifecycles, respectively.

Definition 1 (Database schema). *A* database schema *is a set* $\mathcal{D} = \{P_1/a_1, \ldots, P_n/a_n\}$ *of* relation (or predicate) symbols P_i*, each associated with its arity* $a_i \in \mathbb{N}$.

Definition 2 (Database interpretation). *Given a database schema* $\mathcal{D}$*, a* $\mathcal{D}$-interpretation (or $\mathcal{D}$-instance) over an countable interpretation domain U *is a mapping* D *associating each relation symbol* P_i *with a* finite a_i*-ary relation over* U*, i.e.,* $D(P_i) \subseteq U^{a_i}$.

The set of all $\mathcal{D}$-interpretations over a given domain U is denoted by $\mathcal{I}_{\mathcal{D}}(U)$. The *active domain* of D, $adom(D)$, is the set of all U-elements occurring in some tuple of some predicate interpretation $D(P_i)$.

2.1 Artifact systems

To model transitions between states of the underlying databases, we use *unprimed* and *primed* relational symbols from $\mathcal{D}$, that refer to relations in the current and the successor state, respectively. Intuitively, given two states (i.e., two $\mathcal{D}$-interpretations) D and D', the operator $\oplus$ constructs a new "joint" interpretation $D \oplus D'$, interpreting unprimed relational symbols in D, and primed in D'.

As we study artifacts systems whose transitions are described by various logics, below we introduce the notion of an *artifact system over a logic* $\mathcal{L}_{\mathcal{D}}$.

Definition 3 ($\mathcal{L}_{\mathcal{D}}$-artifact system). *An* $\mathcal{L}_{\mathcal{D}}$-artifact system *is a tuple* $\mathcal{S} = \langle \mathcal{D}, U, D_0, \mathbb{T} \rangle$*, where:*

- $\mathcal{D} = \{P_1/a_1, \ldots, P_n/a_n\}$ *is a database schema;*
- U *is a countable interpretation domain;*
- D_0 *is an* initial database instance*;*
- $\mathbb{T}$ *is a finite set of sentences of the logic* $\mathcal{L}_{\mathcal{D}}$*, called* artifact transitions*.*

In the definition above we assume that the sentences of the logic $\mathcal{L}_{\mathcal{D}}$ state properties of $D \oplus D'$, i.e., the notion "$D \oplus D' \models_{\mathcal{L}_{\mathcal{D}}} \Phi$" is defined for every sentence Φ of $\mathcal{L}_{\mathcal{D}}$.

The semantics of an artifact system is given in terms of its possible executions, captured by a Kripke structure, whose states are instances of the database schema and whose transitions correspond to executions of artifact transitions.

Definition 4 (Kripke structures). *A Kripke structure is a tuple* $\mathcal{K} = \langle \Sigma, D_0, \tau, \pi \rangle$*, where* Σ *is the* set of states*;* $D_0 \in \Sigma$ *is the* initial state*;* $\tau \subseteq \Sigma \times \Sigma$ *is the* transition relation*;* π *is the labelling function.*

For convenience, we assume a single initial state, but all the results presented below also hold if we allow any finite number of initial states. When the labelling function is irrelevant, we will drop it and represent a Kripke structure as a triple $\mathcal{K} = \langle \Sigma, D_0, \tau \rangle$.

Note that in the definition above we include states not reachable from D_0 by τ. This is not the case below.

Definition 5 (Model of an artifact system). *Given an artifact system* $\mathcal{S} = \langle \mathcal{D}, U, D_0, \mathbb{T} \rangle$ *over* $\mathcal{L}_{\mathcal{D}}$*, the* model of $\mathcal{S}$ *is the Kripke structure* $\mathcal{K}_{\mathcal{S}} = \langle \Sigma, D_0, \tau \rangle$*, where:*

- $\Sigma \subseteq \mathcal{I}_{\mathcal{D}}(U)$ *is the* set of states *reachable from* D_0 *using* τ*;*
- $D_0 \in \Sigma$ *is the* initial state*;*
- τ *is the* transition relation *such that* $\tau(D, D')$ *for some artifact transition* $\Phi \in \mathbb{T}$*,* $D \oplus D' \models_{\mathcal{L}_{\mathcal{D}}} \Phi$*.*

We denote the unique model of an artifact system $\mathcal{S}$ by $\mathcal{K}_{\mathcal{S}}$.

Following (Belardinelli, Lomuscio, and Patrizi 2011), we define *runs* on a Kripke structure.

Definition 6 ($\mathcal{K}$-runs). *Given an artifact system* S *and its model* $\mathcal{K} = \langle \Sigma, D_0, \tau \rangle$*, a* $\mathcal{K}$-run r *from a* $\mathcal{K}$*-state* $D \in \Sigma$ *is an infinite sequence of* $\mathcal{K}$*-states* $r = D^0 \rightarrow D^1 \rightarrow \cdots$ *such that* $D^0 = D$ *and* $\tau(D^i, D^{i+1})$*, for* $i \geq 0$*. For every run* r *and* $i \geq 0$*, we define* $r(i)$ *as* D^i*.*

Note that, unlike much of the literature on the subject, we do not require the runs to be bounded.

Also note that we consider only infinite, countable interpretation domains. To make the notation lighter, we assume without loss of generality that the interpretation domain is always the set of naturals $\mathbb{N}$.

2.2 Model checking artifact systems

In the following we use the logic $FO^{V}_{\mathcal{D},C}$ to define the transitions of artifact-centric systems. The logic $FO^{V}_{\mathcal{D},C}$ is the fragment of first-order logic in which formulae are built by using predicates from $\mathcal{D} \oplus \mathcal{D}'$, constants from C, and variables from V.

Definition 7 (Logic $FO^{V}_{\mathcal{D},C}$). *Given a database schema* $\mathcal{D} = \{P_1/a_1, \ldots, P_n/a_n\}$*, the language of the logic* $FO^{V}_{\mathcal{D},C}$ *is defined by the following BNF:*

$$\Phi ::= t = t' \mid P_i(\vec{t}) \mid P'_i(\vec{t}) \mid \neg\Phi \mid \Phi \vee \Phi \mid \forall x \Phi,$$

where $t, \bar{t} \in C \cup V$ *and* $\vec{t}$ *is an* a_i*-tuple of elements from* $C \cup V$*.*

We use parentheses as standard when required.

Let $* = \{x, y, z, x_1, \ldots\}$ be a countable set of variables and $\mathbf{2} = \{x, y\}$. We consider the following logics: $FO^{*}_{\mathcal{D},\mathbb{N}}$, $FO^{*}_{\mathcal{D},\emptyset}$, and $FO^{\mathbf{2}}_{\mathcal{D},\emptyset}$. We denote formulae in these logics with Greek upper case letters Φ, Ψ, while specifications against which systems are checked will be denoted by Greek lower case letters φ, ψ.

We use the standard abbreviations $\exists$, $\top$, $\bot$, $\wedge$, $\Rightarrow$, and $\neq$. Free and bound variables are defined as standard. A *sentence* is a formula with no free variables.

A U*-assignment* is a total function $\sigma : V \mapsto U$. For technical convenience, we assume that every U-assignment σ is extended to C and is the identity on it, i.e., $\forall c \in C, \sigma(c) = c$. Given an assignment σ, we denote by σ^x_u the U-assignment s.t. $\sigma^x_u(x) = u$ and $\sigma^x_u(\overline{x}) = \sigma(\overline{x})$, for every $\overline{x} \in V$ s.t. $\overline{x} \neq x$.

We adjust the standard active-domain semantics used in the artifact systems literature (Belardinelli, Lomuscio, and Patrizi 2011; 2012a) to the setting here defined.

Definition 8 (Active-Domain Semantics for FO-formulae). *Given a database schema* $\mathcal{D}$*, two* $\mathcal{D}$*-interpretations* D, D' *over* $\mathbb{N}$*, an* $\mathbb{N}$*-assignment* σ*, and a FO-formula* $\Phi \in FO^{*}_{\mathcal{D},C}$ *over* $\mathcal{D}$*, we inductively define whether* $D \oplus D'$ *satisfies* Φ *under* σ*, written* $(D \oplus D', \sigma) \models \Phi$*, as follows:*

$(D \oplus D', \sigma) \models t = \bar{t}$ *iff* $\sigma(t) = \sigma(\bar{t})$

$(D \oplus D', \sigma) \models P_i(\vec{t})$ *iff* $\langle \sigma(t_1), \ldots, \sigma(t_\ell) \rangle \in D(P_i)$

$(D \oplus D', \sigma) \models P'_i(\vec{t})$ *iff* $\langle \sigma(t_1), \ldots, \sigma(t_\ell) \rangle \in D'(P_i)$

$(D \oplus D', \sigma) \models \neg\Phi$ *iff* $(D \oplus D', \sigma) \not\models \Phi$

$(D \oplus D', \sigma) \models \Phi \vee \Psi$ *iff* $(D \oplus D', \sigma) \models \Phi$ *or* $(D \oplus D', \sigma) \models \Psi$

$(D \oplus D', \sigma) \models \forall x \Phi$ *iff for every* $u \in adom(D)$ $(D \oplus D', \sigma^x_u) \models \Phi$

A formula Φ *is* true *in* $D \oplus D'$*, written* $D \oplus D' \models \Phi$*, iff* $(D \oplus D', \sigma) \models \Phi$ *for all* $\mathbb{N}$*-assignments* σ*.*

Notice that two constants map the same element iff they are the same constant.

We focus on the problem of verifying an artifact system against a temporal specification of interest. We adjust the notion of sentence-atomic FO-CTL (Belardinelli, Lomuscio, and Patrizi 2011) to the case of logic $FO^{*}_{\mathcal{D},\mathbb{N}}$.

Definition 9 (FO ^{sa} CTL formulae). *Given an artifact system* $\mathcal{S} = \langle \mathcal{D}, \mathbb{N}, D_0, \mathbb{T} \rangle$*, the language of* sentence-atomic *FO-CTL (denoted by FO* ^{sa} *CTL) formulae over* $\mathcal{S}$ *is inductively defined as follows:*

$$\varphi ::= \Phi_P \mid \neg\varphi \mid \varphi \vee \varphi \mid AX\varphi \mid A\varphi\mathcal{U}\varphi \mid E\varphi\mathcal{U}\varphi$$

where Φ_P *is an* $FO^{*}_{\mathcal{D},\mathbb{N}}$ *sentence where no primed terms nor primed predicates appear.*

Note from above that while we use the $FO^{*}_{\mathcal{D},\mathbb{N}}$ logic as the building block for artifacts' descriptions we do not use primed variables in the specifications.

The notions of free and bound variables can be extended in the obvious way to FO ^{sa} CTL. We use the standard abbreviations $EX\varphi \equiv \neg AX\neg\varphi$, $AF\varphi \equiv A\top\mathcal{U}\varphi$, $AG\varphi \equiv \neg E\top\mathcal{U}\neg\varphi$, $EF\varphi \equiv E\top\mathcal{U}\varphi$, and $EG\varphi \equiv \neg A\top\mathcal{U}\neg\varphi$.

For a system S, the semantics of FO ^{sa} CTL formulae is provided in terms of its model $\mathcal{K}_{\mathcal{S}}$.

Definition 10 (Satisfaction for FO ^{sa} CTL). *Consider a system* $\mathcal{S}$ *and its model* $\mathcal{K}_{\mathcal{S}}$*, a formula* φ *of FO* ^{sa} *CTL and a* $\mathcal{K}_{\mathcal{S}}$*-state* $D \in \Sigma$*, the satisfaction relation* $\models$ *is inductively defined as follows:*

$(\mathcal{K}_{\mathcal{S}}, D) \models \Phi_P$ *iff* $D \models \Phi_P$

$(\mathcal{K}_{\mathcal{S}}, D) \models \neg\varphi$ *iff* $(\mathcal{K}_{\mathcal{S}}, D) \not\models \varphi$

$(\mathcal{K}_{\mathcal{S}}, D) \models \varphi \vee \psi$ *iff* $(\mathcal{K}_{\mathcal{S}}, D) \models \varphi$ *or* $(\mathcal{K}_{\mathcal{S}}, D) \models \psi$

$(\mathcal{K}_{\mathcal{S}}, D) \models AX\varphi$ *iff for all* $\mathcal{K}_{\mathcal{S}}$*-runs* r *s.t.* $r(0) = D$*,* $(\mathcal{K}_{\mathcal{S}}, r(1)) \models \varphi$

$(\mathcal{K}_{\mathcal{S}}, D) \models A\varphi\mathcal{U}\psi$ *iff for all* $\mathcal{K}_{\mathcal{S}}$*-runs* r *s.t.* $r(0) = D$*,* $\exists k \geq 0$ *s.t.* $(\mathcal{K}_{\mathcal{S}}, r(k)) \models \psi$ *and* $\forall j$ *s.t.* $0 \leq j < k$*,* $(\mathcal{K}_{\mathcal{S}}, r(j)) \models \varphi$

$(\mathcal{K}_{\mathcal{S}}, D) \models E\varphi\mathcal{U}\psi$ *iff for some* $\mathcal{K}_{\mathcal{S}}$*-run* r*,* $r(0) = D$*,* $\exists k \geq 0$ *s.t.* $(\mathcal{K}_{\mathcal{S}}, r(k)) \models \psi$*, and* $\forall j$ *s.t.* $0 \leq j < k$*,* $(\mathcal{K}_{\mathcal{S}}, r(j)) \models \varphi$

A formula φ is true *in $\mathcal{K}_\mathcal{S}$, written $\mathcal{K}_\mathcal{S} \models \varphi$, iff $(\mathcal{K}_\mathcal{S}, D_0) \models \varphi$. We say that $\mathcal{S}$ satisfies φ, written $\mathcal{S} \models \varphi$, iff $\mathcal{K}_\mathcal{S} \models \varphi$.*

Observe that satisfaction of $FO^*_{\mathcal{D},\mathbb{N}}$ is defined on joins $D \oplus D'$ as it deals with primed and unprimed predicates. Here we write $D \models \Phi_P$ because we only need to interpret only the unprimed predicates.

In the rest of this paper we focus on the following problem.

Definition 11 (Model checking problem). *Given a logic $\mathcal{L}_\mathcal{D}$, an $\mathcal{L}_\mathcal{D}$-artifact system $\mathcal{S}$ and a FO $\underline{^{sa}}$ CTL specification φ, the* model checking problem *involves establishing whether $\mathcal{K}_\mathcal{S} \models \varphi$.*

Observe that the input can be given in finite terms, as the description of an $\mathcal{L}_\mathcal{D}$-artifact system is finite; so the problem is well-defined. This problem can be shown to be undecidable in the general case.

Theorem 12. *Model checking an arbitrary $FO^*_{\mathcal{D},\mathbb{N}}$-artifact system against a FO $\underline{^{sa}}$ CTL specification is undecidable.*

Proof idea. The proof in (Belardinelli, Lomuscio, and Patrizi 2011) can be adapted to this case. □

In the following we will explore the decidability for restrictions of the problem above.

3 Model Checking $CARL_{\mathcal{D},\mathbb{N}}$–Artifact Systems

One possibility to obtain decidability is to consider a weak form of quantification when writing artifacts' descriptions. For example we could consider the two variable fragment of first-order logic (Grädel, Kolaitis, and Vardi 1997) or the guarded fragment (Grädel 1999).

In this paper we follow a different approach and address the question of whether one can choose a reasonable logic $\mathcal{L}_\mathcal{D}$ in the artifacts' descriptions so that model checking $\mathcal{L}_\mathcal{D}$-artifact systems is decidable.

First, we identify some essential properties of the artifact systems. Then, we define the logic capable of expressing only Boolean combinations of such properties. Finally, we show that in most cases model checking artifact systems defined using this logic is undecidable.

In the proofs that follow, we often use the FO $\underline{^{sa}}$ CTL specification $EG\,\top$. This is intended to show that the negative results we present cannot be overcome by adopting a weaker specification language.

3.1 The logic $CARL_{\mathcal{D},\mathbb{N}}$

The logic $CARL_{\mathcal{D},\mathbb{N}}$ describes properties of unary relations only. $CARL_{\mathcal{D},\mathbb{N}}$ expresses Boolean combinations of the following properties of an unary relation P:

- P contains a constant c;
- P is empty;
- One element is added to P, i.e., $P' = P \cup \{x\}$ for some $x \notin P$;
- One element is removed from P, i.e., $P = P' \cup \{x\}$ for some $x \notin P'$;
- P does not change, i.e., $P = P'$.

These properties are very basic and natural, but are sufficient to express interesting properties for artifact systems. However, as we see below, even the properties above already induce undecidability of the model checking problem.

Definition 13 (Logic $CARL_{\mathcal{D},C}$). *Given a database schema $\mathcal{D} = \{P_1/1, \ldots, P_n/1\}$, the language of the logic $CARL_{\mathcal{D},C}$ is inductively defined by the following BNF:*

$$\begin{aligned}\Phi ::= \quad & \neg\Phi \mid \Phi \vee \Phi \mid P_i(c) \mid P'_i(c) \mid \textsc{Empty}(P_i) \mid \\ & \textsc{Equal}(P_i) \mid \textsc{Insert}(P_i) \mid \textsc{Delete}(P_i)\end{aligned}$$

where c is an element of the set of constants C.

Recall that $P_i(c)$ refers to the relation P_i *before* the transition, and $P'_i(c)$ refers to the relation *after* the transition. For convenience the formal semantics of $CARL_{\mathcal{D},C}$ is given by translating it into $FO^2_{\mathcal{D},\mathbb{N}}$.

Definition 14 (Semantics of $CARL_{\mathcal{D},\mathbb{N}}$). *We define a translation of $\mathfrak{T}$ to $FO^2_{\mathcal{D},\mathbb{N}}$ as follows.*

$$\begin{aligned}
\mathfrak{T}(\neg\Phi) &= \neg\mathfrak{T}(\Phi) \\
\mathfrak{T}(\Phi_1 \vee \Phi_2) &= \mathfrak{T}(\Phi_1) \vee \mathfrak{T}(\Phi_2) \\
\mathfrak{T}(P_i(c)) &= P_i(c) \\
\mathfrak{T}(P'_i(c)) &= P'_i(c) \\
\mathfrak{T}(\textsc{Empty}(P_i)) &= \forall x.\neg P_i(x) \\
\mathfrak{T}(\textsc{Equal}(P_i)) &= \forall x.P'_i(x) \Leftrightarrow P_i(x) \\
\mathfrak{T}(\textsc{Insert}(P_i)) &= \exists x.\neg P_i(x) \wedge P'_i(x) \\
&\quad \wedge \forall y.y \neq x \Rightarrow (P_i(y) \Leftrightarrow P'_i(y)) \\
\mathfrak{T}(\textsc{Delete}(P_i)) &= \exists x.P_i(x) \wedge \neg P'_i(x) \\
&\quad \wedge \forall y.y \neq x \Rightarrow (P_i(y) \Leftrightarrow P'_i(y))
\end{aligned}$$

Then, the semantics of $CARL_{\mathcal{D},\mathbb{N}}$ is defined using the semantics of $FO^*_{\mathcal{D},\mathbb{N}}$ by considering $(D \oplus D', \sigma) \models \Phi$ iff $(D \oplus D', \sigma) \models \mathfrak{T}(\Phi)$.

3.2 Undecidability of model checking $CARL_{\mathcal{D},\mathbb{N}}$-artifacts systems

A key result of this section is the following theorem.

Theorem 15. *For any database schema $\mathcal{D}$ that contains two unary relation symbols, model checking $CARL_{\mathcal{D},\mathbb{N}}$-artifact systems against FO $\underline{^{sa}}$ CTL is undecidable.*

The proof uses two-counter finite automata (Minsky machines) defined as follows.

Definition 16. *A* two-counter automaton *is a tuple $\mathcal{A} = \langle Q, q_0, q_f, R\rangle$, where $Q = \{q_0, q_1, \ldots, q_f\}$, q_0 is an initial state, q_f is a final state, and $R : Q \times \{\top, \bot\} \times \{\top, \bot\} \times Q \times \{-1, 0, 1\} \times \{-1, 0, 1\}$ is the transition relation.*

A *configuration* for a two-counter automata is a triple (q_i, n, m) where $q_i \in Q$ and $n, m \in \mathbb{N}$. Let $Empty(x)$ be equal $\top$ if $x = 0$ and $\bot$ otherwise. We define a relation $\rightarrow^R$ such that for two configuration $\beta_1 = (q_i, n, m)$, $\beta_2 = (q_j, n', m')$ we have $\beta_1 \rightarrow^R \beta_2$ iff we have $(q_i, Empty(n), Empty(m), q_j, n' - n, m' - m) \in R$. A *run* is a possibly infinite sequence of configurations such that for all consecutive configurations β_1, β_2 we have $\beta_1 \rightarrow^R \beta_2$.

A run is *accepting* if it contains a configuration containing q_f.

The following lemma follows from (Minsky 1967).

Lemma 17. *The problem whether there exists an infinite run of a given two-counter automaton is undecidable.*

We can now we prove Theorem 15.

Proof. For a given two-counter automaton $\mathcal{A} = \langle Q, q_0, q_f, R\rangle$, we show how to define a $CARL_{\mathcal{D},\mathbb{N}}$-artifact systems $S^{\mathcal{A}}$ and an FO^{sa}CTL formula φ such that $S^{\mathcal{A}} \models \varphi$ iff $\mathcal{A}$ has an infinite run. Firstly, we construct a system with tree relations, and then we show how one of the relations can be removed.

Three relations. Let $S^{\mathcal{A}} = \langle \mathcal{D}^{\mathcal{A}}, \mathbb{N}, D_0^{\mathcal{A}}, \mathbb{T}^{\mathcal{A}}\rangle$, where $\mathcal{D}^{\mathcal{A}} = \{P_1/1, P_2/1, P_3/1\}$, $D_0^{\mathcal{A}}$ be such that P_1 and P_2 are empty and P_3 is a singleton relation containing 0. Our aim is to define the set $\mathbb{T}^{\mathcal{A}}$ so that each database interpretation $D = \{P_1^D, P_2^D, P_3^D\}$ in the model $\mathcal{K}_{S^{\mathcal{A}}}$ of $S^{\mathcal{A}}$ satisfies $|P_3^D \cap \{0, \dots, f\}| = 1$ and represents a configuration $(q_i, |P_1^D|, |P_2^D|)$ where $q_i \in P_3^D$. In other words, the size of P_1^D/P_2^D represents the value of the first/second counter and P_3^D contains the state.

Let $empty_{\top}(R) = \textsc{Empty}(R)$ and $empty_{\bot}(R) = \neg\textsc{Empty}(R)$. Let $modify_{-1}(R) = \textsc{Delete}(R)$, $modify_0(R) = \textsc{Equal}(R)$, and $modify_{+1}(R) = \textsc{Insert}(R)$.

For each tuple $t = (q_i, \phi_1, \phi_2, q_j, \Delta_1, \Delta_2) \in R$, we define an artifact transition α_t as:

$$P_3(i) \wedge empty_{\phi_1}(P_1) \wedge empty_{\phi_2}(P_2) \wedge P_3'(j) \wedge \bigwedge_{k\neq j, k\leq f} \neg P_3(k) \wedge modify_{\Delta_1}(P_1) \wedge modify_{\Delta_2}(P_2)$$

Finally, let $\mathbb{T}^{\mathcal{A}}$ be the set of all α_t. It can be observed that paths in $\mathcal{K}_{\mathcal{S}^{\mathcal{A}}}$ represent the computations of $\mathcal{A}$. Therefore, there is an infinite path in $\mathcal{K}_{\mathcal{S}^{\mathcal{A}}}$ if and only if there is an infinite run in of $\mathcal{A}$. The existence of an infinite path corresponds to the truth of the formula $EG\top$.

Two relations. We show that we do not need a relation to store the states. The *configuration description* of a configuration (q, n_1, n_2) of $\mathcal{A}$ is a triple (q, v_1, v_2) for $v_i \in \{\top, \bot, ?\}$ s.t. if $v_i = \top$ then $n_i = 0$, and if $v_i = \bot$ then $n_i > 0$. The *transition description* is a triple (q, Δ_1, Δ_2) for $\Delta_i \in \{-1, 0, 1\}$ that is intended to represent the artifact transition "change the value of the i-th counter by Δ_i and change the state to q".

Let $\mathcal{Z}_c = \{0, 1, \dots, 9|Q| - 1\}$ and $\mathcal{Z}_a = \{9|Q|, \dots, 18|Q| - 1\}$. We choose an arbitrary bijection function $encode_c : Q \times \{\bot, \top, ?\} \times \{\bot, \top, ?\} \to \mathcal{Z}_c$ to encode the configuration descriptions as numbers and $encode_a : Q \times \{-1, 0, +1\} \times \{-1, 0, +1\} \to \mathcal{Z}_a$ to encode transition descriptions. Below we identify descriptions with their encodings.

To simplify the proof, we describe the set $\mathbb{T}$ informally.

For $X \subseteq \mathcal{Z}_a \cup \mathcal{Z}_c$, let $exactly(X, R)$ be a formula stating that $R \cap (\mathcal{Z}_a \cup \mathcal{Z}_c) = X$. For $R \in \{P_1, P_1', P_2, P_2'\}$, such a formula can be easily expressed in $CARL_{\mathcal{D},\mathbb{N}}$.

A configuration $\beta = (q_i, n, m)$ will be encoded as a database interpretation $D^{\beta} = (P_1^{\beta}, P_2^{\beta})$ such that $exactly(\{(q, ?, ?)\}, P_1)$, $exactly(\emptyset, P_2)$, $|P_1^{\beta}| = n + 1$ and $|P_2^{\beta}| = m$. So, the initial interpretation of $\mathcal{S}^{\mathcal{A}}$ will be s.t. $P_1 = \{(q_0, ?, ?)\}$ and $P_2 = \emptyset$.

The update of a configuration is performed in several steps by using the rules described below. We will denote transitions informally; e.g., "add n to P_1" stands for $\neg P_1(n) \wedge P_1'(n) \wedge \textsc{Insert}(P_1)$, etc. The rules below should be defined for all appropriate $q, q' \in Q$, $e_1, e_2 \in \{\bot, \top\}$ and $\Delta_1, \Delta_2 \in \{-1, 0, 1\}$.

We use the following example to illustrate the encoding. Let $\nu = (q_1, 0, 1)$, $\nu' = (q_2, 1, 1)$, be such $\nu \to^R \nu'$ and assume that $|Q| = 5$, i.e. $\mathcal{Z}$ contains only numbers less than 90. Assume that ν is encoded as $P_1 = \{(q_1, ?, ?)\}, P_2 = \{95\}$.

1. If $P_1((q, ?, ?))$, then if $\textsc{Empty}(P_2)$, add $(q, ?, \top)$ to P_2, otherwise add $(q, ?, \bot)$ to P_2. In both cases, remove $(q, ?, ?)$ from P_1.
   In the example, P_1 and P_2 change as follows: $P_1 = \{\}, P_2 = \{95, (q_1, ?, \top)\}$.
2. If $\textsc{Empty}(P_1)$ and $P_2((q, ?, e_2))$, add $(q, \top, e_2)$ to P_1, otherwise add $(q, \bot, e_2)$ to P_1. In both cases, remove $(q, ?, \bot)$ from P_2.
   In the example, P_1 and P_2 change as follows: $P_1 = \{(q, \top, \bot)\}, P_2 = \{95\}$.
3. If $P_1((q, e_1, e_2))$ and $(q, e_1, e_1, q', \Delta_1, \Delta_2) \in R$, then add (q', Δ_1, Δ_2) to P_1.
   In the example, P_1 and P_2 change as follows: $P_1 = \{(q, \top, \bot), (q', +1, 0)\}, P_2 = \{95\}$.
4. If $P_1((q', \Delta_1, \Delta_2))$ and $P_1((q, e_1, e_2))$, remove (q, e_1, e_2) from P_1 and modify P_2 according to Δ_2, i.e., if $\Delta_2 = -1$ then remove one element and so forth.
   In the example, P_1 and P_2 change as follows: $P_1 = \{(q', +1, 0)\}, P_2 = \{95\}$.
5. If $P_1((q', \Delta_1, \Delta_2))$ and P_2 does not contain (q, e_1', e_2') for any e_1', e_2', and $\neg P_2((q', \Delta_1, \Delta_2))$, add (q', Δ_1, Δ_2) to P_2.
   In the example, P_1 and P_2 change as follows: $P_1 = \{(q', +1, 0)\}, P_2 = \{95, (q', +1, 0)\}$.
6. If P_1 and P_2 contain (q', Δ_1, Δ_2), remove (q', Δ_1, Δ_2) from P_1 and add $(q', ?, ?)$ to P_2. *In the example, P_1 and P_2 change as follows:* $P_1 = \{\}, P_2 = \{95, (q', +1, 0), (q', ?, ?)\}$.
7. If $P_2((q', \Delta_1, \Delta_2))$ and $\neg P_1((q', \Delta_1, \Delta_2))$, then modify P_1 according to Δ_1 and remove (q', Δ_1, Δ_2) from P_2.
   In the example, P_1 and P_2 change as follows: $P_1 = \{1543\}, P_2 = \{95, (q', ?, ?)\}$.
8. If $P_2((q', ?, ?))$, remove $(q', ?, ?)$ from P_2 and add it to P_1.
   In the example, P_1 and P_2 change as follows: $P_1 = \{1543, (q', ?, ?)\}, P_2 = \{95\}$.

Clearly, $P_1 = \{1543, (q', ?, ?)\}, P_2 = \{95\}$ describes the configuration $(q', 1, 1)$.

Note that the rules above are formalised by means of conjunctions. For example, and instance of the rule 1 is formalised as $P_1((q,?,?)) \wedge \textsc{Empty}(P_2) \wedge \neg P_2((q,?,\top)) \wedge P_2'((q,?,\top)) \wedge \neg P_1'((q,?,?)) \wedge \textsc{Insert}(P_2) \wedge \textsc{Delete}(P_1)$. In this case, the conjunct $\textsc{Delete}(P_1)$ assures that $(q,?,?)$ is the only element deleted from P_1, while $\textsc{Insert}(P_2)$ and $\neg P_2((q,?,\top))$ guarantee that $(q,?,\top)$ is the only element added to P_2.

Paths in $\mathcal{K}_{\mathcal{S}^{\mathcal{A}}}$ are such that each 8-th state represents the configuration of $\mathcal{A}$, and the subpath containing every 8-th state of paths of $\mathcal{K}_{\mathcal{S}^{\mathcal{A}}}$ represents computations. So there exists an infinite path in $\mathcal{K}_{\mathcal{S}^{\mathcal{A}}}$ if and only if there is an infinite run of $\mathcal{A}$. □

3.3 Undecidability of model checking $CARL_{\mathcal{D},\emptyset}$-artifacts systems

In the proof of Theorem 15 we use arbitrary many constants. However, this is not the source of undecidability.

Theorem 18. *Model checking $CARL_{\mathcal{D},\emptyset}$-artifact systems against FO $\underline{^{sa}}$ CTL is undecidable.*

Proof. For a given two-counter automaton $\mathcal{A}$, we show how to define $CARL_{\mathcal{D},\emptyset}$-artifact systems $S_{\mathcal{A}}$ and an FO $\underline{^{sa}}$ CTL formula φ such that $S \models \varphi$ iff $\mathcal{A}$ has an infinite run. The proof is similar to the proof of Theorem 15 in case of three relations, except that now we use additional relations to represent the state of $\mathcal{A}$.

More precisely, we define $S^{\mathcal{A}}$ as $\langle \mathcal{D}^{\mathcal{A}}, \mathbb{N}, D_0^{\mathcal{A}}, \mathbb{T}^{\mathcal{A}} \rangle$, where $\mathcal{D} = \{P_1/1, \ldots, P_{|Q|+2}/1\}$, D_0 is such that all P_i are empty except for P_3 which is a singleton relation containing 0.

For each tuple $t = (q_i, \phi_1, \phi_2, q_j, \Delta_1, \Delta_2) \in R$, we define an artifact transition α_t as:
$\neg\textsc{Empty}(P_{i+2}) \wedge \mathit{empty}_{\phi_1}(P_1) \wedge \mathit{empty}_{\phi_2}(P_2) \wedge \neg\textsc{Empty}(P'_{j+2}) \wedge \bigwedge_{k \neq j} \textsc{Empty}(P'_{k+2}) \wedge \mathit{modify}_{\Delta_1}(P_1) \wedge \mathit{modify}_{\Delta_2}(P_2)$

It can be shown that $\mathcal{K}_{\mathcal{S}^{\mathcal{A}}}$ represent the computations of $\mathcal{A}$. □

3.4 Further results

Since there is a translation from $CARL_{\mathcal{D},\mathbb{N}}$ to $FO^{\mathbf{2}}_{\mathcal{D},\mathbb{N}}$, we obtain the following.

Corollary 19. *Model checking $FO^{\mathbf{2}}_{\mathcal{D},\mathbb{N}}$-artifact systems against FO $\underline{^{sa}}$ CTL whose database schema contains two unary symbols is undecidable.*

Corollary 20. *Model checking $FO^{\mathbf{2}}_{\mathcal{D},\emptyset}$-artifact systems against FO $\underline{^{sa}}$ CTL is undecidable.*

It can also be shown that including a single binary relation leads to undecidability. This result can be extended to any relations of arity greater that two.

Theorem 21. *Model checking $FO^{\mathbf{2}}_{\mathcal{D},\mathbb{N}}$-artifact systems whose database contains a single binary relation against FO $\underline{^{sa}}$ CTL is undecidable.*

Proof. We use the constants $1, 2, 3$ to simulate three relations.

As before we define $S^{\mathcal{A}}$ as $\langle \mathcal{D}^{\mathcal{A}}, \mathbb{N}, D_0^{\mathcal{A}}, \mathbb{T}^{\mathcal{A}} \rangle$. This time, we take $\mathcal{D} = \{P_1/2\}$ and D_0 is such that $P_1 = \{(3,0)\}$. We modify the set of artifact transitions from the proof in case of three unary relations in the following manner:

- Replace $P_i(t)$ by $P_1(i,t)$ and $P_i'(t)$ by $P_1'(i,t)$.
- Replace $\textsc{Empty}(P_i)$ by $\forall x \neg P_1(i,x)$.
- Replace $\textsc{Equal}(P_i)$ by $\forall x. P_1'(i,x) \Leftrightarrow P_1(i,x)$.
- Replace $\textsc{Insert}(P_i)$ by $\exists x. \neg P_1(i,x) \wedge P_1'(i,x) \wedge \forall y. y \neq x \Rightarrow (P_1(i,x) \Leftrightarrow P_1'(i,x))$.
- Replace $\textsc{Delete}(P_i)$ by $\exists x. \neg P_1'(i,x) \wedge P_1(i,x) \wedge \forall y. y \neq x \Rightarrow (P_1(i,x) \Leftrightarrow P_1'(i,x))$.

It can be checked that paths in $\mathcal{K}_{\mathcal{S}^{\mathcal{A}}}$ represent the computations of $\mathcal{A}$. So an infinite path exists iff there exists an infinite computation of $\mathcal{A}$. □

4 Model Checking $FO^{*}_{\mathcal{D},\mathbb{N}}$–Artifact Systems with a Single Unary Relation

While the results of the previous section are negative, in the following we identify a fragment for which the model checking problem is decidable.

Theorem 22. *Model checking $FO^{*}_{\mathcal{D},\mathbb{N}}$-artifact systems whose database consists of a single unary relation symbol against FO $\underline{^{sa}}$ CTL is decidable.*

The above identifies a restriction on the database schema, but allows the most general logic here considered to define the transitions of the systems. It is instructive to see that restricting our attention to unary relations still enables us to define interesting classes of systems.

Example 23. *An infinite state counter machine can help organising queues. The task of the machine is to print numbered tickets, display the ticket number on a screen, and remove the number from memory. The machine has three states: ON where it prints tickets and displays numbers, $CLOSING$ where it displays numbers but will not print tickets, and OFF where it remains idle.*

The machine can be described as an artifact system with a database consisting of a single unary relation. We can use the constants 0, 1 and 2 to represent the states ON, $CLOSING$ and OFF, and all other natural numbers to represent tickets. An example of a property that may be expressed in FO $\underline{^{sa}}$ CTL is whether it is always possible to remove all numbers from the machine's memory. It follows from Theorem 22 that checking this specification is decidable.

The rest of this section is organised as follows. Firstly, we investigate the expressive power of the logic $FO^{*}_{\mathcal{D}\oplus\mathcal{D}',\mathbb{N}}$. In the following subsection we define the logic $\mathfrak{Card}$ and we show that any set of artifact transitions defined in $FO^{*}_{\mathcal{D}\oplus\mathcal{D}',\mathbb{N}}$ can be replaced by an equivalent set of formulae from the logic $\mathfrak{Card}$. Then, in Subsection 4.2 we show how to transform an artifact system $\mathcal{S}$ into an infinite Kripke structure $\mathcal{K}'$ and an FO $\underline{^{sa}}$ CTL property φ into a CTL property φ' such that $\mathcal{K}_{\mathcal{S}} \models \varphi$ iff $\mathcal{K}' \models \varphi'$. In Subsection 4.3 we define a pushdown system $\mathcal{P}$ and a CTL* formula φ'' such that $\mathcal{K}' \models \varphi'$ iff $\mathcal{P} \models \varphi''$. We conclude in Subsection 4.4 by giving the algorithm solving the decidability of Theorem 22.

In the following we assume $\mathcal{D} = \{P/1\}$.

4.1 The logic Card

A *grounded literal* over $\mathcal{D}$ is one of the following formulae: $P(c)$, $\neg P(c)$, $P'(c)$, $\neg P'(c)$, where c stands for any constant.

Definition 24. *A formula is called a* Card-transition *if it is of the form $\Upsilon \wedge \bigwedge_{i\in I} \exists_{\gamma_i b_i} x\Phi_i$ where Υ is a conjunction of grounded literals, $\gamma_i \in \{\geq, \leq\}$, b_i are natural numbers (including 0), and Φ_i are a boolean combinations of $P(x)$ and $P'(x)$.*

The formulae of the logic Card *are disjunctions of* Card-transitions.

Intuitively, $\exists_{\leq b} x\Phi(x)$ represents the fact that there are at most b distinct elements satisfying Φ; conversely $\exists_{\geq b} x\Phi(x)$ signifies that there are at least b distinct elements satisfying Φ. The formal semantics of the logic Card is defined by the translation into $FO^*_{\mathcal{D},\mathbb{N}}$ that simply replaces each $\exists_{\geq b}\Phi(x)$ with $\exists x_1, \ldots, x_b. \bigwedge_{i\neq j} x_i \neq x_j \wedge \bigwedge_i \Phi(x_i)$ and $\exists_{\leq b}\Phi(x)$ with $\forall x_1, \ldots, x_{b+1}. \bigwedge_{i\neq j} x_i \neq x_j \Rightarrow \bigvee_i \neg\Phi(x_i)$.

As we prove below, the logics Card and $FO^*_{\mathcal{D},\mathbb{N}}$ have the same expressive power.

Example 25. *Consider the formula $\forall y(y \neq c_1 \Rightarrow (P(y) \Leftrightarrow P'(y)))$. This is equivalent to the disjunction of the following formulae:*

- $P(c_1) \wedge P'(c_1) \wedge \exists_{\leq 0} x(P(x) \Leftrightarrow \neg P'(x))$
- $\neg P(c_1) \wedge \neg P'(c_1) \wedge \exists_{\leq 0} x(P(x) \Leftrightarrow \neg P'(x))$
- $P(c_1) \wedge \neg P'(c_1) \wedge \exists_{=1} x(P(x) \wedge \neg P'(x))$ $\wedge \exists_{\leq 0} x(\neg P(x) \wedge P'(x))$
- $\neg P(c_1) \wedge P'(c_1) \wedge \exists_{\leq 0} x(P(x) \wedge \neg P'(x))$ $\wedge \exists_{=1} x(\neg P(x) \wedge P'(x))$

where $\exists_{=1}\Phi$ stands for $\exists_{\leq 1}\Phi \wedge \exists_{\geq 1}\Phi$.

Lemma 26. *Let Ψ be a $FO^*_{\mathcal{D}\oplus\mathcal{D}',\mathbb{N}}$ sentence. Then, there is a Card formula Ψ' equivalent to Ψ such that the size of Ψ' is exponential in the size of Ψ.*

Proof. The logic $FO^*_{\mathcal{D}\oplus\mathcal{D}',\mathbb{N}}$ is a fragment of first-order logic, so we can use standard tools. The result follows by applying Ehrenfeucht-Fraisse games to the case of unary relations. Indeed, for any property Ψ of $FO^*_{\mathcal{D}\oplus\mathcal{D}',\mathbb{N}}$ there is a number $n \leq |\Psi|$ such that if duplicator wins an n rounds game on the two structures, then both structures satisfy Ψ or none of them does.

Let C be the set of constants from Ψ. Given two structures $\mathcal{A}, \mathcal{B}$ we write $\mathcal{A} \sim_C \mathcal{B}$ if for all constants $c \in C$ we have $P^{\mathcal{A}}(c)$ iff $P^{\mathcal{B}}(c)$ and $P'^{\mathcal{A}}(c)$ iff $P'^{\mathcal{B}}(c)$.

Let $cnt(\Phi(x))$ be the number of elements not from C satisfying $\Phi(x)$ and $cnt_n(\Phi(X))$ be equal to $min(n + 1, cnt(\Phi(x)))$. For each model $\mathcal{A}$, we define $cnt_n(\mathcal{A})$ as a tuple (r, s, t, u) where

$$\begin{aligned} r &= cnt_n(P_{\mathcal{A}}(x) \wedge P'_{\mathcal{A}}(x)) \\ s &= cnt_n(P_{\mathcal{A}}(x) \wedge \neg P'_{\mathcal{A}}(x)) \\ t &= cnt_n(\neg P_{\mathcal{A}}(x) \wedge P'_{\mathcal{A}}(x)) \\ u &= cnt_n(\neg P_{\mathcal{A}}(x) \wedge \neg P'_{\mathcal{A}}(x)) \end{aligned}$$

That is, if $cnt_n(\mathcal{A}) = (1, n + 1, 3, 4)$, then $\mathcal{A}$ contains 1 world not from C satisfying $P_{\mathcal{A}}(x) \wedge P'_{\mathcal{A}}(x)$, more than n worlds not from C satisfying $P_{\mathcal{A}}(x) \wedge \neg P'_{\mathcal{A}}(x)$ and so on.

Let $\mathcal{A}$ and $\mathcal{B}$ be two structures such that $\mathcal{A} \sim_C \mathcal{B}$ and $cnt_n(\mathcal{A}) = cnt_n(\mathcal{B})$. On these structures, duplicator has a winning strategy and therefore Ψ cannot distinguish them.

We construct a Card-transition $\Psi_{A,A',r,s,t,u}$ such that $\mathcal{A}$ satisfies $\Psi_{A,A',r,s,t,u}$ iff $cnt_n(\mathcal{A}) = (r, s, t, u)$ and $\mathcal{A} \sim_C \mathcal{B}$. Let $r' = r + |A \cap (C \setminus A')|$, $s' = s + |(C \setminus A) \cap A'|$, $t' = t + |A \cap A'|$ and $u' = u + |(C \setminus A) \cap (C \setminus A')|$. Let $\Psi_{A,A',r,s,t,u}$ be the conjunction of the following formulae:

1. $\bigwedge_{c\in A} P(c) \wedge \bigwedge_{c\in C\setminus A} \neg P(c)$
2. $\bigwedge_{c\in A'} P'(c) \wedge \bigwedge_{c\in C\setminus A'} \neg P'(c)$
3. $\exists_{\geq r'} x(P(x) \wedge P'(x))$
4. only if $r < n + 1$: $\exists_{\leq r'} x(P(x) \wedge P'(x))$
5. $\exists_{\geq s'} x(P(x) \wedge \neg P'(x))$
6. only if $s < n + 1$: $\exists_{\leq s'} x(P(x) \wedge \neg P'(x))$
7. $\exists_{\geq t'} x(\neg P(x) \wedge P'(x))$
8. only if $t < n + 1$: $\exists_{\leq t'} x(\neg P(x) \wedge P'(x))$
9. $\exists_{\geq u'} x(\neg P(x) \wedge \neg P'(x))$
10. only if $u < n + 1$: $\exists_{\leq u'} x(\neg P(x) \wedge \neg P'(x))$

The formula $\Psi_{A,A',r,s,t,u}$ is indeed a Card-transition.

Let $\mathcal{X}_\Psi$ be the set of all the formulae of the form $\Psi_{A,A',r,s,t,u}$ such that there is a structure that satisfies $\Psi \wedge \Psi_{A,A',r,s,t,u}$, and let Ψ' be the disjunction of all the formulae in $\mathcal{X}_\Psi$. We show that any structure $\mathcal{A}$ satisfies Ψ if and only if it satisfies Ψ'.

Assume that $\mathcal{A}$ satisfies Ψ. Let $A = \{c \in C \mid P^{\mathcal{A}}(c)\}$, $A' = \{c \in C \mid P'^{\mathcal{A}}(c)\}$ and $(r, s, t, u) = cnt_n(\mathcal{A})$. Obviously, $\mathcal{A}$ satisfies $\Psi_{A,A',r,s,t,u} \wedge \Psi$, therefore $\Psi_{A,A',r,s,t,u}$ is in $\mathcal{X}_\Psi$ and $\mathcal{A}$ satisfies Ψ'.

Assume that $\mathcal{A}$ satisfies Ψ'. It follows that $\mathcal{A}$ satisfies $\Psi_{A,A',r,s,t,u}$ for some A, A', r, s, t, u such that there is a structure $\mathcal{B}$ satisfying $\Psi_{A,A',r,s,t,u} \wedge \Psi$. So $\mathcal{A} \sim_C \mathcal{B}$ and $cnt_n(\mathcal{A}) = cnt_n(\mathcal{B})$, and therefore, by the Ehrenfeucht-Fraisse argument presented above, $\mathcal{A}$ satisfies Ψ.

Therefore we have constructed a Card formula Ψ' that is equivalent to Ψ. A quick check shows that the number of elements in $\mathcal{X}_\Psi$ is bounded by $2^{2|C|} \cdot n^4$, which is exponential in size of Ψ. Note that if we consider formulae with a fixed number of constants, then the resulting formula is polynomial in size of Φ. □

The above proof is constructive and can be mechanised. As remarked, the construction gives a Card formula which is exponential in the size of the original $FO^*_{\mathcal{D}\oplus\mathcal{D}',\mathbb{N}}$ formula.

Note that for any set of artifact transitions $\mathbb{T}$ and formulae Ψ, Ψ', the sets $\mathbb{T} \cup \{\Psi, \Psi'\}$ and $\mathbb{T} \cup \{\Psi \vee \Psi'\}$ are equivalent; i.e., they prescribe the same transitions. Therefore, in the rest of this section we assume without loss of generality that all the artifact transitions are Card-transitions.

4.2 Infinite Kripke structures

Let $\mathcal{S} = \langle \mathcal{D}, \mathbb{N}, D_0, \mathbb{T}\rangle$ be a Card-artifact system and let $\mathcal{K}_\mathcal{S} = \langle \Sigma, D_0, \tau\rangle$ be the model of $\mathcal{S}$. Let φ be an FO $\underline{sa}$ CTL formula and $\mathcal{C}_a$ be the set of all constants appearing in $\mathbb{T}$ and φ. We define a Kripke structure $\mathcal{K}'$ and a CTL specification φ' such that $\mathcal{K}_\mathcal{S} \models \varphi$ iff $\mathcal{K}' \models \varphi'$.

Recall that the states of $\mathcal{K}_\mathcal{S}$, the model of $\mathcal{S}$, are in fact instances of P. The aim of this section is to define a Kripke structure $\mathcal{K}$ whose states represent the instances of P in the following way: an instance $D = \{P\}$ is represented by a pair $abs(D) = (P \cap \mathcal{C}_a, |P|)$, where $P \cap \mathcal{C}_a$ is the set of *relevant* constants that are in P and $|P|$ is the number of elements in P.

Let us consider $\mathcal{K}' = \langle \Sigma', s'_0, \tau', \pi' \rangle$ where:

- $\Sigma' = \{abs(s) \mid s \in \Sigma\}$ is the set of abstractions of all states in Σ,
- $s'_0 = abs(D_0)$,
- $\pi' : \Sigma' \to \mathcal{C}_a \cup \{e_0, e_1, \dots\}$ is a labelling such that $\pi((A, n)) = A \cup \{e_0, e_1, \dots, e_n\}$,
- $\tau' = \{(abs(D), abs(D')) \mid \tau(D, D')\}$.

We define a translation $\mathfrak{T}_{CTL}$ from FO^{sa} CTL formulae into CTL formulae. Let Ψ be a $FO^*_{\mathcal{D},\mathbb{N}}$ sentence and Ψ' be an equivalent sentence that is a disjunction of $\mathfrak{C}$ard-transitions. We translate Ψ' into a CTL formula Ψ'' by replacing every $P(c_i)$ with c_i, $\exists_{\geq k} x P(x)$ with e_k, $\exists_{\leq k} x P(x)$ with $\neg e_{k+1}$, $\exists_{\geq k} x \neg P(x)$ with $\top$ (recall that P is always finite), and $\exists_{\leq k} x \neg P(x)$ with $\bot$. Finally, we replace Ψ with Ψ''.

We define $\mathfrak{T}_{CTL}(\psi)$ as the result of applying the above translation to all the $FO^*_{\mathcal{D},\mathbb{N}}$ sentences in ψ, and we define $\varphi' = \mathfrak{T}_{CTL}(\varphi)$.

The following lemma follows from the fact that the logic $\mathfrak{C}$ard cannot distinguish between elements other than constants. So when checking for satisfaction there is no need to keep the precise information about the content of P.

Lemma 27. *For an artifact system S, its model $\mathcal{K}_\mathcal{S}$, an FO^{sa} CTL specification φ, let K' and φ' be the infinite Kripke structure and the CTL specification defined as above. Then, $\mathcal{K}_\mathcal{S} \models \varphi$ iff $\mathcal{K}' \models \varphi'$.*

Proof (sketch). We show by induction that for every subformula ψ of φ and every $D \in \Sigma$, we have $\mathcal{K}_\mathcal{S}, D \models \psi$ iff $\mathcal{K}', abs(D) \models \mathfrak{T}_{CTL}(\psi)$.

Consider the case when $\psi = AX\psi_1$ and let D be any state of Σ. Firstly, assume that $\mathcal{K}', abs(D) \models \mathfrak{T}_{CTL}(\psi)$. Let $D_1, \dots, D_n$ be all successors of D (i.e. $\tau(D, D_i)$ for all i). By the definition of τ', for each i we have $\tau'(abs(D), abs(D_i))$. Since $abs(D)$ satisfies $\mathfrak{T}_{CTL}(AX\psi_1)$, $abs(D_i)$ satisfies ψ_1 and, by inductive assumption, D_i satisfies ψ_1. Therefore, D satisfies ψ.

Assume that $\mathcal{K}_\mathcal{S}, D \models \psi$. Let (A', n') be a successor of $abs(D) = (A, n)$. This means that there are two states E, E' such that $abs(E) = (A, n)$, $abs(E') = (A', n')$, and $\tau(E, E')$. Let $n_c = |P^E \cap P^{E'} \setminus C_a|$ be the number of common elements in the relation P of E and E' except for constants from C_a. Let D' be such that $P^{D'}$ is a sum of A', any n_c elements of D and $n' - n_c - |A'|$ elements that are not in P^D or C_a. Then, for any $\mathfrak{C}$ard-transition Φ defined by using the constants from C_a we have $E, E' \models \Phi$ iff $D, D' \models \Phi$.

Therefore, we have $\tau(D, D')$; so D' satisfies ψ_1 and, by the induction hypothesis, $abs(D') = (A', n')$ satisfies $\mathfrak{T}_{CTL}(\psi_1)$. Since (A', n') was an arbitrary successor of $abs(D)$, we conclude that $\mathcal{K}', abs(D) \models \mathfrak{T}_{CTL}(\psi)$.

The remaining cases are similar and omitted. □

Finite representation. For convenience above we assumed that the labelling π' has an infinite codomain. However, φ' uses only finitely many propositional variables. In the rest of this section we assume that the codomain of π' is $\mathcal{C}_a \cup \{e_0, \dots, e_l\}$, where l is the greatest index such that e_l appears in φ'.

While the relation τ' is infinite, we can give a finite description for it. To do this, let b be the smallest natural number greater than all the numbers that appear in $\mathfrak{C}$ard-transitions of $\mathcal{S}$. Let $bound_b(n) = max(-b, min(n, b))$ be a function that returns $-b$ if $n < -b$, b is $n > b$ and n otherwise.

Let T be a set of tuples such that $(A, n_b, A', n'_b, \Delta) \in T$ if and only if for some n, n' such that $n_b = bound_b(n)$, $n'_b = bound_b(n')$, $\Delta = bound_b(n' - n)$ and $\tau'((A, n,), (A', n'))$.

This representation is sufficient since τ' is defined by $\mathfrak{C}$ard-transitions that do not distinguish sets larger than b. In other words, given a set T, we can construct τ' as follows: $\tau'((A, n,), (A', n'))$ if and only if $(A, bound_b(n_b), A', bound_b(n'_b), bound_b(n' - n)) \in T$.

Clearly, for any $(A, n_b, A', n'_b, \Delta) \in T$ we have $A, A' \subseteq C_a$, $n, n' \in \{0, \dots, b\}$ and $\Delta \in \{-b, \dots, b\}$, so T is finite.

4.3 Pushdown systems

Definition 28. *A* pushdown system *is a tuple $\mathcal{P} = (\Sigma^\mathcal{P}, q_0^\mathcal{P}, \Gamma^\mathcal{P}, \bot^\mathcal{P}, \tau^\mathcal{P}, \pi^\mathcal{P})$, where $\Sigma^\mathcal{P}$ is a set of states containing $q_0^\mathcal{P}$, $\Gamma^\mathcal{P}$ is a set of stack symbols containing the stack bottom symbol $\bot^\mathcal{P}$, $\Delta^\mathcal{P} \subseteq (\Sigma^\mathcal{P} \times \Gamma^\mathcal{P}) \times (\Sigma^\mathcal{P} \times (\Gamma^\mathcal{P} \setminus \{\bot^\mathcal{P}\})^*)$ is a finite set of transition rules, and $\pi^\mathcal{P} : \Sigma^\mathcal{P} \times \Gamma^\mathcal{P} \to Var$ is a labelling function for some fixed set of propositional variables Var.*

A configuration *of a pushdown system is a pair (s, α), where $s \in \Sigma^\mathcal{P}$ and $\alpha \in \Gamma^{\mathcal{P}*}$ starts from $\bot^\mathcal{P}$ and does not contain $\bot^\mathcal{P}$ at any other position. We define the transition relation $\to_\mathcal{P}$ as follows: $(s, \alpha\gamma) \to_\mathcal{P} (s', \alpha\alpha')$, where $\gamma \in \Gamma^\mathcal{P}$ and $\alpha, \alpha' \in \Gamma^{\mathcal{P}*}$, iff $(s, \gamma, s', \alpha') \in \tau^\mathcal{P}$.*

Runs are defined as usual (Hopcroft and Ullman 1979). It is known that model checking pushdown systems against CTL* is decidable (Bozzelli 2007).

In what follows, given a Kripke model we define a pushdown system whose configurations represent states (A, n) of the Kripke structure by using the system states to encode A and the stack to store n. In doing so we will ensure that the content of the stack is always a prefix of the word $012 \dots (b-1)b^\omega$. This will allow us to check easily the exact value of n if $n < b$. Since we can remove only one element from the stack at a time, we will use a number of auxiliary configurations to simulate a change of state of Kripke structure.

Formally, let $B = \{-b, \dots, b\}$, $B_+ = \{0, \dots, b\}$ and $P_C = \{A \mid A \subseteq C_a\}$. Below we define a pushdown system $\mathcal{P} = (P_C \cup P_C \times B \times B, \emptyset, B_+, 0, \tau'', \pi'')$ and a CTL* formula φ'' s.t. $\mathcal{P} \models \varphi''$ iff $\mathcal{K}' \models \varphi'$.

We represent a configuration of $\mathcal{P}$ of the form (q, α) as $(q, |\alpha| - 1)$. Since $(q, 0)$ is represented by $(q, 0)$, no ambiguity arises.

A configuration of the form (A, n) represents the state (A, n) of $\mathcal{K}'$. A configurations of the form $((A, n, k), m)$ for

$|n| < b$ is an auxiliary configuration that represents an intermediate state such that $min(b, n+m) = k$ and that the state precedes the state $(A, n+m)$ that will appear in $n+1$ steps. Similarly, a configuration of the form $((A, b, k), m)$ represents the situation where the value stored in the stack can be increased by any number greater than or equal to b. Finally, a configuration of the form $((A, -b, k), m)$ encodes the situation where the value stored in the stack can be decreased by any number greater than or equal to b.

Let $add\_one(m) = m.(min(m+1, b))$ where "." stands for concatenation. Formally, τ'' contains the following rules.

- $((A, b, k), m, (A, b, k), add\_one(m))$ for all possible A, k, m.
- $((A, n, k), m, (A, n-1, k), add\_one(m))$ for all $n > 0$ and all possible A, k, m.
- $((A, n, k), m, (A, n+1, k), \emptyset)$ for all $n < 0$ and all possible A, k, m.
- $((A, -b, k), m, (A, -b, k), \emptyset)$ for all possible A, k, m.
- $(A, n_b, (A', n, n'_b), n_b)$ for all $(A, n_b, A', n'_b, n) \in T$.
- $((A, 0, n'_b), n'_b, A, n'_b)$ and all possible A, n'_b.

Example 29. *Assume that* $\tau'((\emptyset, 4), (\{7\}, 3))$ *and* $b = 2$. *The corresponding computation of* $\mathcal{P}$ *is* $(\emptyset, 01222) \rightarrow_{\mathcal{P}} ((\{7\}, -1, 2), 01222) \rightarrow_{\mathcal{P}} ((\{7\}, 0, 2), 0122) \rightarrow_{\mathcal{P}} (\{7\}, 0122)$.

For $\tau'((\{7\}, 3), (\emptyset, 6))$, *the corresponding computation is:* $(\{7\}, 0122) \rightarrow_{\mathcal{P}} ((\emptyset, 2, 2), 0122) \rightarrow_{\mathcal{P}} ((\emptyset, 2, 2), 01222) \rightarrow_{\mathcal{P}} ((\emptyset, 1, 2), 012222) \rightarrow_{\mathcal{P}} ((\emptyset, 0, 2), 0122222) \rightarrow_{\mathcal{P}} (\emptyset, 0122222)$.

Finally, we define π'' as $\pi''((A, n, k), m) = \emptyset$ and $\pi''(A, m) = A \cup \{e_0, \ldots, e_m\}$.

Note that not all runs of $\mathcal{P}$ correspond to runs of $\mathcal{K}'$. For example, for $b = 2$ the run $(\emptyset, 0) \rightarrow_{\mathcal{P}} ((\emptyset, 2, 2), 0) \rightarrow_{\mathcal{P}} ((\emptyset, 2, 2), 01) \rightarrow_{\mathcal{P}} ((\emptyset, 2, 2), 012) \rightarrow_{\mathcal{P}} \ldots$ continuously increases the stack and will never reach a state of the form (A, m). To avoid such runs, we add a fairness constraint by considering only the paths satisfying e_0 infinitely often.

To transform φ' to a CTL* formula φ'', we define a function $\mathfrak{T}^*$ by induction as follows.

$$
\begin{array}{lcl}
\mathfrak{T}^*(p) & = & p, \text{ where } p \text{ is a propositional variable} \\
\mathfrak{T}^*(\neg\psi) & = & \neg\mathfrak{T}^*(\psi) \\
\mathfrak{T}^*(\psi_1 \vee \psi_2) & = & \mathfrak{T}^*(\psi_1) \vee \mathfrak{T}^*(\psi_2) \\
\mathfrak{T}^*(AX\psi) & = & A(GFe_0 \Rightarrow \neg e_0 U(e_0 \wedge \mathfrak{T}^*(\psi))) \\
\mathfrak{T}^*(A\psi_1 \mathcal{U} \psi_2) & = & A(GFe_0 \Rightarrow (e_0 \Rightarrow \mathfrak{T}^*(\psi_1))U \\
 & & (e_0 \wedge \mathfrak{T}^*(\psi_2))) \\
\mathfrak{T}^*(E\psi_1 \mathcal{U} \psi_2) & = & E(GFe_0 \wedge (e_0 \Rightarrow \mathfrak{T}^*(\psi_1))U \\
 & & (e_0 \wedge \mathfrak{T}^*(\psi_2)))
\end{array}
$$

Consider $\varphi'' = \mathfrak{T}^*(\varphi')$. We have the following.

Lemma 30. *For an infinite Kripke structure* K' *and a CTL specification* φ', *let* P *and* φ'' *be the pushdown system and the CTL** *specification defined as above. Then,* $\mathcal{K}' \models \varphi'$ *iff* $\mathcal{P} \models \varphi''$.

The proof of the above lemma follows from the construction of $\mathcal{P}$ and φ''.

4.4 Model checking

In view of the translation defined above we can now give the algorithm that establishes Theorem 22.

Algorithm `Input`: $FO^*_{\mathcal{D},\mathbb{N}}$-artifact system $\mathcal{S}$ built on a unary relation, FO $\underline{sa}$ CTL formula φ.
`Output`: TRUE or FALSE.

1. Transform the set of artifact transitions to the set of €ard-transitions as described in Subsection 4.1.
2. Generate a finite representation of the Kripke structure $\mathcal{K}'$ and a CTL formula φ' as described in Subsection 4.2.
3. Generate a pushdown system $\mathcal{P}$ and a CTL* formula φ'' as defined in Subsection 4.3.
4. Return the result of model checking $\mathcal{P}$ against φ''.

The Algorithm above gives the proof of Theorem 22. Notice that in the last step we employ the algorithm for model checking the whole of CTL*; so it can also be applied against sentence atomic FO-CTL*.

An upper bound for the model checking problem of Theorem 22 can be established by observing that model checking pushdown systems against CTL* is 2EXPTIME-complete (Bozzelli 2007) and it is applied to a pushdown system exponential in the size of the input.

Corollary 31. *The problem of model checking artifact systems whose database consists of a single unary relation against sentence-atomic FO-CTL** *is in* 3EXPTIME.

5 Conclusions

Artifact-centric systems have been put been forward as a new paradigm in data-aware services and they are increasingly being used as a user-oriented architecture upon which services can be deployed. The issue of verification of artifact-centric systems remains of paramount importance both at theoretical and at practical level.

A number of classes of artifact-centric systems have been proposed for which the verification problem is decidable. As discussed in the related work part of the introduction, a key requirement made of all these system is boundedness of the systems' executions. While it has been shown this can be imposed on the system at program level (Belardinelli, Lomuscio, and Patrizi 2011), there remain classes of scenarios whereby no bound can in principle be set either on the states or the runs of the system.

To explore the implications of this we have here addressed the verification of unbounded artifact-centric systems against sentence-atomic FO-CTL specifications. Our results show that not only the problem is undecidable in general, but that it remains so even when admitting only the simple artifact-centric descriptions built on the logics $CARL_{\mathcal{D},\mathbb{N}}$ and $CARL_{\mathcal{D},\emptyset}$.

While this points to a bleak picture for the verification of unbounded systems in general terms, we were able to identify a class of unbounded systems for which verification against sentence-atomic FO-CTL is decidable. This class is in a way "maximal" with respect to the relations in the database schema.

Abstract

In this paper we develop a general framework that allows for both knowledge acquisition and forgetting in the Situation Calculus. Based on the Scherl and Levesque (Scherl and Levesque 1993) possible worlds approach to knowledge in the Situation Calculus, we allow for both sensing as well as explicit forgetting actions. This model of forgetting is then compared to existing frameworks. In particular we show that forgetting is well-behaved with respect to the contraction operator of the well-known AGM theory of belief revision (Alchourrón, Gärdenfors, and Makinson 1985) but that knowledge forgetting is distinct from the more commonly known notion of logical forgetting (Lin and Reiter 1994).

Introduction

Typical Situation Calculus models do not consider the need for agents to forget knowledge. This reflects the types of applications to which formal models of agent action and behaviour have typically been applied. However, it is possible to identify classes of applications for which the need to model forgetting in an agent becomes crucial. Consequently, in this paper we develop a general model for forgetting acquired knowledge in the Situation Calculus. We then highlight useful sub-classes of this model.

The focus of this paper is to develop the theoretical machinery of agent forgetting. However, in order to motivate the importance of forgetting, we highlight two broad classes of potential applications: the modelling of bounded agents and the formal analysis of security protocols.

The most immediate application of forgetting is to model agents with limited resources (e.g., robots), or agents that need to deal with vast knowledge bases (e.g., cloud computing), or more ambitiously, dealing with the problem of lifelong learning. In all such cases it is no longer reasonable to assume that all knowledge acquired over the operation of an agent can be retained indefinitely. Furthermore, recent research on bounded Situation Calculus theories (Giacomo, Lespérance, and Patrizi 2012; 2013) shows that ensuring bounds on such theories can guarantee decidability of progression. The theory of forgetting we introduce here can be used to guarantee bounded Situation Calculus theories.

Copyright © 2014, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

A further motivation for the concept of forgetting is evident in the formal analysis of security and cryptographic protocols. Cryptographic protocols have previously been analysed using the Situation Calculus equipped with a notion of the knowledge of agents (Delgrande, Hunter, and Grote 2010). However, such an encoding cannot always represent the class of *nonmonotonic cryptographic protocols* (Rubin and Honeyman 1994), where a notion of forgetting can be important. For example, in the analysis of credit card protocols it is a critical requirement to model vendors that forget (i.e., not retain) customer credit card details.

In order to illustrate our approach to forgetting we consider the following running example. *A robot needs to enter a room that is protected by a closed door with a keypad lock. When the robot senses that the door is closed, it needs to download the key combination from an external data source (e.g., the cloud or a database). It can then use this key combination to open the door and enter the room. Furthermore, since the door will now be open, the robot no longer needs the key combination, so is free to forget this information.*

The rest of the paper proceeds as follows. First we introduce the Situation Calculus (McCarthy 1963; Reiter 2001) and its epistemic extension (Lesperance et al. 1995) that allows for knowledge acquisition without forgetting. We then present our approach that handles both knowledge acquisition and forgetting and perform an extensive analysis of its properties and the conditions under which both knowledge acquisition and forgetting can occur. Having established our approach to forgetting, we then place it within the broader context of two of the main models that have been developed within the literature: *AGM belief revision* (Alchourrón, Gärdenfors, and Makinson 1985) and *logical forgetting* (Lin and Reiter 1994). In particular, we show that our approach is well-behaved with respect to the AGM belief contraction postulates, but is distinct from that of logical forgetting since knowledge forgetting can provide for more fine-grained control over what is forgotten. Finally, we provide some concluding remarks and discuss directions for future research.

Background

Situation Calculus

The Situation Calculus provides a formal language based on classical first-order logic to describe dynamic domains (Mc-

Carthy 1963; Reiter 2001). It distinguishes three types of terms: *situations* representing histories as the world evolves; *fluents* denoting domain properties that may change as a result of actions; and, *actions* that can be performed by the reasoner.

The function $do(a, s)$ represents the situation that results from performing action a at situation s, while S_0 denotes the initial situation where no actions have taken place. For each action, a *precondition axiom* $Poss(a, s)$ specifies the conditions under which action a is possible in situation s and *successor state axioms* specify how the value of fluents change as the result of actions. Assuming perfect knowledge and no sensing actions, the precondition and successor state axioms for our example scenario can be encoded as follows:

$$\begin{array}{lcl} Poss(enter, s) & \equiv & Open(s) \wedge \neg InRoom(s) \\ Poss(usekey, s) & \equiv & \exists c.Key(c, s) \wedge \neg Open(s) \\ InRoom(do(a, s)) & \equiv & InRoom(s) \vee a = enter \\ Key(c, do(a, s)) & \equiv & Key(c, s) \\ Open(do(a, s)) & \equiv & Open(s) \vee a = usekey \end{array}$$

The first states that it is possible to enter the room if the robot is not already there and the door is open. The second states that it is possible to use the key code to open the door if there is a key code and the door is not already open. Finally, three successor state axioms are defined to indicate that: the robot will be in the room if it just entered it or was already there; key codes for the door do not change; and, the door will be open if it was already opened or the key code was entered.

With this formalisation it is possible to follow how the world evolves as actions are performed and, in particular, that the robot will be in the room if it inputs the key code, thus opening the door, and then enters the room.

It is useful to be able to refer to the relationship between situations resulting from a sequence of actions. In order to do this a partial order relation $<$ is defined over situations in order to indicate that one situation is the result of performing a sequence of actions in another situation:

$$\neg s < S_0, \quad s < do(a, s') \equiv s \leq s'$$

where $s \leq s'$ is shorthand for $s < s' \vee s = s'$. For a more comprehensive formulation of what is required of a Situation Calculus basic action theory, we refer to (Reiter 2001).

Situation Calculus with Knowledge

In its basic form the Situation Calculus can be used to show how the world changes in the face of actions. However, it lacks the ability to model how an agent with imperfect knowledge can both gain knowledge and act on that knowledge. To deal with this broader problem the Situation Calculus has been extended using a possible worlds framework to capture a notion of knowledge with sensing actions (Scherl and Levesque 1993). As we shall be drawing repeated comparisons between this extension and our own approach we shall refer to this extension as the *SL framework*.

Within the SL framework, an agent can be said to *know* that some fact ϕ is true if and only if ϕ is true in all possible states of the world that the agent can be in. This can be formalised using a special epistemic predicate $K(s', s)$ to represent the fact that in situation s the agent considers the world could equally be in situation s'. Situation s' is said to be *accessible* from s. Notions of knowledge are defined in terms of this epistemic relation:[1]

$$\begin{array}{l} \mathbf{Know}(\phi, s) \stackrel{\text{def}}{=} \forall s'.K(s', s) \supset \phi[s'] \\ \mathbf{KnowIf}(\phi, s) \stackrel{\text{def}}{=} \mathbf{Know}(\phi, s) \vee \mathbf{Know}(\neg\phi, s) \end{array}$$

The first definition states that an agent in situation s *knows* that fluent ϕ holds when ϕ holds in all *K* accessible situations. The second states that to *know if* something holds means to either know that it holds or to know that it doesn't hold. The predicate *K* is required to be reflexive, transitive and Euclidean, ensuring that the agent has introspection about its knowledge; it knows whether it knows something.

To allow for introspective statements, that is, to represent that an agent knows that it knows something, **Know** can be treated as a term when used in conjunction with the pseudo-variable *now* (Lesperance et al. 1995). This usage is made clear from the following expansion:

$$\mathbf{Know}(\mathbf{Know}(\phi, now), s) \equiv \forall s'.K(s', s) \supset \mathbf{Know}(\phi, s')$$

Now, reasoning about knowledge is not very interesting unless that knowledge can itself change over time and sensing actions provide a mechanism to achieve this. As with non-sensing actions, sensing actions require precondition axioms to determine when they are executable. For our example scenario we introduce two sensing actions *isopen* and *getkey* that are always executable. The first senses if the door is open while the second models the process of querying a data source for the correct key combination:

$$\begin{array}{lcl} Poss(getkey, s) & \equiv & True \\ Poss(isopen, s) & \equiv & True \end{array}$$

Next, the process of knowledge acquisition is encoded through the successor state axiom of the *K* relation. An example of such a successor state axiom, containing sensing actions for our robot scenario is as follows:

$$\begin{array}{l} K(s^*, do(a, s)) \equiv \exists s'.s^* = do(a, s') \wedge Poss(a, s') \wedge K(s', s) \\ \qquad \wedge a = isopen \supset [Open(s') \equiv Open(s)] \\ \qquad \wedge a = getkey \supset [\forall k.Key(k, s') \equiv Key(k, s)] \end{array}$$

For non-sensing actions, the accessible situations are simply the successors of all the situations that were previously accessible. However, for sensing actions only those situations that agree with the actual situation on the sensed fluent remain accessible. So, in the example scenario, the *isopen* sensing action ensures that only situations where the state of the door is the same are accessible, while the *getkey* action ensures that only the situations where all the keys are the same are accessible. Effectively, after performing the *isopen* action, the agent will know if the door is open and after the *getkey* action the agent will know about any keys.

The final component of the representation is to specify the truth of fluents in the initial situation and their possible

[1] $\phi[s]$ is the commonly used notation to represent that formula ϕ holds in the situation s; we use the name **KnowIf** rather than **KnowWhether** introduced in (Scherl and Levesque 1993).

alternatives. For example, that the door is closed but the robot doesn't know it and the door's key combination is C_1 but the robot only knows that it must be one of C_1 or C_2. Figure 1(a) shows a visualisation of this scenario and the accessibility of the alternative possible situations as the robot executes the sequence of actions resulting in it entering the room. Note, for simplicity and presentation we have only specified two possible keys but, of course, this could be extended to many key combinations through the specification of more alternative initial situations.

There is an important observation that can be made from the inclusion of the *K* relation and sensing actions. Namely, that it is possible to construct cases of hybrid sensing actions that both sense and change the environment by allowing sensing actions to also be contained in the non-*K* (i.e., fluent) successor state axioms. In such cases knowledge acquisition cannot be guaranteed because the sensing action could itself change the value of the sensed fluent. To avoid such pathological cases it is typical to consider only *pure* sensing actions where the sensing action only occurs in the successor state axiom for *K*.

A General Account of Knowledge and Forgetting

In this section we present our extension to the SL framework by incorporating the ability to forget the results of past sensing actions. The possible worlds approach is maintained, however we provide a simpler construction in terms of a possible situations relation, $W(s, s')$, which is then used to derive more complex epistemic properties.

Axiom 1 *Let* W *be a relation that is reflexive, transitive and Euclidean. The* possible worlds successor state axiom *for* W *is:*

$$\mathrm{W}(s^*, \mathrm{do}(a, s)) \equiv \exists s'.(s^* = \mathrm{do}(a, s') \wedge \mathrm{W}(s', s) \wedge \mathit{Poss}(a, s'))$$

This successor state axiom works in a similar manner to the original axiom for *K* in the sense that it tracks the evolution of possible situations as a result of actions. However, unlike the original *K* relation, *W* makes no reference to how the agent's knowledge changes as a result of these actions.

To account for sensing actions we first introduce the notion of a *sensing equivalence* relation *SEQ* as a means of separating the generic aspects of the formalism from those that are specific to a particular scenario:[2]

Definition 1 *Consider a Situation Calculus basic action theory* Σ*, a set of sensing actions* $a_1, \ldots, a_n$ *and corresponding sensed fluents* $\phi_1, \ldots, \phi_n$*. Then* $\mathrm{SEQ}(a, s', s)$ *is a* sensing equivalence *relation iff there exists an axiom in* Σ *of the form:*

$$\mathrm{SEQ}(a, s', s) \equiv \bigwedge_{i=1}^{n} a = a_i \supset [\nabla_i.(\phi_i[s'] \equiv \phi_i[s])],$$

where each ∇_i *is a composition of first-order quantifiers over the non-situation free variables in* ϕ_i*.*

[2]Later versions of the SL framework use similar approaches, introducing a sensing result function (Scherl and Levesque 2003) or sensing fluent (Levesque 1996).

In the definition of sensing equivalence each of the sensing actions a_i senses whether a formula ϕ_i is true or whether it is false in a given situation. For brevity we simply say that a_i *senses* ϕ_i. The equivalence specified by an *SEQ* relation is problem specific and encodes the knowledge that is acquired by the sensing actions. For the example scenario we can provide the following sensing equivalence relation:

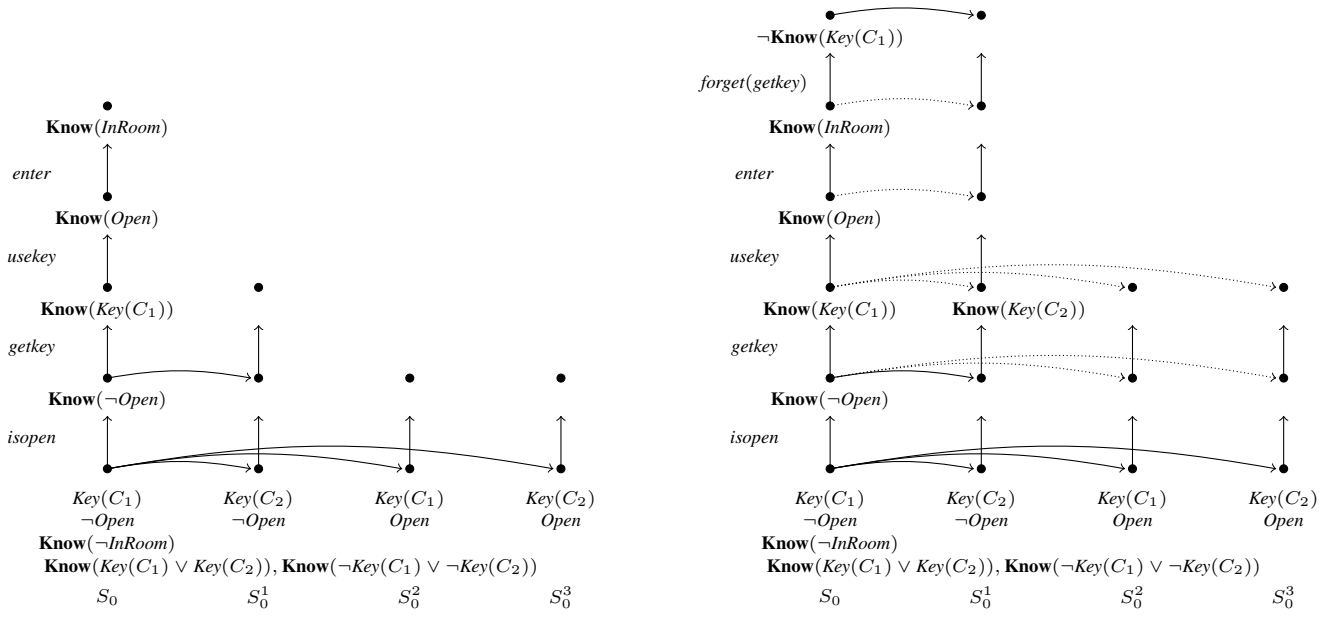
$$\begin{aligned}\mathit{SEQ}(a, s', s) \equiv\ & (a = \mathit{isopen} \supset [\mathit{Open}(s') \equiv \mathit{Open}(s)]) \wedge \\ & (a = \mathit{getkey} \supset [\forall k.\mathit{Key}(k, s') \equiv \mathit{Key}(k, s)])\end{aligned}$$

The *W* relation and successor state axiom in combination with the sensing equivalence relation can now be used to both capture the original Scherl and Levesque notion of knowledge as well as define a more general notion of knowledge that allows for forgetting actions.

Definition 2 *Consider a Situation Calculus basic action theory, extended with the successor state axiom for* W *and a sensing equivalence relation* SEQ*. Then* $\mathrm{K_M}$ *is a* knowledge acquisition relation *defined as:*

$$\begin{aligned}\mathrm{K_M}(s', s) \stackrel{\mathrm{def}}{=}\ & \mathrm{W}(s', s) \wedge \\ & [\neg\exists \hat{s}', \hat{s}, a.\mathrm{W}(\hat{s}', \hat{s}) \wedge \neg\mathrm{SEQ}(a, \hat{s}', \hat{s}) \wedge \\ & \quad \mathrm{do}(a, \hat{s}') \leq s' \wedge \mathrm{do}(a, \hat{s}) \leq s]\end{aligned}$$

Essentially, this definition states that every *W* relation is also a K_M relation unless it has been *blocked* by a sensing action for which the two situations disagree with respect to the sensed fluents. The definition of **Know** would then be defined in terms of K_M in the standard manner outlined earlier. For space reasons we do not prove this here but it is straightforward to observe that the original notion of agent knowledge is exactly captured by this new formulation.



However, we are interested in defining a more general notion of knowledge. This is possible with the help of an explicit forgetting action *forget* that enables an agent to forget previously acquired knowledge.

Definition 3 *Consider a Situation Calculus basic action theory extended with the successor state axiom for* W *and a sensing equivalence relation* SEQ*. Then* K *is a* general knowledge relation *defined as:*

$$\begin{aligned}\mathrm{K}(s', s) \stackrel{\mathrm{def}}{=}\ & \mathrm{W}(s', s) \wedge \\ & [\neg\exists \hat{s}', \hat{s}, a.\mathrm{W}(\hat{s}', \hat{s}) \wedge \neg\mathrm{SEQ}(a, \hat{s}', \hat{s}) \wedge \\ & \quad \mathrm{do}(a, \hat{s}') \leq s' \wedge do(a, \hat{s}) \leq s \wedge \\ & \quad \{\neg\exists s^{*\prime}, s^*, b.b = \mathrm{forget}(a) \wedge \\ & \qquad \mathrm{do}(a, \hat{s}') < \mathrm{do}(b, s^{*\prime}) \leq s' \wedge \\ & \qquad \mathrm{do}(a, \hat{s}) < \mathrm{do}(b, s^*) \leq s\}]\end{aligned}$$

Again, here **Know** is defined in the usual manner. *K* works in a similar manner to K_M in that it allows sensing actions to act as a block on the accessible situations. However, it further allows this block to itself be blocked by a forgetting action, thus re-instating a *K* accessible situation that might otherwise be inaccessible. In effect the agent will have forgotten what it had previously learned by sensing.

It is important to note that the single parameter of the forgetting action is itself an action, with the only useful case being that of a sensing action. Consequently, this construction formalises the notion of an agent that forgets the epistemic commitments of a previous sensing action rather than directly forgetting the value of a specified fluent.

(a) Knowledge in the SL Framework

(b) Knowledge with Forgetting

Figure 1: The progression of actions leading to the robot being in the room, and in (b) forgetting the key combination. Vertical lines indicate actions that are performed from the accessible situations. Solid curved horizontal lines represent *K* accessibility from the actual situation S_0 to the alternative possible situations, while in (b) dotted lines represent *W* only accessibility.

Furthermore, the agent retains the knowledge that the sensing action itself did in fact take place by virtue of the action history encoded in the situation. However, it simply cannot remember the result of that action. We can understand this behaviour as the distinction between *semantic* and *episodic* memory (see, for example, (Schacter, Gilbert, and Wegner 2011)). Specifically, we are concerned with forgetting semantic memory. Forgetting of episodic memory corresponds to the robot forgetting some of its past actions which can be achieved in a Situation Calculus context through the use of *progression* (Reiter 2001).

In order to simplify the encoding of knowledge acquisition and forgetting as part of a Situation Calculus basic action theory we introduce some restrictions as follows:

Definition 4 A Situation Calculus Epistemic Basic Action Theory (EBAT) *is a Situation Calculus Basic Action Theory* Σ *extended with the successor state axiom for* W *such that:*

1. *A precondition axiom for forgetting actions:* $Poss(\text{forget}(a), s) \equiv True$*;*
2. *The successor state axioms of* Σ *do not contain a reference to the function symbol* forget*;*
3. *The sensing equivalence relation (*SEQ*) does not contain a reference to the function symbol* forget*;*
4. *All sensing actions are* pure*; and,*
5. *Along with the other standard basic action theory axioms for the Situation Calculus extended with knowledge (see (Scherl and Levesque 2003)).*

These restrictions result in three distinct and non-overlapping sets of actions: sensing actions, forgetting actions and actions that change the world. As they are concerned with the agent's knowledge, where convenient we refer to the sensing and forgetting actions as *epistemic actions*.

The requirement for forgetting actions to always be executable and not mentioned in the successor state axioms is not strictly necessary but simplifies the formalisation. In particular, not allowing forgetting actions to be contained in either successor state axioms or the sensing equivalence relation ensures that forgetting actions serve only one purpose, namely to forget, and cannot be misappropriated for multiple purposes. Of course, one can always simulate such multi-purpose actions if necessary by introducing individual actions that must be executed in a block. Clearly these restrictions are not onerous.

Framework Analysis and Properties

We now turn to analysing the properties of our framework. In particular, we establish intuitive knowledge theorems for the framework. This does however require certain restrictions on the formalisation of a given scenario, the reasons for which require some explanation.

Limits of the Possible Worlds Approach

Contingent facts Firstly, it is important to observe that our framework inherits the limitations of the SL framework in that the set of initial situations establishes the boundaries over what knowledge about the world is subject to change and what must remain either known or unknown throughout. We refer to such changeable knowledge as *contingent* and

define this notion in relation to individual situations:

$$\textbf{Contingent}(\phi, s) \stackrel{\text{def}}{=} (\exists s'.W(s', s) \wedge \phi[s']) \wedge (\exists s'.W(s', s) \wedge \neg\phi[s'])$$

This establishes that a proposition is contingent in a situation if there is at least one related possible situation in which the proposition is true and another in which it is false. For completeness we say that a proposition is *necessarily* the case in a situation if it is not contingent in that situation.

The contingent facts are precisely those facts that are potentially discoverable about the world and therefore the target for sensing actions. However, it is important to observe that the set of contingent facts can vary as situations evolve. For example, if a door being open is contingent in some initial situation but an agent subsequently senses that the door is open and walks through it, then in the resulting situation the state of the door will no longer be contingent because there cannot be a possible world in which the agent walked through the closed door. Less obviously, a fact that was previously necessarily the case can become contingent after performing some action. For example, the action of replicating the truth value of a contingent fluent.

Knowledge acquisition without sensing While sensing is the primary means by which an agent can acquire knowledge, the theoretical construction of the framework masks a second method by which knowledge can be acquired without explicit sensing actions. This is a property that is implicit in the original SL framework as well as its various extensions, such as that of Shapiro *et al.* (Shapiro et al. 2011).

In essence the problem stems from how the precondition axioms are encoded and whether the representation of these axioms is intended to model the actions that an agent knows that it can execute, or the executability of actions irrespective of the agent's knowledge of whether those actions are executable. To clarify this problem, consider the scenario where the robot does not initially know if the door is open. Now, if the door happens to be open in the actual situation, then a precondition axiom defined without reference to the robot's knowledge allows it to walk through the door without knowing that it is open. However, in the alternative possible situation where the door was closed, this action was not possible, hence there will be no successor situation corresponding to the situation where the door is closed. Consequently, by definition the robot will "know" that the door is closed, despite never having sensed this about its environment.

At first blush this may not appear to be problematic. One might, for example, argue that if a person has their eyes closed and successfully walks through a door then they will know that the door must have been open in order for the action to have succeeded. However, such reasoning ignores the many sensing actions that would be taking place in such a scenario. Namely, that the person is able to know that the action was successful because they didn't feel the pain of hitting the door and finding themselves on the floor.

This problem can in practice be avoided with some added theoretical machinery. In particular, in order to formalise reasoning about agent *abilities*, the SL framework has been extended with the notion of an *action selection function* (Lesperance et al. 1995). This is a second-order construct that allows conditions to be defined such that an agent *can know whether or not it can get* to a situation where some property holds. Provided that one only considers sequences of actions where the agent knows that it can get to some state, then the problem of knowledge acquisition without sensing can be avoided.

Nevertheless the issue remains a troubling property of the framework. It is particularly problematic for our extension as it can affect the contingency of facts and consequently the conditions under which forgetting can take place.

Fortunately, the solution to this problem is relatively simple. Namely, to ensure that all action preconditions are specified so as to model the actions that the agent knows that it can execute. We shall refer to these as actions with *known preconditions*. With this in mind, the precondition axioms for the sample scenario can now be re-stated as follows:

$$\mathit{Poss}(\mathit{enter}, s) \equiv \textbf{Know}(\mathit{Open}, s) \wedge \textbf{Know}(\neg \mathit{InRoom}, s)$$
$$\mathit{Poss}(\mathit{usekey}, s) \equiv \exists k.\textbf{Know}(\mathit{Key}(k), s) \wedge \textbf{Know}(\neg \mathit{Open}, s)$$

Now it is possible for the robot to execute the *enter* action only when it knows that it is not currently in the room and knows that the door is open. Similarly, in order for the robot to use the key combination to open the door, it must know the combination and know that the door is closed. Note, actions that are always executable, such as the example sensing actions, implicitly have known preconditions (i.e., a tautology is true in every possible world and hence is known).

Epistemic Properties

We can now turn to establishing that the knowledge with forgetting framework genuinely satisfies the intuitive properties of an epistemic action theory. Namely, we establish that it satisfies the basic introspective properties of knowledge, that knowledge can indeed be acquired through sensing actions and, finally, that knowledge can also be forgotten through forgetting actions.

Introspection As is the case of the SL framework, our extension can be shown to also satisfy a strong notion of knowledge introspection. As a first step, it is useful to establish some key properties of the defined *K* relation.

Lemma 1 *Consider a Situation Calculus EBAT. The defined relation* K *is* reflexive*,* transitive *and* Euclidean*.*

Proof: Reflexivity is immediate since for every $W(s, s)$ relation $K(s, s)$ exists by definition. We now consider only the transitive case as the Euclidean case follows an identical argument. Consider if $K(s, s')$ and $K(s', s'')$ but $\neg K(s, s'')$. W is transitive so as $W(s, s')$ and $W(s', s'')$ therefore $W(s, s'')$. Hence $K(s, s'')$ is being blocked from holding by some sensing action a such that the fluent it senses, ϕ, is different between s and s''. But then the value of ϕ in s' must be different to one of either s or s''. Hence either $K(s, s'')$ or $K(s', s'')$ must be false and a contradiction follows. □

These properties of the *K* relation can now be used to establish that knowledge is indeed introspective.

Theorem 1 (Introspection) *Let Σ be a Situation Calculus EBAT, then for any ϕ and situation s:*

$$\Sigma \models \textbf{Know}(\phi, s) \textit{ iff } \Sigma \models \textbf{Know}(\textbf{Know}(\phi, now), s)$$

Proof: Assume that LHS holds but the RHS doesn't hold. Hence $\forall s'.K(s', s) \supset \phi[s']$ holds but $\forall s'.K(s', s) \supset (\forall s''.K(s'', s') \supset \phi[s''])$ does not. However, the only way for the second formula not to hold is if there is some s' and s'' such that $K(s', s)$ and $K(s'', s')$ and $\neg\phi[s'']$. But, from Lemma 1, K is transitive so $K(s'', s)$ must hold and contradicts with the LHS.

Now assume that the RHS holds but the LHS doesn't. So there exists some s^* such that $K(s^*, s)$ and $\neg\phi[s^*]$. Substituting s^* for an instance of s' in the RHS we have that $\forall s''.K(s^*, s) \supset K(s'', s^*) \supset \phi[s'']$ and since $K(s^*, s)$ holds so $\forall s''.K(s'', s^*) \supset \phi[s'']$. Now K is reflexive so $K(s^*, s^*)$ holds and therefore $\phi[s^*]$ must hold, which contradicts the assumption that the LHS doesn't hold. □

Knowledge Acquisition Naturally, it is important that an agent can actually gain knowledge through sensing actions, namely after sensing a contingent fluent the agent will know the truth value of that fluent.

Theorem 2 *Let Σ be a Situation Calculus EBAT, a_ϕ be a pure sensing action that senses fluent ϕ and is executable in situation s, then:*

1. $\Sigma \models \textbf{Know}(\phi, \text{do}(a_\phi, s))$*, where ϕ is true in s, or*
2. $\Sigma \models \textbf{Know}(\neg\phi, \text{do}(a_\phi, s))$*, otherwise.*

Proof: Case 1. Consider any s' such that $W(s', s)$ and $\neg\phi[s']$. If $Poss(a, s')$, then there will be a $W(do(a_\phi, s'), do(a_\phi, s))$ but a_ϕ detects the value of ϕ therefore $\neg SEQ(a_\phi, s', s)$ holds. Alternatively, $\neg Poss(a, s')$ so there will be no $W(do(a_\phi, s'), do(a_\phi, s))$. In either case $K(do(a_\phi, s'), do(a_\phi, s))$ will not hold. Hence the only situations in which $K(do(a_\phi, s'), do(a_\phi, s))$ holds will be those where the fluent ϕ will also hold, so $\textbf{Know}(\phi, do(a_\phi, s))$. Case 2. follows in an identical manner. □

Together Theorems 1 and 2 establish that the new framework does indeed capture the properties of the SL framework.

Forgetting In a similar manner to the establishment that not all facts are *contingent*, forgetting allows only some facts to be forgotten. We now establish precise conditions under which this can take place.

The simplest case of forgetting is where a forgetting action is performed immediately after its corresponding sensing action. Interestingly, even in this case there are some conditions that are required. The critical property is to preserve the contingency of a fluent after the sensing action. Unfortunately, even for a pure sensing action, contingency is not necessarily preserved, and it is possible to provide a simple example to highlight this fact.

Consider a sensing action a_ϕ that senses ϕ and has the precondition that it can sense ϕ only when ϕ is itself known (i.e., $Poss(a_\phi, s) \equiv \textbf{Know}(\phi, s)$). A set of possible situations can then be defined such that ϕ is both known and contingent. In such a case, after performing the sensing action, ϕ will still be known but will no longer be contingent.

The contrived nature of this example provides some hint that such sensing actions are not the typical types of sensing actions that we would want to consider and therefore we restrict our actions to remove such pathological cases.

Definition 5 *An action a is* contingency preserving *w.r.t. ϕ in s if ϕ is contingent in s iff ϕ is contingent in* $\text{do}(a_\phi, s)$.

In general it is reasonable to expect that an action that senses a fluent should be contingency preserving for that fluent, although not necessarily other fluents. Furthermore, it is straightforward to observe that, because forgetting actions are always possible, therefore they are contingency preserving for all fluents in all situations. We now establish the simplest condition under which forgetting can take place; cases where a fluent is forgotten immediately after sensing.

Lemma 2 *Let Σ be a Situation Calculus EBAT such that fluent ϕ is contingent in s and a_ϕ is a pure sensing action that preserves the contingency of ϕ in s, then:*

$$\Sigma \models \neg\textbf{KnowIf}(\phi, \text{do}([a_\phi, \text{forget}(a_\phi)], s))$$

Proof: Both, $\Sigma \models \neg\textbf{Know}(\phi, do([a_\phi, forget(a_\phi)], s))$ and $\Sigma \models \neg\textbf{Know}(\neg\phi, do([a_\phi, forget(a_\phi)], s))$ must be shown, but the proofs are identical so consider only the first. Similarly, whether ϕ is *true* or *false* in s are mirrored so only consider the first case. ϕ is contingent in s and a_ϕ preserves contingency, therefore after executing a_ϕ, ϕ will be contingent in $do(a_\phi, s)$ although ϕ will also be known (Theorem 2). Hence there is some $\neg SEQ(a, s', do(a_\phi, s))$ that is blocking $K(s', do(a_\phi, s))$ from holding. Forgetting actions preserve contingency so, after performing the forgetting action $forget(a_\phi)$, then any such block will itself be blocked by the forgetting action and therefore there will exist a world s'' such that $K(s'', do([a_\phi, forget(a_\phi)], s))$ and $\neg\phi[s'']$ hence ϕ will not be known. □

Of course, sensing followed immediately by forgetting is not a particularly useful scenario. Therefore we now consider the case where some arbitrary number of actions are executed in between performing the sensing and forgetting actions. However, in order for this to be possible, it is necessary to establish that the actions that occur between a sensing action and its corresponding forgetting action are in some sense independent of the fact being forgotten.

The key point in establishing a notion of the independence of fluents and actions is to observe that the preconditions and successor state axioms of a basic action theory establish dependencies between actions in terms of how they relate to fluents. If the value of some fluent is related to an action, then it may not be possible to forget the value of that fluent without first forgetting the action itself. However, as already outlined, our framework only provides a mechanism to forget the value of fluents and does not provide a mechanism to forget the history of past actions.

To properly capture these notions requires the definition of a number of properties. Firstly, it is important to capture how non-epistemic actions interact with particular fluents.

Definition 6 (Consequential Independence) *For a Situation Calculus EBAT Σ, an action a is said to be* consequentially independent *from ϕ iff:*

$$\Sigma \models \forall s.\phi[s] \equiv \phi[\text{do}(a, s)]$$

This definition captures whether or not an action can change the value of a fluent under some condition. Importantly, it makes no reference to the executability of an action in a situation. Instead, it only examines the effects of actions irrespective of whether some precondition has been satisfied. Hence it is a strong requirement that genuinely establishes that an action can have no direct effect on some property of the environment. For example, that picking up a cup has no direct effect on the state of a light.

As well as consequential independence, it is also necessary to consider the *epistemic independence* of fluents from an agent's actions.

Definition 7 (Epistemic Independence (non-forgetting)) *For a Situation Calculus EBAT Σ, a non-forgetting action a is said to be* epistemically independent *of ϕ in s iff:*

$$(\mathbf{Know}(\phi, s) \equiv \mathbf{Know}(\phi, \mathrm{do}(a, s))) \wedge$$
$$(\mathbf{Contingent}(\phi, s) \equiv \mathbf{Contingent}(\phi, \mathrm{do}(a, s)))$$

This establishes two specific criteria for an action to be considered epistemically independent of a fluent. Most obviously it cannot change the agent's knowledge of that fluent. This applies to directly sensing the fluent but also any indirect epistemic ramifications of the action. For example, sensing that a light is on means knowing that the switch is also turned on. However, equally important is that the action must preserve the contingency of a fluent.

Definition 7 only captures the notion of epistemic independence for non-forgetting actions. However, forgetting actions also affect what an agent knows and it is therefore necessary to extend this notion to forgetting actions.

Definition 8 (Epistemic Independence (forgetting)) *For a Situation Calculus EBAT Σ, a forgetting action* $\mathrm{forget}(a_\phi)$ *is said to be* epistemically independent *from ϕ in s iff a_ϕ is epistemically independent of ϕ in s.*

Simply, a forgetting action is epistemically independent of a fluent in exactly the cases where its corresponding sensing action is epistemically independent of that fluent.

We can now define a general notion of the independence of actions from fluents by grouping together the various specific types of independence.

Definition 9 (Independence) *For a Situation Calculus EBAT Σ, an action a is independent from fluent ϕ in situation s iff a is consequentially independent of ϕ in s and a is epistemically independent (forgetting and non-forgetting) of ϕ in s.*

Now that we are armed with a formal notion of the independence of actions from fluents, we can establish the conditions under which a fluent will be forgettable in a situation.

Definition 10 (Forgettable) *We say that a fluent ϕ is* forgettable *in situation s iff there is a situation s' such that $s = \mathrm{do}([a_\phi, a_1, \ldots, a_n], s')$, where ϕ is contingent in s', a_ϕ is a pure sensing action that senses ϕ and preserves the contingency of ϕ in s', and:*

1. *action a_1 is independent of ϕ in $\mathrm{do}(a_\phi, s')$; and,*
2. *for each $1 \leq i < n$, action a_{i+1} is independent of ϕ in $\mathrm{do}([a_\phi, a_1, \ldots, a_i]), s')$.*

It can now be established that our defined notion of forgettability does indeed capture the right conditions to allow the results of a sensing action to be known in one situation but forgotten in a some later situation.

Theorem 3 *Let Σ be a Situation Calculus EBAT such that fluent ϕ is forgettable in situation s and action a_ϕ senses ϕ, then:*

$$\Sigma \models \neg\mathbf{KnowIf}(\phi, \mathrm{do}(\mathrm{forget}(a_\phi), s))$$

Proof: Expanding, both $\Sigma \models \neg\mathbf{Know}(\phi, do(forget(a_\phi), s))$ and $\Sigma \models \neg\mathbf{Know}(\neg\phi, do(forget(a_\phi), s))$ must be shown, but the proofs are identical so consider only the first case. Similarly, whether ϕ is *true* or *false* in s are mirrored so only consider the first case. Applying the definition of ϕ being forgettable in s we have situation $s = do([a_\phi, a_1, \ldots, a_n], s')$, where ϕ is contingent in s'. Now provable by induction on the size of $a_1, \ldots, a_n$. Base case consider $n = 1$: Similar to Lemma 2. ϕ is known but contingent after action a_ϕ. Now, a_1 is independent of ϕ in $do(a_\phi, s')$ so ϕ is known and contingent in $do([a_\phi, a_1], s')$. Because ϕ is contingent in $do([a_\phi, a_1], s')$ so there is some $W(s'', do([a_\phi, a_1], s'))$ where $\neg\phi[s'']$ holds but is being blocked by some $\neg SEQ(a_\phi, s', s^*)$. Hence after executing $forget(a_\phi)$ this block will itself be blocked so there will be some $K(s''', do([a_\phi, a_1, forget(a_\phi)], s')$ where $\neg\phi[s''']$ so will not be known in $do([a_\phi, a_1, forget(a_\phi)], s')$. Now assume that this holds for $n = i$ and prove for $n = i + 1$. The proof for this is similar to the base case and stems from ϕ being contingent and known in $do([a_\phi, \ldots, a_i], s')$. Since ϕ is independent of a_{i+1} in $do([a_\phi, \ldots, a_i], s')$ so ϕ will also be known and contingent in $do([a_\phi, \ldots, a_{i+1}], s')$. ϕ being unknown in $do([a_\phi, \ldots, a_{i+1}, forget(a_\phi)], s')$ then follows in a straightforward manner. □

Theorem 3 establishes that knowledge can indeed be forgotten; after having been previously acquired through a sensing action.

It is worth observing that a sensing action immediately followed by its corresponding forgetting action results in an agent forgetting both the sensed value and any derived consequences. However, the presence of intermediate actions in between sensing and forgetting can prevent these consequences being lost. For example, if our example scenario (Figure 1(b)) had also included an initially accessible situation where there was no actual key, then after performing all the actions and forgetting the value of the key, the robot would nevertheless have retained the acquired knowledge that a key did in fact exist.

Introspection about Action Consequences A final property that is worth noting concerns the introspective nature of knowledge and what the agent currently knows about what it will know in the future. It is possible to show that in the current situation the agent knows that after sensing a fluent it will know if that fluent is true or false, however it also knows that it will no longer know this fact after subsequently forgetting the sensing action. Due to space restrictions we only state the theorem without proofs.

Theorem 4 *Let Σ be a Situation Calculus EBAT such that ϕ is forgettable in situation s and action a_ϕ senses ϕ, then:*

$$\Sigma \models \begin{array}{l} \mathbf{Know}(\mathbf{KnowIf}(\phi, \mathrm{do}(a_\phi, now)), s) \ \wedge \\ \mathbf{Know}(\neg\mathbf{KnowIf}(\phi, \mathrm{do}([a_\phi, \mathrm{forget}(a_\phi)], now)), s) \end{array}$$

Relationship to Existing Frameworks

In this section we explore the relationship of our framework to well-known formalisms in the literature that provide for similar behaviours.

AGM Belief Contraction

While we are concerned with notions of knowledge, there is nevertheless a close link to the research on belief change. Belief change is concerned with establishing how (rational) agents should change their beliefs in light of new information. The most well-known formal account of belief change is that of AGM belief revision (Alchourrón, Gärdenfors, and Makinson 1985) which defines rationality postulates that should be preserved by belief change operators.

Of particular interest to our account of forgetting is that the effects of a forgetting action are comparable to the AGM belief contraction operator. For reference, the traditional AGM belief contraction postulates are as follows.

(K–1) For any sentence ϕ and any belief set K, $K - \phi$ is a belief set. (**closure**)
(K–2) If $\phi \notin Cn(\emptyset)$, then $\phi \notin K - \phi$. (**success**)
(K–3) $K - \phi \subseteq K$. (**inclusion**)
(K–4) If $\phi \notin K$, then $K - \phi = K$. (**vacuity**)
(K–5) If $\phi \in K$, then $K \subseteq Cn((K - \phi) \cup \{\phi\})$. (**recovery**)
(K–6) if $\phi \leftrightarrow \psi \in Cn(\emptyset)$ then $K - \phi = K - \psi$. (**extensionality**)

In showing the link to belief contraction, it is first necessary to provide a bridge from the AGM framework to ours. Fortunately, we can adopt the approach already outlined in Shapiro *et al.* (Shapiro et al. 2011). In particular Shapiro *et al.* observe that, in the Situation Calculus framework, an agent is said to believe (in our case, know) a formula if the theory entails that the formula is believed (known). However, unless the theory is complete with respect to the beliefs (knowledge) of the agent, then we may not be able to determine whether some formulas are actually believed (known) or not. In contrast, within belief change frameworks, the beliefs of an agent are explicitly associated with a belief set, with the implicit closed-world assumption that those formulas not in the belief set are not believed. To align the two frameworks Shapiro *et al.* therefore assume a model M of the theory Σ which is used to fix the belief state of the agent. We adopt this approach here and assume a model of the theory in order to fix on the *knowledge state* of the agent.

Definition 11 *We denote the* knowledge state *of a situation s (in M) by $\mathbf{K}(s)$ as:*

$$\mathbf{K}(s) = \{\phi : M \models \mathbf{Know}(\phi, s)\}$$

We can now provide a definition of what it means to expand a knowledge state by a formula.

Definition 12 *We denote the expansion of a knowledge state at situation s by ϕ (in M) by:*

$$s + \phi \stackrel{\text{def}}{=} \{\psi : M \models \mathbf{Know}(\phi \supset \psi, s)\}$$

It is worth observing that this notion of knowledge state expansion should not be confused with sensing. Sensing actions sense particular fluents and have precondition axioms that determine when that action is possible. On the other hand, knowledge state expansion simply defines the resulting state when given an initial state and an arbitrary formula that is taken to be known.

The AGM allows for the contraction of any (non-tautological) formula. However, our framework is more selective about what can be forgotten and therefore requires some qualifications.

Definition 13 *We denote the* forgettable *formulas at a situation s by $\mathbf{F}(s)$ as:*

$$\mathbf{F}(s) = \{\phi, \neg\phi : \phi \textit{ is forgettable in } s\}$$

An AGM belief contraction-like operator can now be defined within our extended Situation Calculus framework that specifies the conditions under which contraction is possible.

Definition 14 ($s - \phi$) *We denote the contraction of s by ϕ as $s - \phi$ and define it as follows:*

$$s - \phi \stackrel{\text{def}}{=} \begin{cases} \mathrm{do}(\mathrm{forget}(a_\phi), s), & \textit{if } a_\phi \textit{ senses } \phi \textit{ and} \\ & \phi \textit{ is forgettable in } s; \\ s, & \textit{otherwise.} \end{cases}$$

As a notational convenience we can indicate when two formulas are equivalent with respect to a Situation Calculus basic action theory Σ:

$$\phi \equiv_\Sigma \psi \stackrel{\text{def}}{=} \Sigma \models \forall s.\phi[s] \equiv \psi[s]$$

Finally, we can provide and prove rationality postulates for our contraction operator that mirror the original AGM belief contraction postulates.

Theorem 5 (Contraction) *For any situation s and fluents ϕ and ψ that are forgettable in s:*

(**K**–1) $\mathbf{K}(s - \phi)$ *is deductively closed.* (**closure**)
(**K**–2) $\phi \notin \mathbf{K}(s - \phi)$. (**success**)
(**K**–3) $\mathbf{K}(s - \phi) \subseteq \mathbf{K}(s)$. (**inclusion**)
(**K**–4) *If* $\phi \notin \mathbf{K}(s)$ *and* $\neg\phi \notin \mathbf{K}(s)$ *then* $\mathbf{K}(s - \phi) = s$. (**vacuity**)
(**K**–5) *If* $\phi \in \mathbf{K}(s)$, *then* $\mathbf{K}(s) \subseteq \mathbf{K}(s - \phi) + \phi$ *or* $\mathbf{K}(s) \subseteq \mathbf{K}(s - \phi) + \neg\phi$ (**recovery**)
(**K**–6) *if* $\phi, \psi \in \mathbf{F}(s)$ *and* $\phi \equiv_\Sigma \psi$ *then* $\mathbf{K}(s - \phi) = \mathbf{K}(s - \psi)$. (**extensionality**)

Proof: For (**K**–1) it is straightforward to see that *K* as defined is always deductively closed. (**K**–2) is a direct consequence of Theorem 3. (**K**–3) can be shown by examining the definition of *K* and confirming that what is known after a forgetting action will be a subset of what is known before the forgetting action. (**K**–4) is a direct result of the definition of contraction that only forgettable fluents (or their negations)

can be contracted and that only fluents in the knowledge state can be forgotten. (**K**–5) is a consequence of deductive closure, expansion operator $s + [\neg]\phi$, and the defined contraction operator. (**K**–6) is a consequence of the deductive closure of $\mathbf{K}(s)$, $\mathbf{K}(s - \phi)$ and that the resulting knowledge states $\mathbf{K}(s - \phi)$ and $\mathbf{K}(s - \psi)$, ϕ is true in every situation in which ψ in true. □

Theorem 5 shows that forgetting in the Situation Calculus is well-behaved with respect to the AGM contraction postulates. It is worth clarifying the definition of the recovery postulate (**K**–5). While contraction is defined here with respect to a forgetting action, expansion is not defined in terms of sensing actions but rather in terms of a knowledge set. One reason for this is that an expansion operator defined in terms of sensing actions could easily be shown to fail recovery in cases where a sensing action's precondition is not satisfied after the forgetting action. For example, consider a robot that senses whether a light is on in the bedroom, then moves to the kitchen. If it then forgets that the light was on in the bedroom it cannot simply re-sense the fluent as it would first need to move back to the bedroom. However, an important aspect of the AGM recovery postulate is that it provides a notion of minimality; namely, that contraction does not throw away more than it needs to. Consequently, the chosen definition of expansion fits closely the intention of the AGM in defining a notion of recovery.

Literal Forgetting

In this paper we are interested in the notion of *knowledge forgetting*. However, the more commonly studied form of forgetting is that of *logical forgetting* (Lin and Reiter 1994). In a formal sense, logical forgetting involves the replacement of a formula with one that is logically weaker and comes in two forms: forgetting a grounded literal or fact (also known as *literal forgetting*) and forgetting a relation.

While logical and knowledge forgetting are superficially unrelated, nevertheless recent work has established a connection between literal forgetting and belief erasure (Nayak, Chen, and Lin 2007). Therefore, it is worth exploring whether there is any connection between logical and knowledge forgetting. However, we shall show that in general there is no direct equivalence between the two and that logical forgetting is more drastic in what is forgotten than is strictly necessary for knowledge forgetting.

In the following discussion we only provide a brief outline of the formalism behind literal forgetting, however the interested reader is referred to (Lin and Reiter 1994). Literal forgetting is defined in terms of models of theories where conditions are provided such that a theory T' is the result of *forgetting about* ground atom p in theory T (written *forget*$(T; p)$). A key result is that, for finite theories, literal forgetting can be achieved through a number of purely syntactic manipulations:

1. For formula φ and ground atom $P(\vec{t})$, let $\varphi[P(\vec{t})]$ denote the replacement of occurrences of $P(\vec{t'})$ in ϕ by the disjunctive tautology: $[\vec{t} = \vec{t'} \wedge P(\vec{t})] \vee [\vec{t} \neq \vec{t'} \wedge P(\vec{t'})]$.
2. Denote $\varphi^+_{P(\vec{t})}$ as the result of replacing $P(\vec{t})$ by $true$ in $\varphi[P(\vec{t})]$, and $\varphi^-_{P(\vec{t})}$ as the result of replacing $P(\vec{t})$ by $false$ in $\varphi[P(\vec{t})]$.

Hence for $T = \{\varphi\}$ and ground atom p:

$$\mathit{forget}(T, p) = \{\varphi^+_p \vee \varphi^-_p\}$$

Example 1 (from (Lin and Reiter 1994)) *Let $T = \{\varphi\}$, where $\varphi = \forall x.student(x)$ and we want to forget that $student(John)$. Now, $\varphi[student(John)]$ is:*

$$\forall x.[x = John \wedge student(John)] \vee [x \neq John \wedge student(x)].$$

Hence $\varphi^+_{student(John)}$ is equivalent to:

$$\forall x.x \neq John \supset student(x)$$

and $\varphi^-_{student(John)}$ is equivalent to:

$$\forall x.x \neq John \wedge student(x)$$

So forget$(T; student(John))$ *is equivalent to:*

$$\{\forall x.x \neq John \wedge student(x)\}$$

As is clear from Example 1, literal forgetting provides for a strong form of forgetting that removes the given literal entirely from the theory. Unfortunately, for our purposes, this is too strict a requirement for the form of knowledge forgetting that we require. This can be seen with reference to the robot scenario.

Firstly, in order to align the two frameworks, we can reuse the notion of a knowledge state defined in terms of a model (Definition 11). Now, consider the knowledge state of the robot in the example scenario from the point after it has entered the room but before it performs the forgetting action (Figure 1(b)). At this point the robot will certainly know that C_1 is the key combination. However it will also have the base knowledge that exactly one of C_1 and C_2 is the key combination. Hence the robot's knowledge state will contain the following key related clauses: $\mathit{Key}(C_1), \mathit{Key}(C_1) \vee \mathit{Key}(C_2), \neg\mathit{Key}(C_1) \vee \neg\mathit{Key}(C_2)$. Then, after forgetting, the robot will no longer know that C_1 is the key but critically it will still know that the key is exactly one of C_1 or C_2. Hence it will retain the key related facts: $\mathit{Key}(C_1) \vee \mathit{Key}(C_2), \neg\mathit{Key}(C_1) \vee \neg\mathit{Key}(C_2)$. The robot has forgotten the result of the sensing action and no more.

On the other hand, if we were to perform logical forgetting of $\mathit{Key}(C_1)$ on the robot's state, then applying the syntactic method outlined earlier, all references to the literal $\mathit{Key}(C_1)$ will be removed from the knowledge state and each of the three key related clauses will be replaced by $True$. Hence the robot will not only have forgotten that C_1 is the key but also that the key is one of C_1 or C_2.

This example highlights that knowledge forgetting is indeed distinct from logical forgetting. In particular, the knowledge forgetting approach can provide for a more fine-grained form of forgetting where appropriate.

Conclusion and Future Work

In this paper we have motivated the need for agents to be able to forget knowledge. Based on an existing approach to

modelling agent knowledge acquisition in the Situation Calculus (Scherl and Levesque 1993), we developed a formal framework that allows for an agent to both acquire and forget knowledge. An extensive analysis of the framework was provided, highlighting important cases under which knowledge acquisition and forgetting can take place. We further evaluated our new framework against existing models that provide for similar behaviour. In particular, we showed that our model is well-behaved with respect to the well-known AGM contraction postulates (Alchourrón, Gärdenfors, and Makinson 1985), but is distinct from the notion of logical forgetting (Lin and Reiter 1994). In this latter case it was shown that knowledge forgetting can provide for more fine-grained control over what information can be forgotten.

This work presents a number of interesting avenues for future research. Importantly, the relationship to notions of forgetting in epistemic logics (Zhang and Zhou 2009; van Ditmarsch et al. 2009) should be explored. While not concerned with environmental change as a result of actions, nevertheless there are commonalities with Situation Calculus formalisms that deserve further exploration. For example, the formalisation of knowledge forgetting from Zhang and Zhou (Zhang and Zhou 2009) defines four postulates for a forgetting operator, which it should be possible to show are satisfied by our notion of forgetting.

It would also be useful to see if the techniques used to achieve forgetting in epistemic logics, for example the *introspective forgetting* approach (van Ditmarsch et al. 2009), can be applied to our framework. Depending on the requirements of the problem domain, this could potentially provide for alternative forgetting actions, perhaps with different properties and fewer restrictions over what knowledge can and cannot be forgotten.

Finally, it would be interesting to explore the applications that were motivated in the introduction. In particular, the application to the analysis of nonmonotonic cryptographic protocols would most probably necessitate an extension of this model to the multi-agent context. Using previous research that extends the original Scherl and Levesque knowledge framework to the multi-agent setting in the context of game playing (Schiffel and Thielscher 2011), it would then be necessary to see if similar techniques could be applied to our extended framework.

Computing Narratives of Cognitive User Experience for Building Design Analysis KR for Industry Scale Computer-Aided Architecture Design

Mehul Bhatt, Carl Schultz, Madhura Thosar
Cognitive Systems, and
Spatial Cognition Research Center (SFB/TR 8)
University of Bremen, Germany

Abstract

We present a cognitive design assistance system equipped with analytical capabilities aimed at anticipating architectural building design performance with respect to people-centred functional design goals. The paper focuses on the system capability to generate *narratives of visuo-locomotive user experience* from digital computer-aided architecture design (CAAD) models. The system is based on an underlying declarative narrative representation and computation framework pertaining to conceptual, geometric, and qualitative spatial knowledge. The semantics of the declarative narrative model, i.e., the overall representation and computation model, is founded on: (**a**) conceptual knowledge formalised in an OWL ontology; (**b**) a general spatial representation and reasoning engine implemented in constraint logic programming; and (**c**) a declaratively encoded (narrative) construction process (based on search over graph structures) implemented in answer-set programming.

We emphasise and demonstrate: complete system implementation, scalability, and robust performance & integration with industry-scale architecture industry tools (e.g., Revit, ArchiCAD) & standards (BIM, IFC).

Motivation

Professional planners, designers, engineers, and architects are required to imagine and anticipate user experiences and requirements given a *design*;[1] designers embed these aspects into their designs typically via an iterative refinement process that is primarily driven by creativity, heuristics, and interdisciplinary domain expertise. Whilst achieving the correspondence between physical (design) *structure and function*, architects go through a process of creative visuo-spatial abstraction, design conceptualisation, and the translation of an abstract specification into a concrete product that can be built in the physical world. In doing so, the architect must adopt and anticipate the perspective of a range of possible stakeholders, people groups, and situations, e.g., regular users, users with special needs (blindness, wheel-chair access, elderly), children, fire-fighters, and emergency situations. Put simply, the architect is confronted with the task to produce an elaborate human-centred description of the *perceptual* and *locomotive experience* of the users of the building being designed.

Contemporary CAAD Technology A Computer-Aided Architecture Design (CAAD) model consists of a detailed 3D description of a physical environment. Built on basic geometric primitives such as *point, line-segments, and polygons*, professionally designed CAAD models produced using contemporary design tools such as ArchiCAD and Autodesk consist of an elaborate specification sufficiently suited for civil engineering and product deployment tasks, e.g., involving ensuring structural consistency, advanced building simulation of aspects such as energy, air-flow, and cost-estimation.

Within architectural computing, recent years have witnessed the development of novel forms of representational and computational paradigms, also inherently geometrically-driven, such as parametric and generative design. However, what CAAD models and advanced structural engineering and simulation methods lack is a human-centred, semantic perspective of the design. In essence, within state of the art CAAD technology, the design conception, semantic modelling, and design communication (e.g., by 3D visualization) modalities have continued to retain their essential engineering-centred "*geometric*" character over the years.

Next-Generation CAAD Next-generation people-centred design *systems, frameworks, assistive tools, educational aids, and design policies* necessitate foundational abstraction and computational building blocks where the modalities of human perception, action, environmental experience, and design conception and semantics are central. Our research in this context addresses the following questions:

Q1. Contemporary computer-aided architecture design (CAAD) tools provide robust geometric modeling and structural engineering methods; how can the future evolution of (architectural) design computing bring notions of design semantics, structure, function, and people-centred design to the fore at an ontological, representational and computational level?

Q2. What is the role of specialized forms of visuo-spatial

[1] By design, we refer to spatial design in general, and building architecture design in particular. By conventional design systems, we mean computer-aided architectural design (CAAD) tools.

perception, abstraction, and commonsense spatial reasoning, within the broader realm of design computing, spatial design assistance, and tools for design learning and education?

Q3. What is the nature and form of the analytical feedback that designers and planners expect during the early design conception and iterative refinement phase? What are the implications of this from the viewpoint of the usability, interface, and human-computer interaction design aspects of architectural design (assistance) systems?

From the viewpoint of (Q1–Q3), the particular emphasis of our research has been on investigating the in-roads from the field of KR as foundational technologies within next-generation CAAD systems. Our perspective on artificial intelligence (AI) for (architecture) design is founded on the articulation of the *Science of Design* by Herbert Simon, and with Simon's interpretation of design as a "*decision-making process under constraints of physics, logic, and cognition*" (Baldwin, 2007). This view of the scientific design process underlies much of what artificial intelligence has to offer by way of its formal representational and computational apparatus to the domain of design computing.[2]

Cognitive CAAD Our basic proposition is that the foundational informatics of (architecture) design systems, tools, and assistive analytical aids concerned with creative spatial design and engineering tasks should also be based on modalities of visual and spatial cognition at the scale of everyday human perception and thinking. Toward this end, we propose that *design semantics, commonsense spatial reasoning and cognition*, and *visuo-spatial abstraction and computing* should be the driving forces underlying the foundations of next-generation design computing systems and paradigms. Next-generation CAAD should approach architecture computing from the perspective of *spatial informatics*, and appeal to *space* at the scale of everyday human perception and thinking in the context of *spatial cognition* (Bhatt, Schultz, and Freksa, 2013).

Our research addresses the representation of *space* from a formal modelling and computational viewpoint, i.e., *space*, as it is interpreted within the computer science disciplines concerned with the investigation of artificial intelligence and knowledge representation in general, and logic-based geometric and spatial representation and reasoning in particular (Bhatt et al., 2011). This field report focusses on the KR-specific aspects in the backdrop of system components concerned with design knowledge abstraction, representation, and reasoning. This report elaborates on (F1–F5):

I. Scope — Architecture Design

F1. *professional architectural design* as a function-driven iterative refinement process involving the structuring of *empty space*

F2. the *structuring of empty space* by an architect as being driven by the anticipation of visuo-spatial and locomotive user experience of people in built-up space (and in different situations)

II. Methods — AI for Design Computing

F3. the need for next-generation design tools and frameworks to regard human-centred modalities of *visuo-spatial perception and cognition* as being central;

F4. with respect to the "design as problem solving" paradigm of Simon (Simon, 1969, 1996), the development of artificial intelligence and spatial cognition & computation driven people-centred *analytical design computing* foundations for next-generation design systems

III. Demonstration — Declarative Narrativisation

F5. the computational *narrativisation of user experience* by way of declaratively modelled analytical descriptions of user experience externalised using natural language. This serves as: (1) a concrete example of our concept for KR for next-generation design computing foundations; and (2) a narrative-based *cognitivity benchmark* for qualitatively evaluating the functionality of our people-centred analytical design computing framework.

The paper presents an overview of the overall cognitive design assistance system, whilst emphasising:

- the underlying (general) declarative techniques for commonsense conceptual and qualitative spatial representation and reasoning rooted in methods such as formal ontology and description logics, constraint logic programming, and answer-set programming (Gelfond and Lifschitz, 1988; Baral, 2003); and
- the system capability to generate *narratives of cognitive user experience* based on the underlying KR-driven model and implementation as a model for next-generation people-centred analytical design computing foundations.

The paper illustrates case-studies and results obtained from a fully implemented system. The case-study focusses on *narratives of user experience* in the Museum Calouste Gulbenkian in Lisbon, Portugal. However, we emphasise that the narrative generation capability is functional for any digital model of a building that conforms to architecture industry standards, namely, the Building Information Model (BIM) (Eastman et al., 2008) and Industry Foundation Classes (IFC) (Froese et al., 1999). In this context, we also provide empirical results about the performance of the computational framework, focussing on the core design analysis algorithms and graph search processes implemented in answer set programming.

[2] In recent years, several interdisciplinary initiatives comprising of computer scientists, engineers, psychologists, and designers have addressed the application of artificial intelligence techniques for solving problems that accrue at several stages of the design process: design creativity and conceptualization, functionality specification, geometric modelling, structural consistency & code-checking, optimization, collaborative (design) workflow management, and a plethora of other issues. The journal "Artificial Intelligence for Engineering Design, Analysis and Manufacturing" completed two decades of publishing in 2007 and its anniversary publication is a good overview of the area (Brown, 2007; Gero, 2007). A sketch of '*40 years of design research*' is available in (Bayazit, 2004).

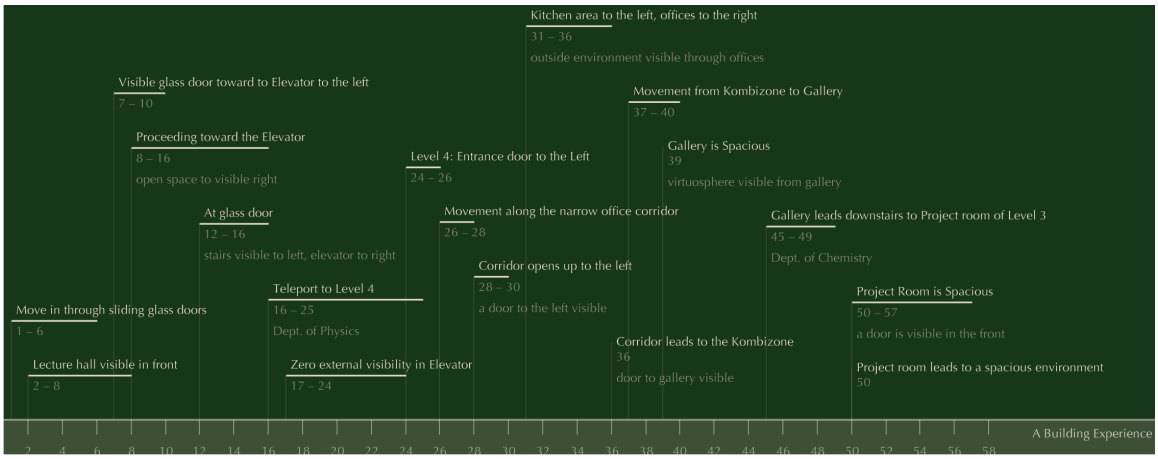

Figure 1: A Visuo-Locomotive Building Experience

Narrative and Design Cognition

A *narrative* in its most general (dictionary definition) form corresponds to "*a spoken or written account of connected events; a story*". Narratives serve a crucial role in everyday human perception and cognition; narrativisation of everyday perceptions by humans, and the significance of narratives in communication, interaction, and belief formation has been investigated under several frameworks, e.g., discourse analysis and narratology (Herman, Jahn, and Ryan, 2005), the narrative paradigm (Fisher, 1987), and through several other interdisciplinary initiatives involving the arts, humanities, and natural sciences. Most recently, the trinity of logic, language, and computer science has begun nurturing the field of "*computational models of narratives*" (Mani, 2012; Finlayson et al., 2013). To understand the nature of narratives from the viewpoint of the research presented in this paper, consider the following task:

> **Moving around in a building**. You enter a building (e.g., a museum, or air-port), possibly for the first time; as you walk around, guided by its internal structure, you (are required to) form and record your experience based on visuo-spatial, locomotive, and environmental affordance-based perceptions in the building.

Given the objective to externalise the observed perceptions in the building as required above, a human subject would be able to achieve the task using a range of modalities grounded in language, diagrams, schematisations etc. The experience may be described using a range of descriptive modalities such as written or spoken natural language (e.g., involving expressive motion, path, and qualitative spatio-linguistic predicates), diagrammatic representations (e.g., sequence graphs, bubble diagrams, schematisations of the environment), wayfinding experience (rotation or turn actions performed, getting lost) etc. For instance, a natural language description of the experience could be as follows (Fig. 1):

> **A Narrative of user experience**. As you move in through the passage of the sliding doors, you see a circular lecture hall directly in front through the glass panel, the elevator on the left...Exiting the elevator on Level four, there is a door to the left, leading up to a long, narrow corridor with an sequence of offices on the right...

Basically, human cognitive processes concerned with perceptual information processing would be able to conceptualise and externalise *a story* —linguistic or otherwise– that reports the building experience with relative ease; a large-scale experiment —typical in the field of environmental psychology (Bechtel and Churchman, 2002)— with many subjects would serve as a good reflection of the collective narrative of user experience in the environment under consideration; Fig. 1 presents one example of such an aggregate qualitative description of the experience of users in a given building. Architects concerned with designing a building are confronted with *imagining and anticipating* the perceptual experience of building users during the initial (design) conception phase, at a time when all that exists is *empty space* (Fig. 3(a), and 3(g)). In general, architects must envision the cognitive experiences of a range of people / user groups in different situations (in addition to externalising their own specialist analyses on functional design performance, and creative & aesthetic preferences).

Assistive design computing systems that can —based on an underlying formal representation and reasoning apparatus— generate narratives of user experience with the descriptive complexity of an architect or a user of a building are therefore needed, and can serve a good developmental benchmark. Methodologically, the objective of such systems is to provide high-level, semantic, analytical design computing capabilities aimed at assisting the architect or designer in a function-driven creative design task.

In this paper, we use the framework of narratives to report on a set of KR-driven *analytical design computing* capabilities concerned with providing decision-support to an architect or planner. Our design assistance system is able to compute narratives of user experience solely from geometric CAAD models or building master plans. Our long-term goal

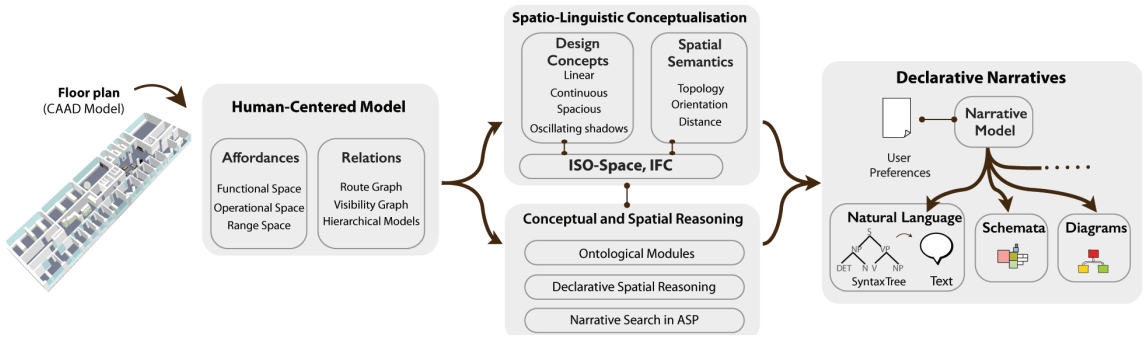

Figure 2: Reverse Engineering CAAD: Overview of Declarative Narrativisation Process

is to achieve a level of analytical accuracy, and semantic and descriptive quality and expressibility that is comparable with the performance of specialist designers, and novice users of buildings – this guides our broad-based work on computational narratives for KR-driven architectural design computing & cognition.

Computing Narratives

We adopt the conceptual framework of *narratives*, and specialise it for computing declarative narratives directly from 3D CAAD models of built-up spaces; this is akin to *cognitively-driven reverse engineering of CAAD models*. The semantic information that is obtainable from the computed narratives of user experience consist of visuo-spatial, locomotive, and affordance-based analytical content conforming to qualitative, spatio-linguistic conceptualisations pertaining to built-up spaces in the minds of people – both specialist architects, as well as potential users of a building.

Declarative Narrativisation Descriptions of user experience in buildings, e.g., in the form of a linguistic narrative, may be human-generated, or they could be generated by a system or suite of algorithms:

1 *Human-Generated Narratives*. Listing 1 (Fig. 4) depicts an example of the kind of natural language description that a human user may generate. The descriptions are representative of a user experience recording in an existing public building. We refer to the descriptions in Listing 1 as "*narratives of user experience*".

2 *System Generated Narratives*. Listings 2 (Fig. 4) is an example of computationally generated narratives of user experience — these have been generated solely on the basis of an elaborate 3D geometric CAAD model (of a real museum building). We refer to the formal knowledge structures and models from which such (linguistic or other) analytical descriptions of user experience can be generated as "*declarative narratives of user experience*". We refer to the process of computationally generating the formally characterised declarative narratives as *declarative narrativisation*.

Why Declarative? The declarative-ness (of narrativisation) signifies the existence of models that can be reasoned and queried upon, e.g., within a traditional declarative KR framework such as logic programming, constraint logic programming, description logic based reasoning, answer-set programming, and even other commonsense reasoners based on expressive action description languages.

The Declarative Narrativisation Framework

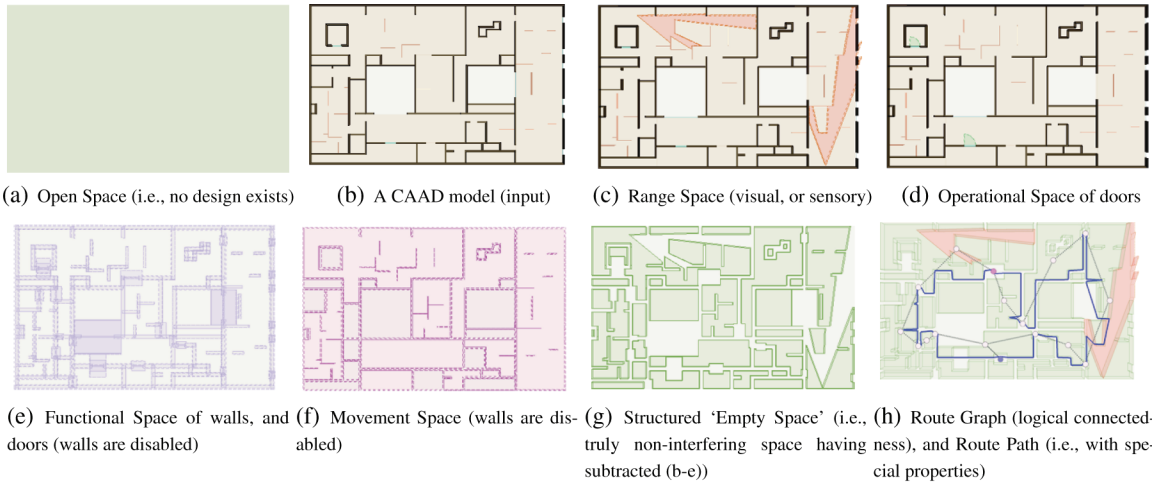
Figure 2 presents a conceptual overview of the narrativisation framework, system components, and the steps leading up to the computation of the declarative narratives, and the generation of language as a way to materialise the analytical information contained in the declarative narratives. Core components (NF1–NF3) are elaborated in the following:

NF1. People-Centered Design Typology Affordance spaces are spatial entities whose geometric extensions in space are derivable from the other (explicitly defined) material objects (e.g., door, wall, furniture; Fig. 3(b)), or their attributes, e.g., the opening space of a door can be computed from basic parameters of the door itself. Affordance spaces are derived from the abstracted shape geometries of physical objects chiefly using (a) polygonal boolean operations (intersection, difference, union) (Lauther, 1988), (b) line-of-sight calculations (Asano et al., 1985), and Minkowski sum (Kaul, O'Connor, and Srinivasan, 1992):

A1. *Movement Spaces*. Union of navigable surfaces (e.g. slabs) subtracted by obstacles such as walls (Fig. 3(f)).

A2. *Range Spaces*. Point-visibility polygons (isovist) restricted to the sensor's angular field of view and focus distance (Fig. 3(c)).

A3. *Operational Spaces*. Sweeping, extruding, translating, rotating, and scaling parts of the physical geometry of the reference object (e.g. sweeping a door panel; Fig. 3(d)).



A4. *Functional Spaces*. Buffer of the physical geometry of the reference object subtracted by obstacles (Fig. 3(e)).

A5. *Empty Spaces*. Union of movement spaces subtracted by other affordance spaces such as functional and range spaces spaces (Fig. 3(g)).

A6. *Route Graph*. Connectivity relations are intersections between movement spaces and waypoints (e.g. doors). Actual route paths provide precise co-ordinates of motion along a route (Fig. 3(h)).

A7. *Visibility Graph*. Visibility relations are intersections between visibility spaces and objects (Fig. 6(c))

The spatial design typology in (A1–A7) provides a basis to further analyse and "make sense" of the "*shape of the*

(a) Open Space (i.e., no design exists) (b) A CAAD model (input) (c) Range Space (visual, or sensory) (d) Operational Space of doors

(e) Functional Space of walls, and doors (walls are disabled) (f) Movement Space (walls are disabled) (g) Structured 'Empty Space' (i.e., truly non-interfering space having subtracted (b-e)) (h) Route Graph (logical connectedness), and Route Path (i.e., with special properties)

Figure 3: Structuring Empty Space. Illustrated using the derivations computed by our design analysis engine. Floor plan: *Museum Calouste Gulbenkian, Lisbon, Portugal*.

Listing 1. Human Generated User Experience (Gaizauskas et al., 2012): (1) The main entrance to the building is located in a corner under an overhang, which does not allow it to be visible to patients easily. (5) The immediate interior area around the entrance feels reassuring because it is open and airy. (11) Most of the windows in the consultation rooms overlook the courtyards. (18) [The] space behind the sculpture could be used for outdoor seating in the summer and passers-by would be able to see that there was a cafe available in the area.

Listing 2. System Computed Specialist Analysis: The layout and spatial organisation of the museum maintains 'continuity' between locations. The overall plan follows a circular structure, starting at the front lobby, passing through Rooms A, B, C, D, and via the North Door of Room E. The rooms flow linearly, and maintain visibility with the external environment (except during the segment between Room C and Room D). By removing Wall Y in Room X, the circular ring structure can be converted to a hierarchical structure with Room Z as the central hub. Direct sunlight exposure is achieved in approximately 85% of the floor plan. Region X never receives any sunlight at anytime during the year.

Figure 4: Extracts of (1) human narratives about buildings (Gaizauskas et al., 2012), and (2) System Computed Narratives from a CAAD model of the Museum Calouste Gulbenkian, Lisbon, Portugal

empty" (Bhatt, Schultz, and Huang, 2012) that results from a configuration of a designed structure as available within a CAAD model. This is done by establishing a formal link between low-level physical design structure, and high-level conceptualisation of design function as identifiable by the spatio-linguistic conceptualisation of architects, i.e., by formalising modelling and reasoning about design semantics.

NF2. Design Semantics and Ontology Whereas the philosophy of *form and function* in design is a well-studied topic, the formal modelling of *structural form* and resulting *artefactual function* within design assistance systems remains elusive. We make these definitions explicit by ontologically modelling architectural domain entities, and their properties and related constraints. We interpret "(structural) form" and "(artefactual) function" by specifying modular ontologies and their interplay for the architectural design domain.

Multi-Perspective Semantics and Modularity. Consider the illustration in Fig. 5: an abstraction such as a Room or Wall may be identified semantically by its placement within an ontological hierarchy and its relationships with other conceptual categories. These different categories are used by a designer during the initial design conceptualisation phase. However, when a design is implemented in a CAAD tool, the same concepts acquire a new perspective, i.e., the designer has to interpret design concepts in terms of points, line-segments, polygons and other geometric primitives available by the design tool. Given the lack of design semantics within contemporary design tools, no solution is available for a knowledge-based system to make inferences about the conceptual design and its geometric interpretation within a CAAD model in a unified manner. Our approach is to model these perspectives and their respective spatial semantics by using modular ontologies that individually comply with one of the perspectives. Presently, we represent conceptual, qualitative, and quantitative ontological modules using the Web Ontology Language (OWL). These modularly specified ontologies not only reflect the thematically different perspectives in a more adequate way but they also provide a clear ontological representation of the interplay and exchange between form and function, and underlying spatial constraints. This also directly supports modular conceptual and spatial reasoning (M1-M3):

M1. *Conceptual Space* This ontological module reflects terminological information of architectural entities. Here, the entities are regarded as such, i.e., they are defined according to their properties without taking into account the

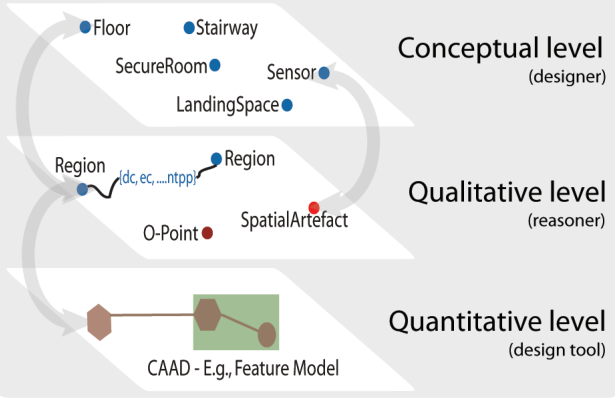


Figure 5: Multi-Perspective Semantics and Ontological Modularity

context in which they are put. The concept space is based on DOLCE (Masolo et al., 2003), in particular, on the OWL version DOLCE-Lite[3]. For instance, the class construction below specifies that types of buildings, e.g., courthouse, museum or university, are non-physical endurants that depend on an actual (physical) building, which provides the building's type or function:

$$\text{BuildingType} \sqsubseteq \text{dolceLite:non-physical-endurant} \sqcap \exists\, \text{dolceLite:generically-dependent-on} \,.\, \text{PhysicalBuilding}$$

Module M1 defines other similar constructs that occur in the design domain, such as VisualSensor, SlidingDoor, LandingSpace, OpenFloor.

M2. *Quality Space* This ontological module reflects qualitative spatial information of architectural entities. In particular, the module uses relations as provided by the topological spatial calculus RCC-8 (Randell, Cui, and Cohn, 1992), and calculi pertaining to other aspects of space. Qualitative spatial relations provide an abstraction method for specifying high-level design knowledge, e.g., a Room is necessarily a *proper part* of a Building. For instance, the category OpSpaceDoor specifies the region that is composed by a door and its opening angle, the category OpSpaceWall specifies the region that is composed by the external boundary of a wall, and the category OpSpaceWindow specifies the region that is composed by a windows and its opening angle.

$$\begin{aligned} \text{OpSpaceDoor} &= \langle \text{has\_operational\_space} \rangle^{M2}\, \text{Door} \\ \text{OpSpaceWall} &= \langle \textit{has\_operational\_space} \rangle^{M2}\, \text{Wall} \\ \text{OpSpaceWindow} &= \langle \textit{has\_operational\_space} \rangle^{M2}\, \text{Window} \end{aligned}$$

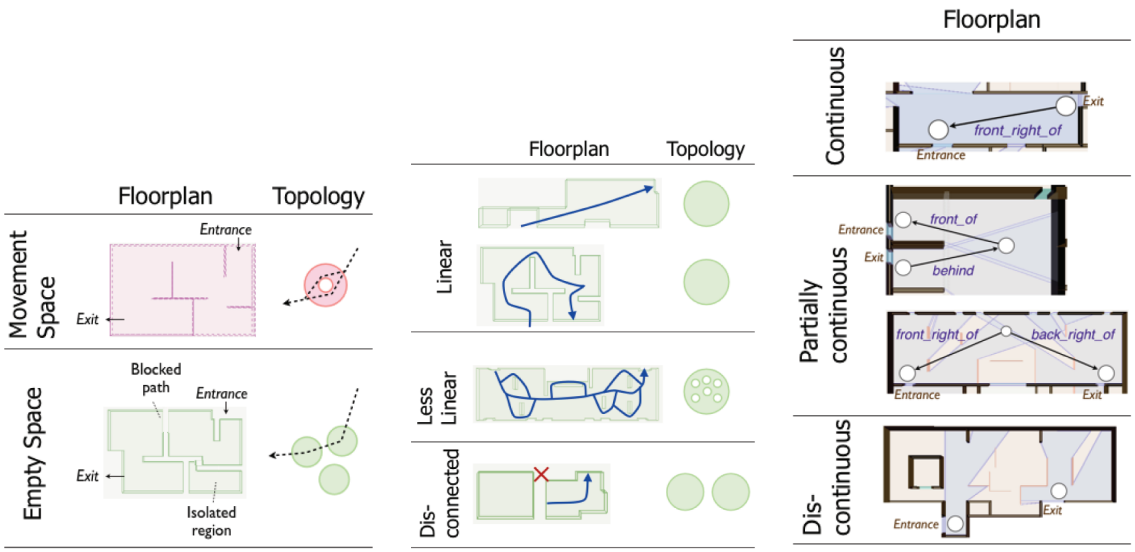
The following constraint encodes the requirement that all doors have to be externally connected (EC) with doors, walls, or windows:

$$EC(\text{OpSpaceDoor},\ \sqcup\ \text{OpSpaceWall} \sqcup \text{OpSpaceWindow})$$

[3]DOLCE-Lite. http://www.loa-cnr.it/ontologies/DOLCE-Lite.owl

M3. *Quantity Space* This ontological module reflects geometric information of architectural entities. It is closely related to the Industry Foundation Class (IFC) data model (Liebich et al., 2006) and partially mirrors the IFC classes; IFC consists of a non-proprietary data model and exchange format to foster interoperability in the building industry.[4] For example, Door, Wall, and Window are characterized together with their properties length, orientation, placement.

$$\begin{aligned} &\text{Door} \sqsubseteq \text{StructuralBuildingElement} \sqcap = 1\ \text{openingAngle} \,.\, \text{float} \\ &\sqcap = 1\ \text{doorknobType} \,.\, \text{ENTITY} \sqcap = 1\ \text{height} \,.\, \text{float} \\ &\sqcap = 1\ \text{length} \,.\, \text{float} \sqcap = 1\ \text{width} \,.\, \text{float} \end{aligned}$$



Data provided by IFC for a concrete building model can then be instantiated with respect to the quantity space ontological module.

Integrated Representation The connection of the three different modules (M1–M3) results in formalizing *link relations* across modules.[5] For example, an instance of Wall from the quantity space is related to an instance of Wall from the quality space, or as a physical endurant in the conceptual space. In the quantitative module, it is described by its length and position, while its counterpart in the qualitative module defines region-based relations to other walls and relations to rooms it constitutes.

Reasoning with Intergated Representation An important conceptual reasoning task in the design context is to determine whether or not a set of conceptual requirement constraints specified by a designer may possibly have a model. This form of reasoning is useful to check if a given set of design requirements are mutually consistent from the viewpoint of a conceptual specification; this kind of reasoning is directly possible with state of the art *Description Logic* (DL) (Baader et al., 2003) based reasoning systems such as RACER (Haarslev, Möller, and Wessel, 2004), PELLET (Sirin et al., 2007). With respect to the semantics of geometric and qualitative spatial knowledge, we have developed the CLP(QS), which is a declarative spatial reasoning system capable of modelling and reasoning about qualitative spatial relations pertaining to multiple spatial domains, i.e., one or more aspects of space such as topology, and intrinsic and extrinsic orientation, distance (Bhatt, Lee, and Schultz, 2011; Schultz and Bhatt, 2012). CLP(QS) also offers mixed geometric-qualitative spatial reasoning capabilities, and in its current form, a limited of quantification support offering

[4]IFC is based on object classes, e.g., *IfcWall* or *IfcWindow*, and their relationships containing metrical data as properties. We apply the stable release IFC2x3 TC1 (Liebich et al., 2006) defining 653 *building entities* (e.g., *IfcWall*) and additionally, several *defined types*, *enumerations*, and *select types* for specifying their properties and relationships.

[5]Bhatt, Hois, and Kutz (2012) provides technical details concerning the implementation of ontological modules using the framework of $\mathcal{E}$-Connections (Kutz et al., 2004). For the purposes of this paper, it suffices to think of link relations as predicates that link categories from respective modules; these links are utilised in a logic programming environment in order to assimilate knowledge from different perspectives within the body of inference rules in the logic program.

(a) Affordance path analysis can identify design malfunctions.

(b) Empty space topology indicates the linearity of a space.

(c) Visibility of landmarks indicated visual continuity

Figure 6: Affordance Paths, and Navigation Linearity and Visual Continuity

the means to go back from qualitative relations to the domain of precise quantitative information. CLP(QS) is implemented as a general library within the context of Constraint Logic Programming (CLP).

NF3. Spatio-Linguistic Conceptualisation & Reasoning Conceptual reasoning is hierarchical, deriving high-level design concepts from qualitative spatial relations based on low-level geometric primitives. Qualitative spatial representation and reasoning (QSR) provides a commonsensical interface to abstract and reason about quantitative spatial information. Qualitative spatial calculi are relational-algebraic systems pertaining to *topology, orientation, direction, size* (Cohn and Renz, 2007). Within computing for spatial design, the use of formal qualitative spatial calculi and conceptual design requirements serve as a link between the *structural form* of a design and the differing *functional capabilities* that it affords or leads to, e.g.:

C1. The FunctionalSpace of the Door of every Office should overlap with the RangeSpace of one or more Camera or MotionSensor.

C2. A MonitoredArea that are connected by doors and/or passages should not have any security blind spots whilst people transition from one room to another.

C3. Figure illustrates an inconsistency with circulation: a physical path exists between two locations if MovementSpace topology is connected, however, when taking FunctionalSpaces of objects into account we find that there is no affordance path; the EmptySpace topology is disconnected.

Examples in (C1–C3) constitute the basic case; more complex requirements are driven by high-level spatio-linguistic patterns and features, e.g., OpenPath, Around, Along etc. The semantics of such spatio-linguistic conceptual information is grounded with respect to the ISO-Space standard, an emerging initiative concerned with formalising the semantics of the representation of motion as it is expressed in language, e.g., *path predicates* and *manner-of-motion-predicates*.[6]. Finally, concepts most closely related to the design concept of an expert architect often involved a mixture of spatial prepositions, and high-level spatial patterns. We present some examples of such design concepts by way of **(A–C)**:

A. *Linearity*. Navigation linearity is associated with the number of path decisions that a person needs to make as they move through a space (Stephen Bitgood, 1992). A room is qualitatively *more linear* than another room if it has a less complex empty space topology, e.g., defined as having fewer regions with fewer holes (assuming that the rooms have the same number of entry and exit points). (Fig. 6(b))

B. *Visual Continuity*. Visual continuity through an environment is maintained if, as visitors move through the environment, they have visual contact with important waypoints (such as entrances, exits, or signage). (Fig. 6(c))

```
visual_continuity(discontinuous, id(LandmarkA), id(LandmarkB)):-
        visibility_space(id(LandmarkA),VisGeometryA),
        visibility_space(id(LandmarkB),VisGeometryB),
        topology(rcc8(dc), VisGeometryA, VisGeometryB).

visual_continuity(partial, id(LandmarkA), id(LandmarkB)) :-
        visibility_space(id(LandmarkA), VisGeometryA),
        visibility_space(id(LandmarkB), VisGeometryB),
        topology(rcc8(po), VisGeometryA, VisGeometryB).

visual_continuity(continuous, id(LandmarkA), id(LandmarkB)):-
        visibility_space(id(LandmarkA),VisGeometryA),
        physical_space(id(LandmarkB),PhyGeometryB),
        mereology(rcc5(pp), PhyGeometryB, VisGeometryA).
```

[6]The formal semantics underlying the ISO-Space framework is in Dynamic Interval Temporal Logic (DITL) and qualitative spatial formalisms as conceived within the QSTR community (Mani and Pustejovsky, 2012)

```

Figure 9: Basic encoding for graph search as an answer set program (minimal example serving illustration purpose)

C. *Oscillating Patterns of Sunlight and Shadows.*

The influence of sunlight (and resulting shadows) in evoking aesthetic impressions is well known in design (Seidler, 1959). For instance, one may identify an oscillating pattern of sunlight and shadows at a given time and place by determining whether the shadows in a room have a particular topology (Fig. 7):[7]

```
sunlight(oscillating_pattern, id(Room), id(Sun)) :-
        movement_space(id(Room),MvGeometry),
        sunlight(id(Sun),SunGeometry),
        SunPattern=intersection(MvGeometry,SunGeometry),
        enumerate(disconnected_regions, SunPattern, N), {N > 3}.
```

NF4. From Declarative Narratives, to Narratives of User Experience NF1–NF3 focussed on the semantic and spatial abstraction and reasoning methods that are used to generate people-cognition centred visuo-locomotive analytical information. The computed and inferentially derived analytical information is available declaratively, i.e., it is possible to query the analytical information using a combination of:

- conceptual reasoning with a DL reasoner such as Racer (Haarslev, Möller, and Wessel, 2004), Pellet (Sirin et al., 2007) (e.g., retrieval tasks)
- (system level) integration of conceptual reasoning with constraint logic based spatial reasoning and question-answering (in Prolog)
- application of answer set programming (Fig. 9) to search over the available analytical information, e.g., wrt. a graph search encoding, thereby computing stable models that satisfy certain design constraints fulfilling an anticipated "visuo-locomotive experience". For instance, a range of routes that fulfil particular user experience criteria may be computed: e.g., routes to a fire-exit (Fig. 8), nearest room from where sunset or sunrise are visible, routes that meet certain experiential constraints (e.g., visibility of at least one Bathroom, visibility to external environment)

The analytical information, in order to be useful to designers, has to be communicated using human-centred modalities; toward this, possible approaches are:

- *simulation*: diagnostic pin-pointing using virtual reality (VR) or similar visual techniques (e.g., 2D and 3D simulation)
- *schematisation*: generation of abstract schematisations, dynamic graph based complex spatio-temporal data visualisations, diagrams (e.g., similar to the timeline in Fig. 1)
- *stories in natural language and speech*: language generation based on the declarative analytical information, i.e., narratives of user experience

For the discussion in this paper, we focus on the use of the analytical declarative knowledge to generate spatio-linguistically grounded narratives of user experience (e.g., Listing 2 in Fig. 4). Template syntax trees for describing particular design concepts (e.g. referring to *linearity* as "the space flows linearly") are encoded, and instantiated with respect to the declarative narrative model.[8]

[7] It is straightforward to determine the sun location based on a given time, or the time that corresponds to a given geospatial location.

[8] We utilise the open source tools available via the Stanford Natural Language Processing Group: http://nlp.stanford.edu/

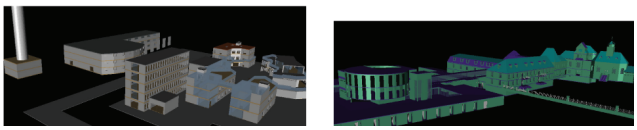

Figure 10: Select CAAD models used for empirical analyses – An Academic Interchange, and the Schloss Dagstuhl Palace

Empirical Performance Evaluation

The reported design analysis system and narrativisation framework have been fully implemented, and have also been used as a workbench for conducting experiments using real, industry-scale building data from CAAD models produced with commercial CAAD tools such as ArchiCAD and Autodesk Revit.

Datasets The dataset consists of 10 CAAD models of large-scale public environments of different sizes (e.g., an international academic interchange building (Germany), parts of the campus redevelopment plan at the University of Arkansa (USA), the Schloss Dagstuhl building(s), model of the Museum Calouste Gulbenkian (Portugal) etc (e.g., see Fig. 10).

Analysis The empirical analysis of the implemented system is performed for the following aspects (E1–E2):

E1. *Design Typology Computation*: Geometric computations are needed to compute the various affordance spaces as per the people-centred design typology.[9] The design typology computation experiments (Fig. 11) were conducted on a MacBookPro, OS X 10.6.8, 2.66 GHz with 4GB RAM. As can be seen Fig. 11, typology computations have been fine-tuned to suit practical applications demanding scalability for real-time performance; see (Schultz and Bhatt, 2013).

E2. *Narrative Generation via a Search Process in ASP*: The derivation of the narrative of user experience that has been implemented using answer set programming is evaluated. The ASP based experiments (Table 1) were conducted on an iMac machine with 2.7GHz, with 8 GB RAM. At this stage, fine-tuning the domain encodings in ASP has not been a principal concern. However, we are presently investigating effective encodings in ASP that specifically target graph structures and dataset sizes that are typical in the computer aided design domain.

Conclusions

We have presented a system for declarative narrativisation of user experience in spatial design. In contrast to the strictly geometric-centric view of building information, our framework explicitly incorporates human-centered perceptual models in the form of affordances and visuo-spatial abstraction. We have conducted experiments using real, industry scale CAAD models using a full implemention of our framework. In the experiments, all human-centered affordance spaces were computed within a relatively short time, thus demonstrating the practicality of the narrativisation framework in real-world settings. In the future we plan to extend the affordances to include a broader range of design features, and to formally benchmark the system-generated narratives wrt. human-generated narratives.

[9]Computing the *isovist* was done using the VisiLibity package (Obermeyer and Contributors, 2008). Polygon operations were performed using General-Polygon-Clipper., www.cs.man.ac.uk/~toby/alan/software

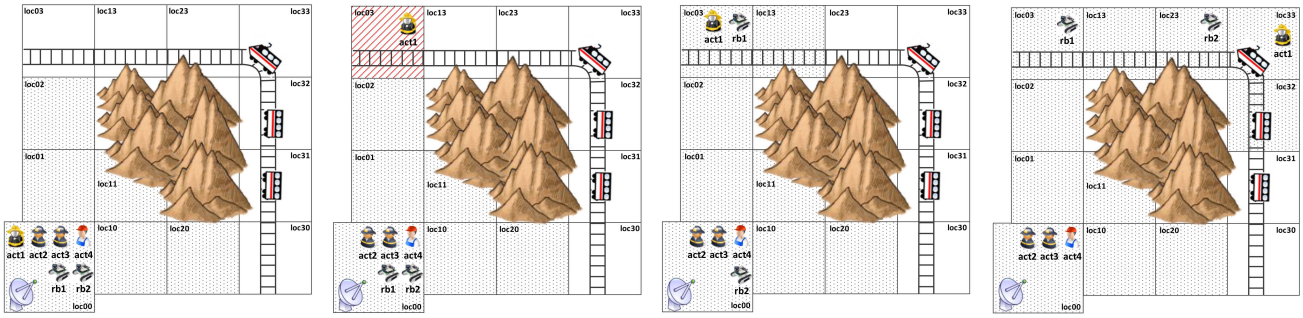
sebastian.sardina@rmit.edu.au

Abstract

In this paper we present SmartPM, a model and a prototype Process Management System featuring a set of techniques providing support for automated adaptation of knowledge-intensive processes at run-time. Such techniques are able to automatically adapt process instances without explicitly defining policies to recover from exceptions and without the intervention of domain experts at run-time, aiming at reducing error-prone and costly manual ad-hoc changes, and thus at relieving users from complex adaptations tasks. To accomplish this, we make use of well-established techniques and frameworks from Artificial Intelligence, such as situation calculus, IndiGolog and classical planning.

1 Introduction

This paper is concerned with the use of of three well-established KR&R techniques—reasoning about actions, high-level programming, and automated planning—for the *automated adaptation* of knowledge-intensive processes that execute in highly dynamic settings. The work falls within the scope of *Business Process Management* (BPM) (van der Aalst, ter Hofstede, and Weske 2003), an active area of research that is highly relevant from a practical point of view while offering many technical challenges.



BPM is based on the observation that each product and/or service that a company provides to the market is the outcome of a number of activities performed. *Business processes* are the key instruments for organizing such activities and improving the understanding of their interrelationships. Examples of traditional business processes include insurance claim processing, order handling, and personnel recruitment. In order to support the design and automation of business processes, a new generation of information systems, called *Process Management Systems* (PMSs) have become increasingly popular during the last decade (Weske 2012). A PMS is a software system that manages and executes business processes involving people, applications, and information sources on the basis of *process models* (Dumas, van der Aalst, and ter Hofstede 2005). The basic constituents of a process model are *tasks*, describing the various activities to be performed by process participants (i.e., software applications, agents, or humans). The procedural rules to control such tasks, described by so-called "routing" constructs such as sequences, loops, parallel and alternative branches, define the *control flow* of the process. A PMS, then, takes a process model (containing the process' tasks and control flow) and manages the process routing by deciding which tasks are enabled for execution. Once a task is ready for execution, the PMS assigns it to those participants capable of carrying it on.

Current maturity of process management methodologies has led to the application of process-oriented approaches in new rich challenging scenarios, such as healthcare (Lenz and Reichert 2007), emergency management (Marrella, Russo, and Mecella 2012), and home automation (Helal et al. 2005). In those settings, processes generally reflect "preferred work practices", and the control flow is influenced by user decision making and coupled with contextual data and knowledge production. Such processes are known as *knowledge-intensive* processes (KiPs) (Di Ciccio, Marrella, and Russo 2012)—genuinely knowledge and data centric—and require the integration of the data dimension with the traditional control flow dimension.

During the enactment of KiPs, variations or divergence from structured reference models are common due to exceptional circumstances arising (e.g., autonomous user decisions or contextual changes), thus requiring the ability to properly *adapt* the process behavior (Sadiq, Sadiq, and Orlowska 2001). In knowledge-intensive scenarios, the fact is that the number of possible exceptions is often too large, and traditional manual implementation of exception handlers at design-time is not feasible (Reichert and Weber 2012). In fact, the designer often lacks the required knowledge to model all the possible exceptions at the outset.

To tackle this issue, we develop in this paper an approach, together with an actual implementation, to *automatically adapt KiPs at run-time* when unanticipated exceptions occur, thus requiring no specification of recovery policies at design-time. To that end, we shall resort to three popular Artificial Intelligence (AI) "technologies": situation calculus (Reiter 2001), IndiGolog (De Giacomo et al. 2009), and classical planning (Nau, Ghallab, and Traverso 2004; Geffner and Bonet 2013). We use the situation calculus formalism to model the domain in which KiPs are to be executed, including available tasks, contextual properties, tasks'

preconditions and effects, and the initial state. On top of such a logic-based model, we use the IndiGolog high-level agent programming language for the specification of the structure and control flow of KiPs. We customize IndiGolog to monitor the online execution of KiPs and detect potential mismatches between the model and the actual execution. If an exception invalidates the enactment of the KiP being executed, an external state-of-the-art planner is invoked to synthesise a recovery procedure for adapting the faulty process instance. We refer to this adaptive framework for KiPs as SmartPM (Smart Process Management), described in Section 4.

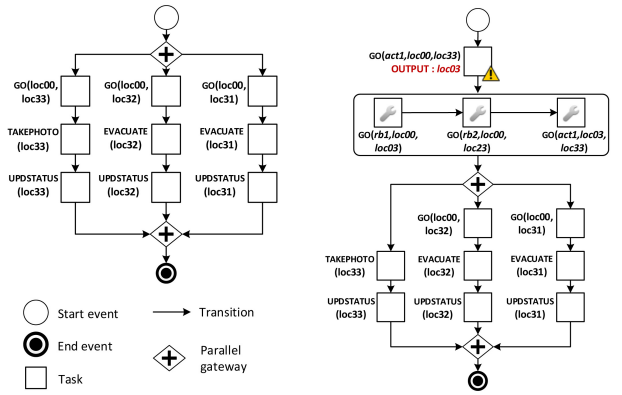
Besides providing the conceptual framework, we validated the approach with a case study based on real KiPs coming from an emergency management domain (Section 5). To do so, we have implemented SmartPM by relying on an existing IndiGolog interpreter (De Giacomo et al. 2009) and the state-of-the-art planning system LPG-td (Gerevini, Saetti, and Serina 2003). In Section 6, we compare SmartPM with other works that exploit AI techniques for enhanced process adaptation. We conclude, in Section 7, by drawing conclusions and discussing limitations and future work.

Before jumping to the technical proposal, let us first start with an overview of our case study and some preliminary notions necessary to understand the rest of the paper.

2 Case Study

Our case study and evaluation involves a disaster management inspired by the WORKPAD project.[1] In particular, it concerns the emergency management scenario described in Figure 1(a), in which a train derailment situation is depicted in a grid-type map. For the sake of simplicity, the train is composed of a locomotive (located at *loc33*) and two coaches (located at *loc32* and *loc31*, resp.).

During the management of complex emergency scenarios, teams of *first responders* act in disaster locations to achieve specific goals. In our train derailment situation, the goal of an incident response plan is to evacuate people from the coaches and take pictures for evaluating possible damages to the locomotive. To that end, a response team is sent to the derailment scene. The team is composed of four first responders, called *actors*, and two *robots*, initially all located at location cell *loc00*. It is assumed that actors are equipped with mobile devices for picking up and executing tasks, and that each provide specific capabilities. For example, actor *act1* is able to extinguish fire and take pictures, while *act2* and *act3* can evacuate people from train coaches. The two robots, in turn, are designed to remove debris from specific locations. When the battery of a robot is discharged, actor *act4* can charge it.



In order to carry on the response plan, all actors and robots ought to be continually inter-connected. The connection between mobile devices is supported by a fixed antenna located at *loc00*, whose range is limited to the dotted squares in Figure 1(a). Such a coverage can be extended by robots *rb1* and *rb2*, which have their own independent (from antenna) connectivity to the network and can act as wireless routers to provide network connection in all adjacent locations.

An incident response plan is defined by a set of activities that are meant to be executed on the field by first responders, and are predicated on specific contexts. Therefore, the information collected on-the-fly is used for defining and configuring at run-time the incident response plan at hand. A possible concrete realization of an incident response plan for our scenario is shown in Figure 2(a), using the Business Process Model and Notation (BPMN).[2] The process is composed of three parallel branches with tasks instructing first responders to act for evacuating people from train coaches, taking pictures of the locomotive, and assessing the gravity of the accident. Due to the high dynamism of the environment, there are a wide range of exceptions that can ensue. Because of that, there is not a clear anticipated correlation between a change in the context and a change in the process.

So, suppose for instance that actor *act1* is sent to the locomotive's location, by assigning to it the task GO(*loc00,loc33*) in the first parallel branch. Unfortunately, however, the actor happens to reach location *loc03* instead. The actor is now located at a different position than the de-

(a) Main process (b) Adapted process

Figure 2: An emergency response plan and its adaptation.

sired one, and most seriously, is out of the network connectivity range (Figure 1(b)). Since all participants need to be continually inter-connected to execute the process, the PMS has to first find a recovery procedure to bring back full connectivity, and then find a way to re-align the process. To that end, provided robots have enough battery charge, the PMS may first instruct the first robot to move to cell *loc03* (Figure 1(c)) in order to re-establish network connection to actor *act1*, and then instruct the second robot to reach location *loc23* in order to extend the network range to cover the locomotive's location *loc33*. Finally, the task GO(*loc03,loc33*) is (re)assigned to actor *act1* (Figure 1(d)). The corresponding updated process is shown in Figure 2(b), with the encircled section being the recovery (adaptation) procedure. Notice that after the recovery procedure, the enactment of the original process can be resumed to its normal flow.

The point is that it is not adequate to assume that the process designer can pre-define all possible recovery activities for dealing with exceptions in domains that are knowledge-intensive as the one just described: the recovery procedure will depend on the actual context (e.g., the positions of participants, the range of the main network, robot's battery levels, whether a location has become dangerous to get it, etc.) and there are too many of them to be considered.

3 Preliminaries

Situation Calculus The *situation calculus* is a logical language designed for representing and reasoning about dynamic domains (Reiter 2001). The dynamic world is seen as progressing through a series of situations as a result of various *actions* being performed. A *situation* s is a first-order term denoting the sequence of actions performed so far. The special constant S_0 stands for the initial situation, where no action has yet occurred, whereas a special binary function symbol $do(a, s)$ denotes the situation resulting from the performance of action a in situation s. Features of the world whose truth value may change from situation to situation are modeled by means of so-called *fluents*. Technically, fluents are predicates taking a situation term as their last argument. For example, fluent $Holding(x, y, s)$ may state that entity x is holding object y at situation s. A special predicate $Poss(a, s)$ is used to state that action a is executable in situation s. We write $\phi(\vec{x})$ to denote a formula whose free variables are among variables $\vec{x}$. A fluent-formula is one whose only situation term mentioned is situation variable s.

Within this language, one can formulate action theories describing how the world changes as the result of the available actions. A *basic action theory* (BAT) (Reiter 2001) $\mathcal{D} = \Sigma \cup \mathcal{D}_{S_0} \cup \mathcal{D}_{poss} \cup \mathcal{D}_{ss} \cup \mathcal{D}_{una}$ includes domain-independent foundational axioms to describe the structure of situations (Σ), one successor state axiom per fluent capturing the effects and non-effects of actions ($\mathcal{D}_{ss}$), one precondition axiom per action specifying when the action is executable ($\mathcal{D}_{poss}$), unique name axioms for actions ($\mathcal{D}_{una}$) and initial state axioms describing what is true initially in S_0 ($\mathcal{D}_{S_0}$). In particular, the *successor state axiom* for a fluent $F(\vec{x}, s)$ is an axiom of the form $F(\vec{x}, do(a, s)) \equiv \Psi_F(\vec{x}, a, s)$,[3] where $\Psi_F(\vec{x}, a, s)$ is a fluent-formula characterizing the dynamics of fluent $F(\vec{x}, s)$. Importantly, $\Psi_F(\vec{x}, a, s)$ can accommodate Reiter (2001)'s solution to the frame problem. In addition, precondition axioms are of the form $Poss(a(\vec{x}), s) \equiv \Pi_a(\vec{x}, s)$, where $\Pi_a(\vec{x}, s)$ is a fluent-formula defining the conditions under which action a can be legally executed in situation s. Finally, $\mathcal{D}_{S_0}$ is a collection of first-order sentences whose only situation term mentioned is S_0.

IndiGolog On top of situation calculus action theories, logic-based programming languages can be defined, which, in addition to the primitive actions, allow the definition of complex actions. In particular, we focus on IndiGolog (De Giacomo et al. 2009), the latest in the Golog-like family of programming languages for autonomous agents providing a formal account of interleaved action, sensing, and planning. IndiGolog programs are meant to be executed *online*, in that, at every step, a legal next action is selected for execution, performed in the world, and its sensing outcome gathered. To account for planning, a special look-ahead construct $\Sigma(\delta)$—the search operator—is provided to encode the need for solving (i.e., finding a complete execution) program δ offline.

IndiGolog allows us to define every well-structured process as defined in (van der Aalst et al. 2003); it is equipped with all standard imperative constructs (e.g., sequence, conditional, iteration, etc.) to be used on top of situation calculus primitives actions. An IndiGolog program is meant to run relative to an action theory, providing meaning to primitive actions and conditions in the program. Here we concentrate on the fragment defined by the following constructs:

a	atomic action
$\phi?$	test for a condition
$\delta_1; \delta_2$	sequence
$\pi x.\delta(x)$	nondeterministic choice of argument
δ^*	nondeterministic iteration
if ϕ **then** δ_1 **else** δ_2 **endIf**	conditional
while ϕ **do** δ **endWhile**	while loop
proc $P(\vec{x})$ **do** $\delta(x)$ **endProc**	procedure

[3] Free variables are assumed to be universally quantified.

$\delta_1 \| \delta_2$	concurrency
$\delta_1 \rangle\!\rangle \delta_2$	prioritized concurrency
$\langle \phi \rightarrow \delta \rangle$	interrupt
$\Sigma(\delta)$	lookahead search

Test program $\phi?$ can be executed if condition ϕ holds true, whereas program $\pi x.\delta(x)$ executes program $\delta(x)$ for *some* nondeterministic choice of a binding for variable x, and δ^* executes δ zero, one, or more times. The interleaved concurrent execution of two programs is represented with constructs $\delta_1 \| \delta_2$ and $\delta_1 \rangle\!\rangle \delta_2$; the latter considering δ_1 at higher priority level (i.e., δ_2 can perform a step only if δ_1 is blocked or completed). Finally, interrupt $\langle \phi \rightarrow \delta \rangle$ states that program δ ought to be executed to completion if ϕ happens to become true, whereas $\Sigma(\delta)$ finds and executes a plan—a sequence of actions—that is guaranteed to fully execute δ.

By properly combining prioritized concurrency and interrupts, together with IndiGolog's default online execution style, it is possible to design processes that are sufficiently open and reactive to dynamic environments. Furthermore, by resorting to the search operator, one can specify local places in programs where lookahead reasoning is required. Both aspects will end up being fundamental for our adaptive process management framework in the next section.

Classical Planning Planning systems are problem-solving algorithms that operate on explicit representations of states and actions (Nau, Ghallab, and Traverso 2004; Geffner and Bonet 2013). PDDL (Edelkamp and Hoffmann 2004) is the standard planning representation language; it allows one to formulate a *planning problem* $\mathcal{P} = \langle I, G, \mathcal{P}_D \rangle$, where I is the initial state, G is the goal state, and $\mathcal{P}_D$ is the planning domain. In turn, a planning domain $\mathcal{P}_D$ is built from a set of *propositions* describing the state of the world (a state is characterized by the set of propositions that are true) and a set of *operators* (i.e., actions) that can be executed in the domain. Each operator is characterized by its preconditions and effects, stated in terms of the domain propositions.

There exist several forms of planning in the AI literature. In this paper, we focus on *classical planning*, characterized by fully observable, static, and deterministic domains. A solution for a classical planning problem $\mathcal{P}$ is a sequence of operators—a plan—whose execution transforms the initial state I into a state satisfying the goal G. Such a plan is computed in advance and then carried out (unconditionally). The field of classical planning has experimented huge advances in the last twenty years, leading to a variety of concrete solvers (i.e., planning systems) that are able to create plans with thousands of actions for problems containing hundreds of propositions. In this work, we represent planning domains and planning problems using PDDL 2.2 (Edelkamp and Hoffmann 2004), which includes operators with disjunctive preconditions and derived predicates.

4 The SmartPM Approach

We adopt a *service-based* approach to process management. Thus, *tasks are executed by services*, such as software applications, human actors, robots, etc. Each task can be seen as a single step consuming input data and producing output data.

In this section, we show how one can put together the three AI frameworks described above to build a PMS, which we shall name SmartPM, that is able to not only enact KiPs, but also to *automatically* adapt processes in case of unanticipated exceptions. Intuitively, situation calculus theories will be used to model the contextual information in which the process is meant to run, IndiGolog programs will encode the KiP to be carried out, and planning systems will be used to support the automated adaptation of a process when needed.

SmartPM Basic Action Theory

A BAT for a SmartPM application specifies:

1. the tasks and services of the domain of concern;
2. the support framework for managing the task life-cycle;
3. the contextual setting in which processes operate; and
4. the support framework for the monitoring of processes.

Let us start by describing the first three ones. So, to encode tasks and services, we use five non-fluent predicates:

- *Service*(srv): *srv* is a service (i.e., a process participant);
- *Task*(t): t is a task (e.g., GO(l_1, l_2) or TAKEPHOTO(l) may denote the tasks of navigating or taking pictures);
- *Capability*(c): c is a capability;
- *Provides*(srv, c): service *srv* provides capability c; and
- *Requires*(t, c): task t requires the capability c.

Observe all these predicates are rigid: they do not depend on a situation term and are hence static. A service *srv* is able to perform certain task t iff *srv* provides all capabilities required by the task t. This is captured formally using the following abbreviation:

$$\mathit{Capable}(srv, t) \stackrel{\text{def}}{=} \forall c.\mathit{Requires}(t, c) \supset \mathit{Provides}(srv, c).$$

To talk about concrete runs of tasks, we associate them with unique identifiers. A *task instance* is then a tuple $t : id$, where t is a task and *id* is an identifier.

The life-cycle of tasks involves the execution of four primitive actions executed by the PMS and two exogenous actions arising from services. More concretely, the protocol for a successful execution of a task t goes as follows:

1. First, the PMS assigns task instance $t : id$ to a service *srv* by performing primitive action ASSIGN$(srv, id, t, \vec{o_e})$, where $\vec{o_e}$ is the *expected* (sensing result) output.
2. When a service is ready for task execution, it generates the exogenous action READYTOSTART(srv, id, t).
3. Next, the PMS performs primitive action START(srv, id, t) to authorize the service in question that is formally allowed to start carrying out the task instance.
4. When the service completes the task, it generates the exogenous action FINISHED$(srv, id, t, \vec{o_r})$, with $\vec{o_r}$ representing the physical *actual* outcome returned by the task execution (we use ϵ to denote the empty output).
5. At this point, the PMS updates the properties (i.e., the fluents) to reflect the effects of the task just completed.

6. Finally, the PMS acknowledges the completion of the task and releases the service from the task via primitive actions $\text{ACKCOMPL}(\mathit{srv}, \mathit{id}, t)$ and $\text{RELEASE}(\mathit{srv}, \mathit{id}, t)$.

The intended meaning of all the above actions is captured by means of a set of domain-independent fluents that are used to keep track of the life-cycle of tasks as well as the resource perspective of a process. For example, fluent $\mathit{Free}(\mathit{srv}, s)$ denotes whether a service *srv* is available for task assignments in situation s, whereas $\mathit{ExOut}(\mathit{id}, t, s)$ denotes the expected output of the task; their dynamics are captured via the following successor state axioms (which include Reiter (2001)'s solution to the frame problem):

$$\begin{aligned}&\mathit{Free}(\mathit{srv}, do(a, s)) \equiv\\ &\quad (\exists t, \mathit{id})a = \text{RELEASE}(\mathit{srv}, \mathit{id}, t) \vee\\ &\quad [\mathit{Free}(\mathit{srv}, s) \wedge (\forall t, \mathit{id}, \vec{o_e})a \neq \text{ASSIGN}(\mathit{srv}, \mathit{id}, t, \vec{o_e})];\\ &\mathit{ExOut}(\mathit{id}, t, do(a, s)) = \vec{o} \equiv\\ &\quad (\exists \mathit{srv}, \vec{o_e})a = \text{ASSIGN}(\mathit{srv}, \mathit{id}, t, \vec{o_e}) \wedge \vec{o} = \vec{o_e} \vee\\ &\qquad \mathit{ExOut}(\mathit{id}, t, s) = \vec{o}.\end{aligned}$$

That is, a service is free (for task assignment) after the execution of an action a iff a releases the service from some task assignment, or it was free before the execution of a and a does not assign a task instance to it. Similarly, the expected output of a task instance is determined by the assignment step (and never changes). Initial expected outcomes are initialized to "no output" via an axiom $(\forall t, \mathit{id}).\mathit{ExOut}(\mathit{id}, t, S_0) = \epsilon$ in $\mathcal{D}_{S_0}$. Other similar fluents are used to manage the life-cycle of tasks.

The BAT shall also contain a set of domain-dependent fluents, together with their corresponding precondition and successor state axioms, capturing the contextual scenario in which the process is meant to to be executed. We call them *data fluents*. In general, such fluents will be affected upon the release of an assignment task, that is, whenever a task is considered fully executed. In addition, the actual outcome result of a task is used to define the fluent in question.

Example 1 Consider the following successor state axiom for functional fluent $\mathit{At}(x, s)$ to keep track of the location of entities (e.g., actors and robots) in our emergency scenario:

$$\begin{aligned}&\mathit{At}(x, do(a, s)) = l \equiv\\ &\quad (\exists \mathit{id}, l_s, l_d)a = \text{FINISHED}(x, \mathit{id}, \text{GO}(l_s, l_d), l) \vee\\ &\quad [\mathit{At}(x, s) = l \wedge\\ &\quad (\neg\exists \mathit{id}, l')a = \text{FINISHED}(x, \mathit{id}, \text{GO}(l_s, l_d), l') \wedge l' \neq l].\end{aligned}$$

In words, service x is in location l if x was just released of a task GO whose actual physical outcome result was l. Observe that l, the new location of x, may happen to be different to the expected (destination) location l_d. ■

An important property of the domain in question is that one stating whether a service is connected to the network. Rather than defining a new data fluent, an abbreviation will be enough.

Example 2 The abbreviation $\mathit{Connected}(x, s)$ denotes that service x is within network connectivity range and is defined as follows:

$$\begin{aligned}&\mathit{Connected}(x, s) \stackrel{\text{def}}{=}\\ &\quad \mathit{Robot}(x) \vee \mathit{Covered}(\mathit{At}(x, s)) \vee\\ &\qquad \exists r.\mathit{Robot}(r) \wedge \mathit{Neigh}(\mathit{At}(x, s), \mathit{At}(r, s)).\end{aligned}$$

That is, service x is connected to the network iff x is actually robot (robots have their own connectivity), or x's location is covered by the main base network, or x is adjacent to a robot providing network connectivity in its surroundings. ■

Now, in KiPs, data fluents and abbreviations will be often used for defining the *preconditions* of domain tasks. By doing so, the PMS can reason, at run-time, about the active process instance relative to the current context.

Example 3 The following precondition axiom defines when the PMS can assign a navigation task to a service:

$$\begin{aligned}&\mathit{Poss}(\text{ASSIGN}(\mathit{srv}, \mathit{id}, \text{GO}(l_s, l_d), l_e), s) \equiv\\ &\quad (\mathit{At}(\mathit{srv}, s) = l_s) \wedge \mathit{Connected}(\mathit{srv}, s) \wedge\\ &\quad (l_e = l_d) \wedge \mathit{Capable}(\mathit{srv}, \text{GO}(l_s, l_d)).\end{aligned}$$

That is, the service (e.g., human actor, robot, etc.) ought to be at the source location l_s, connected to the network, and capable of locomotion. Moreover, the expected outcome of the task needs to be the destination location l_d. ■

This concludes the exposition of the first three aspects of a SmartPM action theory, as listed above.

Exception Monitoring We now turn our attention to the mechanism for automatically detecting failures/exceptions. To that end, we leverage on De Giacomo, Reiter, and Soutchanski (1998)'s technique of adaptation from the field of agent-oriented programming, by specializing it to our KiP setting. We consider adaptation as *reducing the gap* between the *expected reality*, the (idealized) model of reality, and the *physical reality*, the real world with the actual conditions and outcomes. A misalignment of the two realities stems from errors or exceptions in the tasks' outcomes, and may require explicit intervention.

The physical reality is captured using data fluents (together with their corresponding successor state axioms) as described above (e.g., fluent $\mathit{At}(x, s)$). The expected reality, in turn, is captured by a set of automatically generated fluents from the data fluents. Technically, for every fluent $F(\vec{x}, s)$, a new fluent $F_{\text{exp}}(\vec{x}, s)$ (F-expected) is used. Intuitively, $F_{\text{exp}}(\vec{x}, s)$ represents the value of $F(\vec{x}, s)$ in the "expected" (or "desired") execution. If $F(\vec{x}, do(a, s)) \equiv \Psi_F(\vec{x}, a, s)$ is F's successor state axiom, its expected version $F_{\text{exp}}(\vec{x}, s)$ is defined as follows:

$$\begin{aligned}&F_{\text{exp}}(\vec{x}, do(a, s)) \equiv\\ &\quad a = \text{ALIGN} \supset F(\vec{x}, s) \vee\\ &\quad [(\exists \mathit{srv}, \mathit{id}, t, \vec{o_r})a = \text{FINISHED}(\mathit{srv}, \mathit{id}, t, \vec{o_r}) \supset\\ &\qquad \Psi^*_F(\vec{x}, \text{FINISHED}(\mathit{srv}, \mathit{id}, t, \mathit{ExOut}(\mathit{id}, t, s)), s)] \vee\\ &\quad [a \neq \text{ALIGN} \wedge (\forall \vec{y})a \neq \text{FINISHED}(\vec{y}) \supset \Psi^*_F(\vec{x}, a, s)].\end{aligned}$$

where $\Psi^*_F(\vec{x}, a, s)$ is obtained by replacing each fluent X in $\Psi_F(\vec{x}, a, s)$ (the right-hand-side formula of F's successor state axioms) with its expected version X_{exp}.

The first disjunct states that the special action ALIGN assigns the actual value of the fluent to its expected value, thus providing a synchronization mechanism between the expected and physical realities. The remaining two disjuncts state together that the dynamics of F_{exp} is that of F *assuming all task outcomes turn out to be the ones expected*. Technically, this is achieved by replacing all data fluents in Ψ_F

with their expected version and the actual outcomes $\vec{o_r}$ of finished tasks with the expected ones (term $ExOut(id, t, s)$).

Example 4 The corresponding (syntactically simplified) expected version for fluent $At_{\text{exp}}(x, s)$ is as follows:

$$\begin{array}{l} At_{\text{exp}}(x, do(a, s)) = l \equiv \\ \quad a = \text{ALIGN} \supset (At(x, s) = l) \vee \\ \quad [(\exists id, l_s, l_d, l_r) a = \text{FINISHED}(x, id, \text{GO}(l_s, l_d), l_r) \supset \\ \qquad l = ExOut(id, \text{GO}(l_s, l_d), s)] \vee \\ \quad [At_{\text{exp}}(x, s) = l \wedge a \neq \text{ALIGN} \wedge \\ \qquad (\forall id, l_s, l_d, l_r) a \neq \text{FINISHED}(x, id, \text{GO}(l_s, l_d), l_r)]. \end{array}$$

Observe that if the action a denotes the completion of a GO task for x with some actual outcome l_r, the new location of x is that expected (denoted by $ExOut(id, \text{GO}(l_s, l_d), s)$). ■

Similarly, for each abbreviation $A(s) \stackrel{\text{def}}{=} \Psi(s)$, one can define corresponding abbreviation $A_{\text{exp}}(s) \stackrel{\text{def}}{=} \Psi^*(s)$, where $\Psi^*(s)$ is obtained by replacing each fluent (or abbreviation) X in $\Psi(s)$ with its expected version X_{exp} and all actual task outcomes $\vec{o_r}$ with their expected ones $ExOut(id, t, s)$. Of course, one can also define special expected fluent or abbreviations that can encode particular expectations. For example, by simply taking $Connected_{\text{exp}}(x, s) \stackrel{\text{def}}{=} \texttt{true}$, we are able to encode the constraint that actors are expected to always be connected.

So, using the data fluents and their expected versions, a misalignment can be recognized. However, it may only be important to check for mismatches among *some* properties of the world. So, we assume that the designer specifies distinguished abbreviation $Misaligned(s)$ to characterize misalignment situations requiring process adaptation. The general form of this abbreviation is as follows:

$$\begin{array}{l} Misaligned(s) \stackrel{\text{def}}{=} \\ \quad \exists \vec{x_1}.\Phi_{X^1}(\vec{x_1}, s) \supset \neg[X^1(\vec{x_1}, s) \equiv X^1_{\text{exp}}(\vec{x_1}, s)] \vee \\ \qquad\qquad \vdots \\ \quad \exists \vec{x_n}.\Phi_{X^n}(\vec{x_n}, s) \supset \neg[X^n(\vec{x_n}, s) \equiv X^n_{\text{exp}}(\vec{x_n}, s)], \end{array}$$

where $X^i(\vec{x_i}, s)$, with $i \in \{1, \ldots, n\}$, are all the data fluents and abbreviations used in the SmartPM application, and $\Phi_{X^i}(\vec{x_i}, s)$ states when fluent/abbreviation $X^i(\vec{x_i}, s)$ needs to be monitored for misalignment between its physical and expected values. We use $\Phi_{X^i}(\vec{x_i}, s) = \texttt{true}$ and $\Phi_{X^i}(\vec{x_i}, s) = \texttt{false}$ to specify permanent and no monitoring, respectively, for the corresponding fluent/abbreviation.

Example 5 Assuming we are only interested in monitoring the location of actors and their connectivity, we would specify the following definition:

$$\begin{array}{l} Misaligned(s) \stackrel{\text{def}}{=} \\ \quad \exists x_1.Actor(x_1) \supset \neg[At(x_1, s) \equiv At_{\text{exp}}(x_1, s)] \vee \\ \quad \exists x_1.Actor(x_1) \supset \\ \qquad \neg[Connected(\vec{x_1}, s) \equiv Connected_{\text{exp}}(\vec{x_1}, s)]. \end{array}$$

Observe the definition is not concerned about exceptions on the location of robots or their connectivity, for example. ■

This concludes the explanation on what type of situation calculus BAT we shall use in a SmartPM application. Let us call this theory $\mathcal{D}_{\text{SmartPM}}$.

SmartPM High-Level Program

Algorithm 1 shows the IndiGolog program for the SmartPM system. The program, as any high-level program, is meant to be executed relative to the basic action theory $\mathcal{D}_{\text{SmartPM}}$ as developed above, which shall give meaning to conditions and primitive statements in the program (i.e., actions).

The top-level part of PMS involves four interrupts running at different priorities, as long as the domain process is yet not finished. The highest two priority programs deal with automated process adaptation. First, if the system has just been adapted, then the two realities—expected and physical—must be aligned, as a new repair plan has been found and a new synchronization point has been reached. Second, the system checks for a misalignment between the two realities, as explained above. If a mismatch is recognized, the adaptation procedure is triggered (see below).

At medium priority, the PMS runs the IndiGolog program reflecting the actual KiP, represented by procedure **Process**() and corresponds to the process depicted in Figure 1(a). Finally, at the lowest priority (when the process cannot advance a step further) the PMS just waits for an exogenous action to arrive from one of the services (e.g., FINISHED signaling the completion of a task). While waiting, the (human) process designer could also manually intervene (for example, by adding new services or updating the capabilities of existing services).

Managing the life-cycle of a task instance—procedure **ManageExecution**()—involves selecting a free service capable of carrying it out, assigning the task to the chosen service, allowing the start of the service, acknowledging its completion and fully releasing the service from the task. Notice the use of the non-deterministic choice of argument $\pi srv.\delta(srv)$ to select an appropriate service.

The most interesting part of the procedure involves procedure **Adapt**(). An adaptation is very simple: *find a sequence of actions that will resolve the misalignment*. This is exactly what the code inside the search operator Σ does: *pick n actions (and execute them) zero, one, or more times such that abbreviation Misaligned*(s) *becomes false.* The action SETMUSTALIGN at the front of the search construct will just make $MustAlign(s)$ true, which will trigger (provided an actual adaptation plan is found) the top-priority program in the main procedure to force an alignment of the two realities. Observe that because the adaptation mechanism runs at higher priority than the actual process, the recovery plan found will be run *before* whatever part of the domain process remains to be executed.

While this specification of the automated adaptation procedure turns out to be extremely clean and simple, the direct use of the native search operator provided by the IndiGolog architecture (De Giacomo et al. 2009) poses serious problems in terms of efficiency. Indeed, the search operator provided by IndiGolog performs basic blind search and as a result is not able to cope with extremely easy adaptation tasks. The important observation to make is that while the search operator is meant to handle *any* IndiGolog high-level program (including ones containing nested search operators), our SmartPM system uses a specific program that encodes a (classical) planning problem. So, leveraging on

Algorithm 1: IndiGolog high-level program for PMS.

Proc **SmartPM**()
  $\langle \neg \mathit{Finished} \wedge \mathit{MustAlign} \rightarrow \text{ALIGN} \rangle \rangle$
  $\langle \neg \mathit{Finished} \wedge \mathit{Misaligned} \rightarrow \mathbf{Adapt}() \rangle \rangle$
  $\langle \neg \mathit{Finished} \rightarrow [\mathbf{Process}(); \text{FINISH}] \rangle \rangle$
  $\langle \neg \mathit{Finished} \rightarrow [\text{WAIT}] \rangle$.
Proc **Adapt**()
  $\Sigma_{\text{LPG}}[\text{SETMUSTALIGN}; (\pi a.a)^*; \neg \mathit{Misaligned}?]$.
Proc **ManageExecution**(*Task*, *id*, *ExpOut*)
  $(\pi\ srv)$.
    $(\mathit{Capable}(srv, \mathit{Task}) \wedge \mathit{Free}(srv))?$;
    ASSIGN(*srv*, *id*, *Task*, *ExpOut*);
    START(*srv*, *id*, *Task*);

    RELEASE(*srv*, *id*, *Task*)

Proc **Process**()
  [**Branch1**()|| **Branch2**()|| **Branch3**()].
Proc **Branch1**()
  ManageExecution(GO($loc00, loc33$), $id_1, loc33$);
  ManageExecution(TAKEPHOTO($loc33$), id_2, ok);
  ManageExecution(UPDATESTATUS($loc33$), id_3, ok)
Proc **Branch2**()
  ManageExecution(GO($loc00, loc32$), $id_4, loc32$);
  ManageExecution(EVACUATE($loc32$), id_5, ok);
  ManageExecution(UPDATESTATUS($loc32$), id_6, ok)
Proc **Branch3**()
  ManageExecution(GO($loc00, loc31$), $id_7, loc31$);
  ManageExecution(EVACUATE($loc31$), id_8, ok);
  ManageExecution(UPDATESTATUS($loc31$), id_9, ok)

the recent progress of classical planning systems, we implement the search operator call in procedure **Adapt**(), by using an off-the-shelf planner to synthesise the recovery plan, and then fit such a plan back into the IndiGolog framework. In this work, we used the LPG-td system (Gerevini, Saetti, and Serina 2003), one of the many state-of-the-art planning systems available. The basic search scheme of LPG-td is inspired by Walksat (Selman, Kautz, and Cohen 1994), an efficient procedure for solving SAT-problems; as expected, it outperforms the blind search operator by several orders of magnitudes. Nonetheless, our approach is orthogonal to other planning systems.

We do not go over all the details on how the interface between IndiGolog and LPG-td has been implemented but just go over the main ingredients. First of all, given a BAT for a KiP application, the corresponding PDDL planning domain is built offline and stored. Because we are not concerned with the exogenous actions generated by services to acknowledge the start and termination of assigned processes (i.e., actions READYTOSTART and FINISHED), we do not model the full PMS assign-start-acknowledge-release task life-cycle, but just encapsulates them all in the actual name of the task being handled (e.g., GO). By doing that, we assume that the life-cycle of a task instance will follow its normal evolution. The SmartPM BAT will define a form of tasks and services repository, which may include entities not used in the current running process. So, the PDDL domain for our case study will contain, among others, the following action schema:

```
(:action go
 :parameters (?x - srv ?from - loc
              ?to - loc)
 :precondition (and (free ?x)
                (provides ?x movement)
                (at ?x ?from) (connected ?x))
 :effect (and
          (not (at ?x ?from)) (at ?x ?to)))
```

Note that the task-action in the planning system will contain the service in charge and its expected effects.

Then, whenever a search operator adaptation program is called in procedure **Adapt**(), the current situation of the IndiGolog system is encoded as a planning initial state (as the set of fluents that are true) and formula $\mathit{Misaligned}(s)$ is encoded as a goal state (by taking the collection of relevant fluents to be as their expected versions). Those two states, together with the planning domain already pre-computed, are then passed to the LPG-td system.

Finally, if the planner finds a plan that brings about the (desired) expected reality, such a plan—built from task names only—is translated into the typical assign-start-acknowledge-release task life-cycle IndiGolog program. As stated above, the plan will run *before* the actual domain process, which shall resume then, hopefully from the expected reality. In our running example, the full IndiGolog program would encode the KiP depicted in Figure 2(b).

This concludes the complete overview of SmartPM, built from a BAT and an IndiGolog high-level program that uses a classical planner for its specific (classical planning) search operator implementation. Let us now look at some empirical evaluation of such a system.

5 Validation

In order to investigate the feasibility of the SmartPM approach, we performed experiments to study the time required for synthesizing a recovery plan for different adaptation problems. We made our tests by using the LPG-td planner (Gerevini, Saetti, and Serina 2003). We chose LPG-td as *(i)* it treats most of PDDL 2.2 features; and *(ii)* it has been developed in two versions: a version tailored to computation speed, named LPG-td.speed, which produces *sub-optimal plans* that do not prove any guarantee other than the correctness of the solution, and a version tailored for *plan quality*, named LPG-td.quality. LPG-td.quality differs from LPG-td.speed basically in that it does not stop when the first plan is found, but continues until a stopping quality criterion is met. In our experiments, the criterion for plan quality was set to minimal plan length.

The experimental setup was performed with the test case shown in our train emergency running example. We used a tasks repository containing 20 different emergency management tasks, annotated with 28 relational predicates, 2 derived predicates, and 4 functional numeric fluents. We provided 185 different planning problems of different complexity, by manipulating ad-hoc the values of the initial state and the goal in order to devise adaptation problems of growing complexity. The results are reported in Table 1. Each row summarizes the results of various planning instances ($\#I$ instances). Column L-RP indicates the length of the shortest

Table 1: Performances of LPG-td. L-RP = length of the shortest recovery plan; #I = number of problem instances; AT-SOS/AL-SOS = average time/length for sub-optimal plan; and AT-QS = average time for quality plan.

L-RP	#I	AT-SOS	AL-SOS	AT-QS
1	29	6.769	3	7.768
2	36	7.213	3	16.865
3	32	7.846	4	24.123
4	25	8.128	5	37.017
5	21	8.598	8	39.484
6	17	8.736	9	52.421
7	13	9.188	13	73.526
8	12	9.953	14	81.414

plans for all instances. Column AL-SOS indicates the average number of actions of the sub-optimal solutions found by LPG-td.speed; whereas column AT-SOS reports the time it took to find such plan solutions. Those plans will generally include more tasks than the ones strictly needed. Finally, column AT-QS indicates the average time taken by LPG-td.quality to produce a quality plan. For example, on 21 different planning problems requiring a recovery procedure of length 5, the LPG-td planner is able to find, on average, a sub-optimal plan in 8.598 seconds (with an average of three tasks more) and a quality plan (of exactly 5 tasks necessary for recovery) in 39.484 seconds. Consequently, the approach is feasible for medium-sized dynamic processes used in practice.[4]

Effectiveness of SmartPM in Adapting Processes

An important aspect to consider during the development of a PMS with adaptation features concerns its *effectiveness* in supporting process models having control flows with different structures. We define effectiveness as the *ability of a PMS to complete the execution of a process model (i.e., to execute all the tasks involved in a path from the start event to the end event) by adapting automatically its running process instance if some failure/exception arises, without the need of any manual intervention of the process designer at run-time*.

To evaluate the effectiveness of SmartPM, we developed a software module named the SmartPM *Simulator*, which is able to automatically build IndiGolog processes and corresponding $\mathcal{D}_{\text{SmartPM}}$ theories, by simulating their execution on the basis of some customizable parameters:

- *Structure of the control flow*, with tasks organized in sequence or in 3 or 5 parallel branches.
- *Tasks repository size*, equal to 25, 50, or 75 tasks.
- *Number of available services* in the initial situation for task assignment. We fixed this value to 5 services.
- *Number of task preconditions/effects*; we allowed the generation of tasks having a maximum of 5 conditions in the precondition/effect axioms.
- *Number of available fluents*; we allowed the generation of 50 relevant data fluents that may assume boolean values. For each data fluent, the SmartPM Simulator automatically builds the corresponding expected fluent for monitoring possible tasks failures.
- *Percentage of tasks failures* This parameter may assume two possible values (30% or 70%), and affects the percentage of tasks error during the process execution.
- *Percentage of capabilities coverage* (30% or 70%), that affects the ability of each available service to execute the tasks stored in the repository.

Given *(i)* a specific structure of the control flow, *(ii)* a fixed percentage of capabilities coverage and *(iii)* of tasks failures, for each possible size of the tasks repository the SmartPM *Simulator* generated 100 process models with control flows composed respectively by 5 to 25 tasks randomly picked from the tasks repository. In total, we tested 3600 process models. Test results are shown in Figure 3. Collected data are organized in 4 diagrams obtained by combining the percentage of failures (FP) with the the percentage of capabilities coverage (SC). Each bar corresponds to the enactment of 100 different process models with a fixed size of the tasks repository and a specific structure of the control flow.

The analysis of the performed tests points out some interesting aspect. For example, let us consider the diagram in Figure 3(a), that shows the effectiveness of SmartPM in executing processes with a FP equal to 30% and a SC fixed to 30%. When the size of the tasks repository is equal to 75, the effectiveness of SmartPM in executing 100 process models composed by a sequence of tasks is equal to 82%. This means that 82 processes out of 100 that were executed have been correctly enacted and completed, while for the other 18 processes the system did not find any recovery plan for dealing with an exception occurrence. We can note that the effectiveness decreases if the instances have tasks organized in three parallel branches (79%) and in five parallel branches (75%). In general, the effectiveness of the SmartPM system decreases as the number of parallel branches increases, since more services are possibly involved at the same time for tasks execution, by letting only few services available for process adaptation and recovery. Furthermore: *(i)* when the FP increases, the effectiveness of the SmartPM system decreases; *(ii)* when the SC increases, the effectiveness of the SmartPM system increases, because there are more possibilities for a task in the repository to be selected by an available service.

To sum up, the execution of 3600 process models with different structures was a valid test for measuring the effectiveness of SmartPM, that was able to complete 2537 process instances, corresponding to an effectiveness of about 70.5%.

6 Related Work

The AI community has been involved with research on process management for several decades, and AI technologies can play an important role in the construction of PMS engines that manage complex processes, while remaining robust, reactive, and adaptive in the face of both environmental and tasking changes (Myers and Berry 1998). One of the

[4] We did our tests by using an Intel U7300 CPU 1.30GHz Dual Core, 4GB RAM machine.

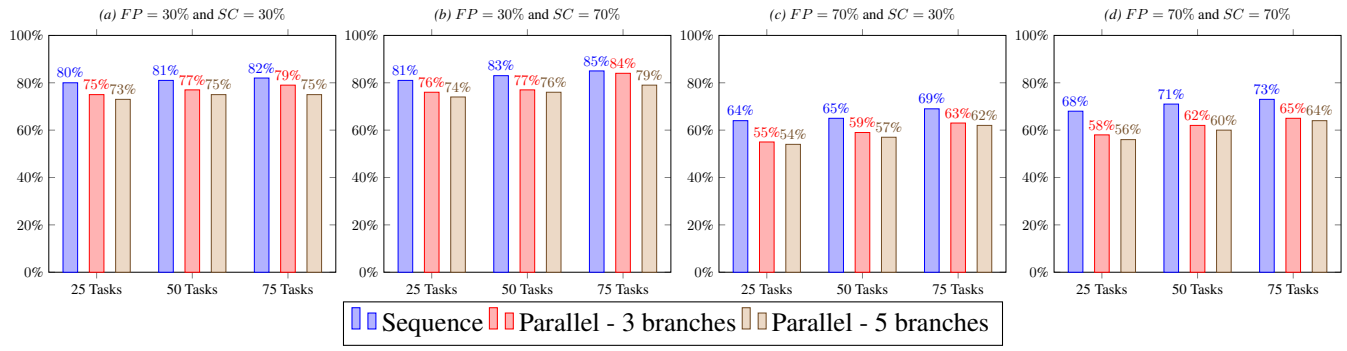

Figure 3: Analysis of the SmartPM effectiveness. The x-axis states the size of the tasks repository, while the y-axis indicates the effectiveness in executing process models with a specific structure of the control flow.

first works dealing with this research challenge is (Beckstein and Klausner 1999). It discusses at high level how the use of an intelligent assistant based on planning techniques may suggest compensation procedures or the re-execution of activities if some expected failure arises during the process execution. In (Jarvis et al. 1999) the authors describe how planning can be interleaved with process execution and plan refinement, and investigates plan patching and plan repair as means to enhance flexibility and responsiveness.

A goal-based approach for enabling automated process instance change in case of emerging exceptions is shown in (Gajewski et al. 2005). If a task failure occurs at run-time and leads to a process goal violation, a multi-step procedure is activated. It includes the termination of the failed task, the sound suspension of the process, the automatic generation (through the use of a partial-order planner) of a new complete process definition that complies with the process goal and the adequate process resumption. A similar approach is proposed in (Ferreira and Ferreira 2006). The approach is based on learning business activities as planning operators and feeding them to a planner that generates a candidate process model that is able of achieving some business goals. If an activity fails during the process execution at run-time, an alternative candidate plan is provided on the same business goals. The major issue of (Gajewski et al. 2005; Ferreira and Ferreira 2006) lies in the replanning stage used for adapting a faulty process instance. In fact, it forces to completely re-define the process specification at run-time when the process goal changes (due to some activity failure), by completely revolutionizing the work-list of tasks assigned to the process participants (that are often humans). On the contrary, our approach adapts a running process instance by modifying only those parts of the process that need to be changed/adapted and keeps other parts stable.

A work dealing with process interference is that of van Beest et al. (2014). Process interference is a situation that happens when several concurrent business processes depending on some common data are executed in a highly distributed environment. During the processes execution, it may happen that some of these data are modified causing unexpected or wrong business outcomes. To overcome this limitation, the work van Beest et al. proposes a run-time mechanism which uses *(i) Dependency Scopes* for identifying critical parts of the processes whose correct execution depends on some shared variables; and *(ii) Intervention Processes* for solving the potential inconsistencies generated from the interference, which are automatically synthesised through a domain independent planner based on constraint techniques. While closely related to van Beest's work, our account deals with changes in a more abstract and domain-independent way, by just checking misalignment between expected/physical realities. Conversely, van Beest's work requires specification of a (domain-dependent) adaptation policy, based on volatile variables and when changes to them become relevant.

7 Conclusion

As discussed in this paper, SmartPM defines a general approach, a concrete framework and a prototype PMS for automated adaptation of processes. Our purpose was to demonstrate that the combination of procedural and imperative models with declarative elements, along with the exploitation of techniques from the field of AI such as situation calculus, IndiGolog and classical planning, can increase the ability of existing PMSs of supporting and adapting KiPs.

The adaptation mechanism is based on execution monitoring for detecting failures and context changes at run-time, without requiring to predefine any specific adaptation policy or exception handler at design-time (as most of the current approaches do). The use of classical planning techniques for the synthesis of the recovery procedure has a twofold consequence. On the one hand, we can exploit the good performance of current state-of-the-art planners to solve medium-sized real-world problems as used in practice. On the other hand, classical planning imposes some restrictions for addressing more expressive problems, including incomplete information, preferences and multiple task effects.

We note that, besides task failures, the execution of a KiP could be also jeopardized by the occurrence of *exogenous events*—e.g., a sudden fire outbreak in a coach—that could change, in asynchronous manner, some *contextual* properties of the scenario in which the process is under execution, hence possibly requiring the KiP to be adapted. Future work

is required to extend our approach to deal such disruptive exogenous events.

The current prototype of SmartPM is developed to be effectively used by process designers and practitioners.[5] Users define processes in the well-known BPMN language, enriched with semantic annotations for expressing properties of tasks, which allow our interpreter to derive the IndiGolog program representing the process. Interfaces with human actors (as specific graphical user applications in Java) and software services (through Web service technologies) allow the core system to be effectively used for enacting processes. Our future work will also improve the current prototype in order to be compliant with many other technologies adopted by process practitioners, e.g., RESTful services and HTML-based user interfaces.

Tweety: A Comprehensive Collection of Java Libraries for Logical Aspects of Artificial Intelligence and Knowledge Representation

Matthias Thimm
Institute for Web Science and Technologies (WeST)
University of Koblenz-Landau
Germany

Abstract

This paper presents Tweety, an open source project for scientific experimentation on logical aspects of artificial intelligence and particularly knowledge representation. Tweety provides a general framework for implementing and testing knowledge representation formalisms in a way that is familiar to researchers used to logical formalizations. This framework is very general, widely applicable, and can be used to implement a variety of knowledge representation formalisms from classical logics, over logic programming and computational models for argumentation, to probabilistic modeling approaches. Tweety already contains over 15 different knowledge representation formalisms and allows easy computation of examples, comparison of algorithms and approaches, and benchmark tests. This paper gives an overview on the technical architecture of Tweety and a description of its different libraries. We also provide two case studies that show how Tweety can be used for empirical evaluation of different problems in artificial intelligence.

1 Introduction

Knowledge Representation and Reasoning (KR) [Brachman and Levesque, 2004] is an important subfield in Artificial Intelligence (AI) that deals with issues regarding formalizing knowledge in such a way that machines can read, understand, and reason with it. Nowadays, KR has a lot of applications within, e. g., the semantic web [Antoniou and van Harmelen, 2004], as a lot of work on description logics [Baader et al., 2003] and ontologies originate from this field (at least the technical or computer-science-oriented perspectives on those). Apart from that, more fundamental work in KR deals with issues regarding uncertainty of beliefs, dynamics of belief, and defeasible reasoning. Many branches of research in knowledge representation and reasoning is theoretical in nature and researchers usually do not put effort in implementation and empirical evaluation. To address this issue we present in this field study the Tweety libraries for logical aspects of artificial intelligence and knowledge representation.

Approaches to knowledge representation follow almost always a specific pattern. Starting from a formal syntax one can build formulas which are collected in knowledge bases. Using knowledge bases one can derive new information using either the underlying semantics of the language or a specific reasoner. For example, propositional logic is the most basic form for knowledge representation. Given some set of propositions (or atoms) one can build complex formulas using disjunction, conjunction, or negation. A set of propositional formulas, i. e., a knowledge base, can be used to derive new propositional formulas as conclusions. For instance, this can be done using the standard model-theoretic semantics of propositional logic or more sophisticated reasoning techniques such as paraconsistent reasoning. Most logical approaches to knowledge representation such as first-order logic, description logics, defeasible logics, default logics, probabilistic logics, fuzzy logics, etc. follow this pattern. Moreover, many other formalisms which are not so obviously rooted in logic such as abstract argumentation or Bayes nets can also be cast into this framework. For example, for abstract argumentation frameworks [Dung, 1995], a knowledge base is given by a conjunction of attack statements between arguments and different kinds of semantics such as grounded or stable semantics determine how sets of arguments can be derived from a knowledge base.

The Tweety libraries support the implementation of such approaches by providing a couple of abstract classes and interfaces for components such as `Formula`, `BeliefBase`, and `Reasoner`. Furthermore, many strictly logic-based approaches to knowledge representation can also utilize further classes such as `Predicate`, `Atom`, and `Variable`, to name just a few. Currently, Tweety already contains implementations of over 15 different approaches to knowledge representation such as propositional logic, first-order logic, several approaches to probabilistic logics, and several approaches to computational models of argumentation.

In this paper, besides giving an overview on the technical details of Tweety and its libraries, we also report on two case studies that use Tweety as a framework for experimentation and empirical evaluation. The first study is on inconsistency measurement for probabilistic logics [Thimm, 2011; 2013b]. In general, probabilistic logics are concerned with using quantitative uncertainty for non-monotonic reasoning. Naturally, these approaches are computationally hard and not easy to understand, as the underlying reasoning mechanisms are quite complicated. Consequently, implementa-

tions serve well to understand examples and to (in-)validate conjectures. Our second case study is about strategic argumentation in multi-agent systems [Thimm and Garcia, 2010; Rienstra, Thimm, and Oren, 2013]. Similarly, when defining agent models and negotiation strategies in such an environment, effects that occur on a larger scale are hard to predict by hand. Moreover, just an analytical evaluation of different negotiation strategies is often also simply too weak to provide meaningful insights [Rienstra, Thimm, and Oren, 2013]. For that reason Tweety can also be used as a tool for empirical evaluation as it has been done in [Rienstra, Thimm, and Oren, 2013] to provide average performance results on a series of experiment runs in random settings. Further works that use Tweety for implementing knowledge representation formalisms or for empirical evaluation are, e. g., [Thimm and Kern-Isberner, 2008; Thimm and Garcia, 2010; Krümpelmann et al., 2011; Thimm, 2011; Kern-Isberner and Thimm, 2012; Thimm, 2012; 2013b; Rienstra, Thimm, and Oren, 2013; Thimm, 2013a; Krümpelmann and Kern-Isberner, 2012].

The rest of this paper is organized as follows. Section 2 gives an overview on the architecture of Tweety and Section 3 presents some technical details on its different libraries. In Section 4 two case studies are presented that show how Tweety can be used for evaluation in scientific research. Section 5 concludes with a summary and pointers to future work.

2 Technical Overview

Tweety is organized as a modular collection of Java libraries with a clear dependence structure. The programming language Java has been chosen as it is easy to understand, commonly used, and platform-independent. Each knowledge representation formalism has a dedicated Tweety library (ranging from a library on propositional logic to libraries on computational models of argumentation) which provides implementations for both syntactic and semantic constructs of the given formalism as well as reasoning capabilities. Several libraries provide basic functionalities that can be used in other projects. Among those is the *Tweety Core* library which contains abstract classes and interfaces for all kinds of knowledge representation formalisms. Furthermore, the library *Math* contains classes for dealing with mathematical sub-problems that often occur, in particular, in probabilistic approaches to reasoning. Most other Tweety projects deal with specific approaches to knowledge representation. In the next section, we have a closer look on the individual libraries.

Each Tweety library is organized as a Maven[1] project (Maven is a tool for organizing dependencies between projects, building, and deploying). Most libraries can be used right away as they only have dependencies to other Tweety libraries. Some libraries provide bridges to third-party libraries such as numerical optimization solvers which are not automatically found by Maven and have to be installed beforehand. However, all necessary third-party libraries can be installed by executing a single install file located within the Tweety distribution.

In order to use and develop with Tweety we recommend using the Eclipse IDE[2] and its Maven plugin[3]. As all Tweety libraries are organized as Maven projects they can all be easily imported and used for other projects within Eclipse. Furthermore, pre-compiled JARs for every library can be downloaded from the Tweety homepage[4] and directly used in other projects. A third way of using the functionalities of Tweety is by using its *Command Line Interface* which is currently under development.

Currently, Tweety contains 161 Java packages which themselves contain 794 Java classes in overall 87421 lines of code. The average cyclomatic complexity number per method (CCN) [McCabe, 1976] is 2.87. This means, that every method roughly contains two to three if-else statements thus reducing complexity on a method-basis and emphasizing the modular nature of Tweety. Furthermore, the average code-to-comment ratio in Tweety is 2.13, meaning that for roughly every two lines of code one line of comment is given.

3 Libraries

In the following we give a detailed description of the currently available libraries within Tweety. An overview of these libraries is given in Table 1 which provides both the name of a library and its Java root package name. Furthermore, the final column lists references to original literature and the implemented reasoning mechanisms and solvers. There, a dagger (†) indicates that a the particular reasoning mechanism has been directly implemented from the original literature, a double dagger (‡) means that a wrapper for the existing original implementation is provided, and an asterisk (*) refers to related literature.

General Libraries

The *General* libraries of Tweety provide basic functionalities and utility classes for all other Tweety classes.

Tweety Core The *Tweety Core* library contains abstract classes and interfaces for various knowledge representation concepts. Among the most important ones are

`Formula` A formula of a representation formalism.

`BeliefBase` Some structure containing beliefs.

`BeliefSet` A set of beliefs, i. e., a set of formulas, it is the most commonly used class derived from `BeliefBase`. Please note that we follow the Java guideline for naming a class containing a set of beliefs a *belief set* (it contains a finite unordered set of elements), opposed to the naming convention in belief dynamics where a *belief set* is usually deductively closed. In terms of belief dynamics research the class `BeliefSet` actually represents a *belief base*.

`Signature` The signature of a representation formalism.

`Interpretation` An interpretation that evaluates the truth of formulas.

`Reasoner` Implements a specific reasoning strategy to answer queries for a representation formalism.

`Parser, Writer` For reading/writing formulas and belief sets.

Most other Tweety libraries provide specific implementations of the above abstract classes and interfaces for their specific representation formalisms. For example, the library *Propositional Logic* implements `Formula` by `PropositionalFormula` (which is recursively defined using conjunction, disjunction, and negation) and `Interpretation` by `PossibleWorld`. In this way, the classical approach to formally define a logical language via syntax and semantics has a one-to-one correspondence with its implementation in Tweety.

Besides the above mentioned abstract classes and interfaces, *Tweety Core* provides abstract implementations of several other knowledge representation concepts and several utility classes for working with sets, subsets, vectors, and general rules.

Plugin The *Plugin* library provides classes for implementing Tweety plugins that can be used by, e. g., the *Command Line Interface*. This library makes use of the *Java Simple Plugin Framework (JSPF)*[5]. Using these classes one can encapsulate the functionalities of a specific knowledge representation formalism and expose them in the same way to user interfaces. The most important class is the abstract class `AbstractTweetyPlugin` which is the basis for developing plugins. Please note that the *Plugin* library is currently in an experimental phase.

Command Line Interface All Tweety libraries can be accessed programmatically in Java through their API (*Application Programming Interface*). However, for non-programmers this way of utilizing the libraries is not very convenient. Using the *Plugin* library the *Command Line Interface* library provides a general command line interface for many Tweety libraries. Every library can expose its functionality through a Tweety plugin that can be plugged into the command line interface and accessed in a uniform way. Please note that the *Command Line Interface* library is currently in an experimental phase.

Math Many algorithms for knowledge representation and reasoning are based on mathematical methods such as optimization techniques. The *Math* library encapsulates those mathematical methods and exposes them through simple interfaces to other libraries for realizing these algorithms. At the core, the *Math* library contains classes for representing mathematical terms (such as `Constant`, `Variable`, `Product`, `Logarithm`) and statements (such as `Equation`). Using these constructs one can represent, e. g., constraint satisfaction problems (`ConstraintSatisfactionProblem`) and optimization problems (`OptimizationProblem`). Through the `Solver` interface the *Math* library provides bridges to several third-party solvers such as the *ApacheCommons* Simplex-algorithm[6], the *OpenOpt* solvers[7], or Choco[8].

Graphs The *Graphs* library contains a simple graph implementation with utility functions as it can be used, e. g., to represent abstract argumentation frameworks (see *Abstract Argumentation* library).

Logic Libraries

The *Tweety Logic* libraries (located under the package `net.sf.tweety.logics`) provide implementations for various knowledge representation formalisms based on classical logics (propositional logic and first-order logic) and non-classical logics such as conditional logic, probabilistic logics, epistemic logics, or description logic. Each library follows a strict approach in defining the formalism by implementing the abstract classes and interfaces `Formula`, `BeliefBase`, `Interpretation`,... from the *Tweety Core* library. Each library contains a sub-package `syntax` which contains the elements to construct formulas of the formalism and a sub-package `semantics` which contains elements for realizing the semantics of the formalism. Besides these two common sub-packages many libraries also contain parsers for reading formulas from file and reasoner that implement a specific reasoning approach.

Logic Commons The *Logic Commons* library contains abstract classes and interfaces which further refine the general `Formula` interface from the *Tweety Core* library. Among these refinements are several concepts that are shared among a great number of knowledge representation formalism such as `Predicate`, `Variable` or `Atom`.

Propositional Logic The *Propositional Logic* library provides an implementation of classical propositional logic. Propositional formulas can be constructed using, e. g., classes `Conjunction` or `Disjunction` and propositional formulas can be put into a knowledge base of type `PlBeliefSet`. Currently, the *Propositional Logic* library supports two different reasoners. The first is a simple brute force approach that directly follows the definition of classical entailment, i. e., in order to prove a given propositional formula wrt. a given set of propositional formulas all possible worlds are enumerated and tested. Obviously, this reasoner only works for small examples but is useful when one is interested in all models of a knowledge base. The second supported reasoner incorporates the Sat4j reasoner[9]. Other SAT-solvers can be added in a straightforward way.

First-Order Logic This library contains an implementation of first-order logic as a knowledge representation formalism. Both the *Propositional Logic* library and the *First-Order Logic* library are used by many other libraries of knowledge representation formalisms.

Conditional Logic The *Conditional Logic* library extends the *Propositional Logic* library by *conditionals*, i. e., non-classical rules of the form $(B \mid A)$ ("A usually implies B"), cf. [Nute and Cross, 2002]. In the literature, several different semantics and reasoning approaches for conditional logics have been proposed and this library can be used to easily compare their reasoning behavior. Currently, the *Conditional Logic* library implements interpretations in the form of ranking functions [Spohn, 1988] and conditional structures [Kern-Isberner, 2001], and provides reasoner based on z-ranking [Goldszmidt and Pearl, 1996] and c-representations [Kern-Isberner, 2001].

Relational Conditional Logic Similar to the *Conditional Logic* library the *Relational Conditional Logic* extends the *First-Order Logic* libraries with relational conditionals (i. e. conditionals that may contain first-order formulas), cf. [Delgrande, 1998; Kern-Isberner and Thimm, 2012]. Currently, this library contains an implementation of the relational c-representation reasoning approach of [Kern-Isberner and Thimm, 2012].

Probabilistic Conditional Logic This library further extends the *Conditional Logic* library by extending conditionals to *probabilistic conditionals* of the form $(B \mid A)[p]$ ("A usually implies B with probability p"), cf. [Rödder, 2000]. Besides a naive implementation of probabilistic reasoning based on the principle of maximum entropy [Paris, 1994] this library also contains several classes for analyzing and repairing inconsistent sets of probabilistic conditionals, cf. [Thimm, 2011; 2013b]. We will discuss this package in more detail in Section 4.

Relational Probabilistic Conditional Logic By combining both the *Relational Conditional Logic* and *Probabilistic Conditional Logic* libraries the *Relational Probabilistic Conditional Logic* library introduces relational conditionals with probabilities, cf. [Kern-Isberner and Thimm, 2010]. It implements both the *averaging* and *aggregating* semantics from [Kern-Isberner and Thimm, 2010] and also allows for lifted inference as proposed in [Thimm, 2011].

Markov Logic This library builds on the *First-Order Logic* library to implement *Markov Logic*, an extension of first-order logic with weights to allow for probabilistic reasoning, cf. [Richardson and Domingos, 2006]. It provides several propriety sampling-based reasoner and a bridge to the Alchemy reasoner[10].

Epistemic Logic This library extends the *Propositional Logic* library with modal operators for epistemic logic and its semantics with accessibility relations and Kripke models. Please note that the *Epistemic Logic* library is currently in an experimental phase.

Description Logic The *Description Logic* library provides a general description logic implementation [Baader et al., 2003] based on the *First-Order Logic* library. Please note that the *Description Logic* library is currently in an experimental phase.

[10] http://alchemy.cs.washington.edu

Logic Translators This library provides the abstract class `Translator` that provides basic functionalities to implement translators between different knowledge representation formalisms. Currently, the *Logic Translators* library contains translators between first-order logic and answer set programming, between nested logic programming and answer set programming, and between propositional logic and first-order logic.

Logic Programming Libraries

The *Logic Programming* libraries (located under the package `net.sf.tweety.lp`) provide implementations of knowledge representation formalisms based on logic programming.

Answer Set Programming The *Answer Set Programming* library provides classes for representing extended logic programs [Gelfond and Leone, 2002]. Answer set programs are logic programs of the form $A \leftarrow B_1, \ldots, B_m$ with first-order literals $A, B_1, \ldots, B_m$ where the body literals $B_1, \ldots, B_m$ may also have a default negation not. This library provides bridges to several established solvers such as DLV[11], DLV Complex[12], and Clingo[13].

Dynamics in Answer Set Programming This library extends the *Answer Set Programming* library by introducing revision and update approaches. The library contains implementations of the approaches introduced in [Krümpelmann and Kern-Isberner, 2012; Delgrande, Schaub, and Tompits, 2007] and also revision approaches based on argumentation.

Nested Logic Programming This library contains an implementation of nested logic programs which allow for complex first-order formulas to appear in logic programming rules [Lifschitz, Tang, and Turner, 1999].

Argumentation Libraries

The argumentation libraries (located under the package `net.sf.tweety.arg`) are one of the most mature libraries of Tweety and contain a wide variety of implementations of different approaches to computational argumentation.

Abstract Argumentation This library implements abstract argumentation as proposed in [Dung, 1995]. An abstract argumentation framework is a directed graph (A, Att) where A is interpreted as a set of arguments and an edge $(A, A') \in Att$ is an attack of A on A'. The library provides implementations of the mostly used semantics and their corresponding reasoner, both in terms of extensions (an extension is a set of arguments that is regarded as accepted by a semantics) and labelings (a labeling is a function with a three-valued truth assignment to each argument). Several utility classes for generating random argumentation frameworks complement this library.

[11] http://www.dlvsystem.com

[12] https://www.mat.unical.it/dlv-complex

[13] http://potassco.sourceforge.net

Deductive Argumentation The *Deductive Argumentation* library provides an implementation of the approach proposed in [Besnard and Hunter, 2001]. In deductive argumentation, an argument is composed of a set of propositional formulas that derive the claim of the argument. Attack between arguments is derived from classical unsatisfiability.

Structured Argumentation Frameworks This library implements the approach of structured argumentation frameworks as proposed in [Thimm and Garcia, 2010]. In structured argumentation frameworks arguments are composed of subarguments and a conclusion.

Defeasible Logic Programming This library provides an implementation of Defeasible Logic Programming (DeLP) [Garcia and Simari, 2004]. In DeLP knowledge bases contain strict and defeasible rules and facts, similar to knowledge representation formalisms for logic programming. Defeasible rules can be collected in arguments and compared by generalized specificity [Stolzenburg et al., 2003].

Logic Programming Argumentation This library provides an implementation of the argumentation approach of [Schweimeier and Schroeder, 2003] which is also based on logic programming techniques.

Probabilistic Argumentation The *Probabilistic Argumentation* library extends the *Abstract Argumentation* library with non-classical semantics based on probabilistic assessments [Thimm, 2012].

Agent Libraries

The agent libraries (located under the package `net.sf.tweety.agents`) provide a framework for analyzing and simulating interactions between agents.

Agents This general library contains an abstract formalization of agents and multi-agent systems. Classes such as `Agent`, `Environment`, `MultiAgentSystem`, and `Protocol` can be used to set up and simulate a system of agents within an environment. This library has a specific focus on the simulation aspect and provides classes such as `MultiAgentSystemGenerator` and `GameSimulator` that allow the automatic generation of test scenarios and their evaluation.

Dialogues The library *Dialogues* extends the *Agents* library with the capability of simulating dialogues between agents, as they are investigated in the context of argumentation in multi-agent systems [Karunatillake et al., 2009]. It also provides an implementation of agents with an opponent model as proposed in [Rienstra, Thimm, and Oren, 2013]. We will discuss this package in more detail in Section 4.

Other Libraries

The above discussed libraries constitute the core of Tweety by providing implementations of several knowledge representation formalisms. This collection is complemented by some further libraries that relate either to topics that do not strictly belong to the field of knowledge representation (such as the *Machine Learning* library) or can be applied across several different knowledge representation formalisms (such as the *Belief Dynamics* library).

Action and Change The *Action and Change* library implements several action languages and their dynamics from [Gelfond and Lifschitz, 1998].

Belief Dynamics This library provides a general implementation for various approaches to belief (base) revision and update [Hansson, 2001]. It provides interfaces and several implementations of many concepts used in belief dynamics such as `BaseRevisionOperator`, `BaseContractionOperator`, `IncisionFunction`, and `LeviBaseRevisionOperator`. Those classes are defined in such a general way that they can be used not only to implement belief dynamics for propositional logic but also for other knowledge representation formalisms implementing the corresponding Tweety interfaces. This library contains also specific revision approaches such as selective revision [Fermé and Hansson, 1999] and argumentative selective revision [Krümpelmann et al., 2011].

Machine Learning The *Machine Learning* library provides several abstract concepts that can be used in a machine learning context such as `Observation`, `Classifier`, and `CrossValidator`. It contains also an implementation of support vector machines utilizing LIBSVM[14].

Preferences This library contains classes for representing preference orders and approaches for aggregating them [Walsh, 2007]. It also contains an implementation of the dynamic preference aggregation approach proposed in [Thimm, 2013a].

4 Case Studies and Evaluation

In this section we discuss two case studies that make use of Tweety as a platform for experimentation and empirical evaluation. The first case study is on inconsistency handling for probabilistic logics [Thimm, 2011; 2013b] while the second study is on strategic argumentation in multi-agent systems [Thimm and Garcia, 2010; Rienstra, Thimm, and Oren, 2013].

Inconsistency Handling for Probabilistic Logics

In order to motivate the work described in this section we give a brief introduction into probabilistic conditional logic and its inconsistency measures, cf. [Thimm, 2011; 2013b].

For propositional formulas ϕ, ψ and a real-value $p \in [0, 1]$ we call $(\phi \mid \psi)[p]$ a *probabilistic conditional*. A probabilistic conditional $(\phi \mid \psi)[p]$ represents a specific form of defeasible rule and has the intuitive meaning "if ψ is true then ϕ is true with probability p". A (probabilistic conditional) *knowledge base* $\mathcal{K}$ is a set of probabilistic conditionals. Semantics are given to probabilistic conditionals by probability functions $P : \Omega \rightarrow [0, 1]$ with Ω being the set of interpretations (possible worlds) of the underlying propositional logic (We assume that the set of propositions is finite and so is the

[14] http://www.csie.ntu.edu.tw/~cjlin/libsvm/

set of possible worlds). A probability function P *satisfies* a conditional $(\phi \mid \psi)[p]$ if and only if $P(\phi \wedge \psi) = pP(\psi)$ (the probability of a formula is defined to be the sum of the probabilities of all possible worlds satisfying it). Note that this follows the definition of conditional probability ($P(\phi \mid \psi) = P(\phi \wedge \phi)/P(\psi) = p$) as long as $P(\psi) \neq 0$. In order to avoid a case differentiation for $P(\psi) = 0$ we use the above definition, cf. [Paris, 1994]. A probability function P satisfies a knowledge base $\mathcal{K}$ if and only if it satisfies all its probabilistic conditionals. A knowledge base is consistent if such a probability function exists.

Example 1 *Consider* $\mathcal{K} = \{(f \mid b)[0.9], (b \mid p)[1], (f \mid p)[0.01]\}$ *with the intuitive meaning that birds* (b) *usually (with probability* 0.9*) fly* (f)*, that penguins* (p) *are always birds, and that penguins usually do not fly (only with probability* 0.01*). The knowledge base* $\mathcal{K}$ *is consistent as a probability function satisfying it can easily be constructed, cf. [Thimm, 2013b]. Note that, e. g., the knowledge base* $\mathcal{K} = \{(x \mid y)[0.9], (y \mid \top)[0.9], (x \mid \top)[0.2]\}$ *is inconsistent (*$\top$ *is a logical tautology): considering just the conditionals* $(x \mid y)[0.9]$ *and* $(y \mid \top)[0.9]$ *we obtain that* x *has to be at the least probability* 0.81 *which is inconsistent with stating that* x *has probability* 0.2*.*

In order to deal with inconsistent knowledge bases the work [Thimm, 2013b] proposes inconsistency measures as a tool for analyzing inconsistencies. An inconsistency measure is a function $\mathcal{I}$ that takes a knowledge base $\mathcal{K}$ and computes an inconsistency value $\mathcal{I}(\mathcal{K}) \in [0, \infty)$ with the intuitive meaning that a larger value indicates a more severe inconsistency (and $\mathcal{I}(\mathcal{K}) = 0$ means that $\mathcal{K}$ is consistent). See [Thimm, 2013b] for more details, some rationality postulates on inconsistency measurement, and specific approaches.

The inconsistency measurement framework for probabilistic logics has been implemented in the *Probabilistic Conditional Logic* library of Tweety (sub-package `net.sf.tweety.logics.pcl.analysis`). However, as inconsistency measurement is a broader topic that can also be used in other knowledge representation formalisms such as classical logics [Grant and Hunter, 2006], the concept *inconsistency measure* is already implemented in the *Logic Commons* library (sub-package `net.sf.tweety.logics.commons.analysis`) as a very general interface (only a simplified version is shown):

```
public interface InconsistencyMeasure
            <T extends BeliefBase> {
  public Double inconsistencyMeasure
                        (T beliefBase);
}
```

The interface above is parametrized by the specific type of belief base using Java Generics. All types of belief bases used within Tweety, such as propositional belief sets (`PlBeliefSet`) or probabilistic conditional knowledge bases (`PclBeliefSet`), are derived from `BeliefBase`. The package `net.sf.tweety.logics.commons.analysis` provides several generally applicable implementations of the above interface such as (only a simplified version is shown):

```
public class MiInconsistencyMeasure
  <S extends Formula,T extends BeliefSet<S>>
  implements InconsistencyMeasure<T> {

  private BeliefSetConsistencyTester<S,T>
      consTester;

  public MiInconsistencyMeasure(
      BeliefSetConsistencyTester<S,T>
      consTester){
    this.consTester = consTester;
  }

  @Override
  public Double inconsistencyMeasure
    (T beliefSet) {
      return new Double(this.consTester.
          minimalInconsistentSubsets(
          beliefSet).size());
  }
}
```

The above measure is an implementation of the MI-inconsistency measure [Grant and Hunter, 2006] and is applicable for all kinds of logics that provide an implementation of an `BeliefSetConsistencyTester`. This measure takes the number of minimal inconsistent subsets of a knowledge as an assessment of its inconsistency. Another example, particularly for the case of probabilistic conditional logic, is the `DistanceMinimizationInconsistencyMeasure` that makes use of the *Math* library. This measure assesses the grade of inconsistency by measuring how much the probabilities of the conditionals have to be modified in order to obtain a consistent knowledge base, cf. [Thimm, 2013b]. This problem is solved by optimization techniques that can be found in the *Math* library.

For probabilistic conditional logic, determining whether a knowledge base is inconsistent and assessing its inconsistency value is not easily done by hand. Using the implementations of various inconsistency measures in Tweety, we were able to compute and compare inconsistency values for various knowledge bases, cf. [Thimm, 2011]. Furthermore, as the interfaces and abstract classes provided by Tweety are very general and force the programmer to work as abstract as possible, even the implementation of such specific concepts such as inconsistency measures yield very generally applicable classes that are easily adapted to other approaches.

Strategic Argumentation

Our second case study is about strategic argumentation in multi-agent systems. In the works [Thimm and Garcia, 2010; Rienstra, Thimm, and Oren, 2013] we investigated systems of agents that are engaged in dialogues and aim at resolving contradiction by exchange of arguments. We give a brief introduction into the topic now, but simplify the formalization for the sake of readability.

We consider two agents PRO (proponent) and OPP (opponent) engaged in a dialogue about a specific argument A

(we use the terminology of abstract argumentation frameworks as mentioned earlier). The proponent has the goal to establish that A is acceptable and the opponent has the goal to establish that A is not acceptable. Both agents have only access to a subset of all available arguments and are, in general, ignorant or uncertain about the arguments the other agent has access to. Both agents take turn in forwarding a set of arguments. In [Rienstra, Thimm, and Oren, 2013] several different belief states with *opponent models* were proposed and discussed that help an agent to act strategically in these kinds of dialogues. The first type T_1 of belief state is a tuple (B, E) where B is the set of arguments a particular agent (either PRO or OPP) has access to, and E is the opponent model which is itself a belief state of type T_1[15]. This type of belief state therefore models what an agent thinks another agent beliefs, etc.. The second T_2 and third T_3 types of belief state extend the first type by introducing uncertainty on the set of arguments believed by the other agent and uncertainty about the arguments themselves. The second type of belief state T_2 is a tuple (B, P) where B is again the set of arguments a particular agent has access to and P is a probability distribution over some set $\{K_1, \ldots, K_n\}$ where each K_i $(i = 1, \ldots, n)$ is again a belief state of type T_2. For a formalization of the belief state of type T_3 see [Rienstra, Thimm, and Oren, 2013]. In [Rienstra, Thimm, and Oren, 2013] it has been analytically shown that the expressiveness of the three models is increasing from T_1 to T_3. However, in order to understand the differences between the three models examples have to be created and computed with different belief states. In the setting of strategic argumentation, this is a hard task to do by hand. In a system with at least two agents where both agents are equipped with a non-trivial belief state that changes with every action, running through a complete example by hand is a tedious task.

The complete setting of [Rienstra, Thimm, and Oren, 2013] has been implemented in the *Dialogues* library which makes heavy use of the general agent classes from the *Agents* library and, of course, the knowledge representation formalism from the *Abstract Argumentation* library. The central class of the implementation is the `ArguingAgent` class (we only show an excerpt):

```
public class ArguingAgent extends Agent {
  private BeliefState beliefState;
  private AgentFaction faction;

  @Override
  public Executable next(Collection<?
      extends Perceivable> percepts) {
    // [env = the environment object]
    this.beliefState.update(env.
        getDialogueTrace());
    return this.beliefState.move(env);
  }
}
```

The central attributes of an arguing agent are its belief state and its faction, e. g., either PRO or OPP. The method `next(...)` (derived from the super-class `Agent`) determines the agent's behavior on receiving some perception from the environment and returns some action (of type `Executable`). Here, the agent first updates its belief state with the current dialogue trace (a sequence of sets of arguments advanced so far) and then returns its own move (a set of arguments). The three different belief state types have been implemented in the classes `T1BeliefState`, `T2BeliefState`, and `T3BeliefState`. Arguing agents are organized in a `GroundedGameSystem` which is of type `MultiAgentSystem<ArguingAgent>` and models an argumentation dialogue ("grounded" refers to the grounded semantics used for this type of game). On top of this implementation of the actual dialogue system a simulation framework was implemented that allows the (random) generation of the above multi-agent systems and measures the performance of the individual agents over a series of runs. The central class for the simulation framework is the `GroundedGameGenerator` which implements the interface `MultiAgentSystemGenerator` and is able to generate (random) multi-agent systems of arguing agents.

In [Rienstra, Thimm, and Oren, 2013], for evaluating performance we generated a random abstract argumentation theory with 10 arguments, ensuring that the argument under consideration is in its grounded extension, i. e., under perfect information the proponent should win the dialogue. However, from these 10 arguments only 50 % are known by the proponent but 90 % by the opponent. We used a proponent without opponent model and generated an belief state of type T_3 for the opponent. From this T_3 belief state we derived T_2 and T_1 belief states by ignoring the added expressivity. For each belief state we simulated a dialogue against the same opponent and counted the number of wins. We repeated the experiment 5000 times, Figure 1 shows our results, cf. [Rienstra, Thimm, and Oren, 2013]. There, it can be seen that increasing the complexity of the belief state yields better overall performance (thus confirming the analytical evaluation). However, this empirical evaluation sheds also more light on the importance of the added expressivity for strategic argumentation. While T_2 is significantly better that T_1, the difference between T_3 and T_2 is nearly marginal. These kinds of nuances are very difficult to discover when considering only analytical evaluation.

5 Summary and Future Work

In this paper we presented Tweety, a comprehensive collection of Java libraries for logical aspects of artificial intelligence and knowledge representation. We gave an overview on the technical aspects and provided details on its individual packages. Finally, we presented two case studies that make use of Tweety as a framework for experimentation and empirical evaluation.

Tweety is an open source project[16,17] and can therefore be used and extended by everyone. In particular, instantiating the abstract Tweety classes for a particular formalism is sim-

[15] Note that this model has originally been proposed in [Oren and Norman, 2010]

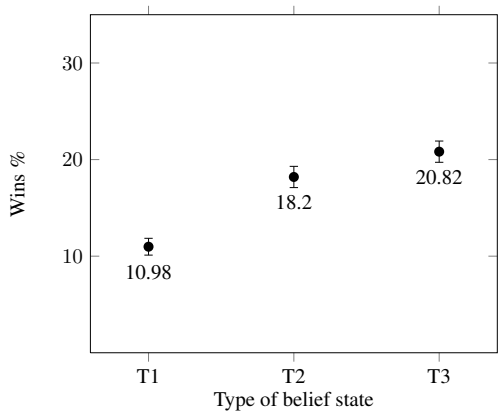

Figure 1: Average performance of T_1, T_2, and T_3 belief state models after 5000 simulation runs (with Binomial proportion confidence intervals)

ple. Although Tweety is implemented in a object-oriented programming language it follows a strict declarative formal way to define concepts from theoretical knowledge representation research. Tweety is available under the GNU General Public License version 3.0. In order to contribute to the main Tweety repository contact the author.

To the best of our knowledge, Tweety is the first attempt to provide a general-purpose framework for a broad variety of knowledge representation formalisms. However, there exist also more specialized frameworks for specific approaches or areas, such as the OWLAPI[18] for working with OWL ontologies, KReator[19] for relational probabilistic knowledge representation, or bcontractor[20] for belief dynamics.

Current and future work on Tweety is mainly concerned with extending the general infrastructure and improving usability. In particular, current work is about implementation of the plugin architecture for all libraries, a command line interface, and a web front-end. The ultimate goal there is to have several standardized user interfaces that are apt to work with any kind of knowledge representation mechanism and thus remove the burden of designing and implementing user interfaces from the researcher.

Acknowledgments

Tweety is being collaboratively developed by several contributors. Thanks go to Sebastian Homann, Tim Janus, Patrick Krümpelmann, Nico Potyka, Tjitze Rienstra, Stefan Tittel, Thomas Vengels, and Bastian Wolf. The research reported here was partially supported by the FP7 project SocialSensor (EC contract number 287975).

Abstract

Graphical belief models are compact and powerful tools for representing and reasoning under uncertainty. Possibilistic networks are graphical belief models based on possibility theory. In this paper, we address reasoning under uncertain inputs in both quantitative and qualitative possibilistic networks. More precisely, we first provide possibilistic counterparts of Pearl's methods of virtual evidence then compare them with the possibilistic counterparts of Jeffrey's rule of conditioning. As in the probabilistic setting, the two methods are shown to be equivalent in the quantitative setting regarding the existence and uniqueness of the solution. However in the qualitative setting, Pearl's method of virtual evidence which applies directly on graphical models disagrees with Jeffrey's rule and the virtual evidence method. The paper provides the precise situations where the methods are not equivalent. Finally, the paper addresses related issues like transformations from one method to another and commutativity.

Introduction

Belief revision and more generally belief dynamics is a fundamental task in artificial intelligence. Indeed, rational agents often need to revise their beliefs in order to take into account new information. In uncertainty frameworks, this task is often referred to as belief revision or reasoning with uncertain inputs. Belief revision has received a lot of attention in artificial intelligence especially in logic-based and some uncertainty frameworks (Benferhat et al. 2010)(Dubois and Prade 1994). In spite of the power of graphical belief models for representing and reasoning with uncertain information, belief revision and reasoning with uncertain inputs in such models is addressed only in few works mostly in the context of Bayesian networks (Chan and Darwiche 2005)(Vomlel 2004).

In this paper, we compare two methods for revising the beliefs encoded in a possibilistic framework when new and uncertain information is available. The two methods compared here are Jeffrey's rule of conditioning (Jeffrey 1965) and the virtual evidence method (Pearl 1988). They were originally proposed and studied in a probabilistic setting where they are shown to be equivalent and differ only in the way they specify the inputs (Chan and Darwiche 2005).

In the possibilistic setting, the counterparts of Jeffrey's rule are proposed in (Dubois and Prade 1997)(Dubois and Prade 1993). In (Benferhat, Tabia, and Sedki 2011), we studied the existence and the uniqueness of the solution in both the quantitative and qualitative possibilistic settings. The possibilistic counterpart of Jeffrey's rule is investigated for belief revision in possibilistic knowledge bases in (Benferhat et al. 2010) where it is claimed that this rule can successfully recover most of the belief revision kinds such as the natural belief revision, drastic belief revision, reinforcement, etc. In (Benferhat, Da Costa Pereira, and Tettamanzi 2013), a syntactic version is proposed for the possibilistic counterpart of Jeffrey's rule. In this paper, we address revising the beliefs encoded by means of possibilistic networks with uncertain inputs. More precisely, the paper provides

- Possibilistic counterparts of Pearl's method of virtual evidence and its generalization named the virtual evidence method in both the quantitative and qualitative settings. Unlike the probabilistic and quantitative possibilistic settings, the inputs for the qualitative counterparts of Pearl's methods should be possibility degrees because of the definition of the qualitative conditioning.
- An analysis of the existence and uniqueness of the solutions using the proposed possibilistic counterparts of Pearl's methods.
- Transformations from Jeffrey's rule to the virtual evidence method and vice versa and comparisons of these methods in both the quantitative and qualitative settings. As in the probabilistic setting, the two methods are shown to be equivalent in the quantitative setting regarding the existence and uniqueness of the solution. However in the qualitative setting, Pearl's method of virtual evidence is not equivalent to Jeffrey's rule since it is impossible using this method to increase the possibility degree of an event but its generalization is shown equivalent to Jeffrey's rule.

Possibility Theory and Possibilistic networks

Let us first fix the notations used in the rest of this paper. V=$\{X, Y, A_1, A_2, ..\}$ denotes a set of variables (in capital letters and indexed when necessary). D_{A_i}=$\{a_1, a_2, .., a_m\}$ denotes the domain of a variable A_i (note that D_{A_i} is assumed a finite domain). a_i denotes an instance (value) of variable A_i, namely $a_i \in D_{A_i}$. Ω=$\times_{A_i \in V} D_{A_i}$ denotes the

universe of discourse (all possible states of the world). It is the cartesian product of all the variable domains involved in V. A tuple w=$(a_1, a_2, .., a_n)$ which is an instance of Ω represents a possible state of the world (also called a model or interpretation). ϕ, φ, λ denote subsets of Ω called events.

Possibility theory

Possibility theory is an alternative uncertainty theory suited for representing and reasoning with uncertain and incomplete information (Dubois and Prade 1988a; Yager 1983). The concept of possibility distribution π is an important building block of possibility theory: It is a mapping from the universe of discourse Ω to the unit scale $[0, 1]$ which can be either quantitative or qualitative (ordinal). In both these settings, a possibility degree $\pi(w_i)$ expresses to what extent it is consistent that w_i can be the actual state of the world. In particular, $\pi(w_i)$=1 means that w_i is totally plausible and $\pi(w_i)$=0 denotes an impossible event. The relation $\pi(w_i)>\pi(w_j)$ means that w_i is more plausible than w_j. A possibility distribution π is said to be normalized if $\max_{w_i \in \Omega}(\pi(w_i))$=1. The second important concept in possibility theory is the one of possibility measure denoted $\Pi(\phi)$ and computing the possibility degree relative to an event $\phi \subseteq \Omega$. It evaluates to what extent ϕ is consistent with the current knowledge encoded by the possibility distribution π on Ω. It is defined as follows:

$$\Pi(\phi) = \max_{w_i \in \phi}(\pi(w_i)). \quad (1)$$

The term $\Pi(\phi)$ denotes the possibility degree of having one of the events involved in ϕ as the actual state of the world.
The necessity measure is the dual of possibility measure and evaluates the certainty implied by the current knowledge of the world. Namely, $N(\phi)$=$1 - \Pi(\overline{\phi})$ where $\overline{\phi}$ denotes the complement of ϕ.
According to the interpretation underlying the possibilistic scale [0,1], there are two variants of possibility theory:

- **Qualitative (or min-based) possibility theory**: In this case, the possibility distribution is a mapping from the universe of discourse Ω to an *ordinal* scale where only the "ordering" of the values is important.
- **Quantitative (or product-based) possibility theory**: In this case, the possibilistic scale [0,1] is numerical and possibility degrees are like numeric values that can be manipulated by arithmetic operators. One of the possible interpretations of quantitative possibility distributions is viewing $\pi(w_i)$ as a degree of surprise as in Spohn's ordinal conditional functions (Spohn 1988).

The other fundamental notion in possibility theory is the one of conditioning concerned with updating the current knowledge encoded by the possibility distribution π when a completely sure event (evidence) is observed. Note that there are several definitions of the possibilistic conditioning (Hisdal 1978)(L.M. De Campos and Moral 1995)(Dubois and Prade 1988b) (Fonck 1997). In the quantitative setting, the product-based conditioning (also known as Dempster rule of conditioning (Shafer 1976)) is defined as follows:

$$\pi(w_i|_p\phi) = \begin{cases} \frac{\pi(w_i)}{\Pi(\phi)} & \text{if } w_i \in \phi; \\ 0 & \text{otherwise.} \end{cases} \quad (2)$$

Conditioning in the qualitative setting is defined as follows (Hisdal 1978):

$$\pi(w_i|_m\phi) = \begin{cases} 1 & \text{if } \pi(w_i)=\Pi(\phi) \text{ and } w_i \in \phi; \\ \pi(w_i) & \text{if } \pi(w_i)< \Pi(\phi) \text{ and } w_i \in \phi; \\ 0 & \text{otherwise.} \end{cases} \quad (3)$$

While there are several similarities between the quantitative possibilistic and the probabilistic frameworks (conditioning is defined in the same way), the qualitative one is significantly different. Note that the two definitions of conditioning satisfy the condition: $\forall \omega \in \phi$, $\pi(\omega)=\pi(\omega|\phi) \otimes \Pi(\phi)$ where $\otimes$ is either the product or min-based operator.

Possibilistic networks

A possibilistic network G=$<\mathcal{G},\Theta>$ is specified by:

i) *A graphical component* $\mathcal{G}$ consisting in a directed acyclic graph (DAG) where vertices represent variables of interest and edges represent direct *dependence* relationships between these variables.

ii) *A quantitative component* Θ allowing to quantify the uncertainty of the relationships between domain variables using local possibility tables (CPTs). The quantitative component or G's parameters consist in a set of local possibility tables Θ_i=$\{\theta_{a_i|u_i}\}$ where $a_i \in D_i$ and u_i is an instance of U_i denoting the parent variables of A_i in $\mathcal{G}$.

Note that all the local possibility distributions Θ_i must be normalized, namely $\forall i$=1..n, $\forall u_i \in D_{U_i}$, $\max_{a_i \in D_i}(\theta_{a_i|u_i})$=1. The structure of G encodes a set of conditional independence relationships I=$\{I(A_i, U_i, Y)\}$ where Y is a subset of variables non descendent from A_i. For example, in the network of Figure 1, variable C is independent of B in the context of A.

Example 1. Figure 1 gives an example of a possibilistic network over four binary variables A, B, C and D.

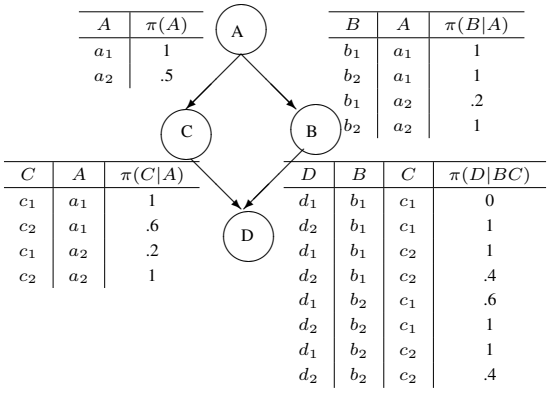

Figure 1: Example of a possibilistic network

In the possibilistic setting, the joint possibility distribution is factorized using the chain rule defined as follows:

$$\pi(a_1, a_2, .., a_n) = \otimes_{i=1}^{n}(\pi(a_i|u_i)), \quad (4)$$

where $\otimes$ denotes the product-based (resp. min-based) operator used in the quantitative (resp. qualitative) setting.

Example 2. In the min-based setting, the joint distribution encoded by the network of Figure 1 is derived as follows:

$$\pi(A, B, C, D) = \min(\pi(A), \pi(C|A), \pi(B|A), \pi(D|BC)).$$

Reasoning with uncertain inputs in the probabilistic setting

In the probabilistic framework, there are two main methods for revising beliefs represented using probability distributions or probabilistic models by uncertain information: Jeffrey's rule (Jeffrey 1965) and the virtual evidence methods (Pearl 1988). Let us first focus on the notions of beliefs and uncertain inputs.

Beliefs and uncertain inputs

The concept of belief used in this paper allows an agent to encode at which extent a given event is believed to be or become the actual state of the world. Generally, beliefs are specified over a universe of discourse Ω using belief measures like probability or possibility measures[1]. Then belief degrees are associated with each singleton event $\omega \in \Omega$ in the form of a belief distribution. According to the chosen setting, belief measures allow to assess the belief of any arbitrary event $\phi \subseteq \Omega$. Now given a set of initial beliefs (also called prior beliefs), an agent may have new information which can be in the form of evidence (also called hard evidence and corresponding for instance to a sure observation of the value of a variable) or in the form of uncertain or soft evidence (e.g. unreliable input) or simply new beliefs regarding some events[2]. In the uncertainty literature, belief change dealing with hard evidence is known as belief update and it is generally based on conditioning while it is known as belief revision in case of uncertain inputs.
In Jeffrey's rule and the virtual evidence methods, the uncertainty bears on an exhaustive and mutually exclusive set of events $\lambda_1,..,\lambda_n$ (namely, $\forall \lambda_i \subseteq \Omega$ and $\forall \lambda_j \subseteq \Omega$ with $i \neq j$, we have $\lambda_i \cap \lambda_j = \emptyset$ and $\lambda_1 \cup \lambda_2 \cup .. \cup \lambda_n = \Omega$). However, the new information is expressed differently:

- In Jeffrey's rule, the new beliefs are a probability distribution over $\lambda_1,..,\lambda_n$ and must consequently sum up to 1. The new information is expressed in the form of (λ_i, α_i) such that $P'(\lambda_i) = \alpha_i$ where p' denotes the revised probability distribution fully accepting the new beliefs.
- In Pearl's methods, the new information is expressed by specifying the amount of increase or decrease of the belief on each event λ_i moving from p to p'. This amount is called in (Darwiche 2009) the Bayes factor and corresponds to the ratio $\frac{P'(\lambda_i)}{P(\lambda_i)}$. For example, a ratio regarding an event λ_i of 2 means that the new belief regarding λ_i is twice as it was before receiving this new information.

[1]The beliefs of an agent can be encoded using other formalisms like belief bases (e.g. probabilistic or possibilistic knowledge bases), graphical belief models, etc.

[2]On the different meanings of hard, soft and uncertain evidence, see (Ma and Liu 2011)(Pan, Peng, and Ding 2006)(Bilmes 2004).

Jeffrey's rule of conditioning

Jeffrey's rule (Jeffrey 1965) is an extension of the probabilistic conditioning to the case where the evidence is uncertain. This method involves a way for:

1. **Specifying the uncertain evidence:** The uncertainty is of the form (λ_i, α_i) with $\alpha_i = P'(\lambda_i)$ meaning that after the revision operation, the posterior probability of each event λ_i must be equal to α_i (namely, $P'(\lambda_i) = \alpha_i$). The uncertain inputs are seen as a constraint or an effect once the new information is fully accepted.
2. **Computing the revised probability distributions:** Jeffrey's method assumes that although there is a disagreement about the events λ_i in the old distribution p and the new one p', the conditional probability of any event $\phi \subseteq \Omega$ given any uncertain event λ_i remains the same in the original and the revised distributions. Namely,

$$\forall \lambda_i \in \Omega, \forall \phi \subseteq \Omega, P(\phi|\lambda_i) = P'(\phi|\lambda_i). \quad (5)$$

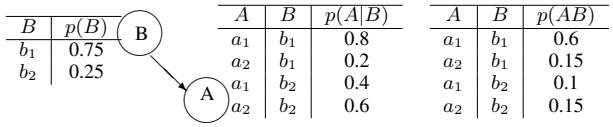
The underlying interpretation of the revision implied by constraint of Equation 5 is that the revised probability distribution p' must not change the conditional probability degrees of any event ϕ given the uncertain events λ_i. To revise the probability degree of any event $\phi \subseteq \Omega$, the following formula is used:

$$P'(\phi) = \sum_{\lambda_i} \alpha_i * \frac{P(\phi, \lambda_i)}{P(\lambda_i)}. \quad (6)$$

The revised distribution p' obtained using Jeffrey's rule always exists and it is unique (Chan and Darwiche 2005). In the following, we first present Pearl's method of virtual evidence applying directly on Bayesian networks then its generalization named virtual evidence method applying directly on probability distributions as in Jeffrey's rule.

Pearl's method of virtual evidence

This method is proposed in (Pearl 1988) in the framework of Bayesian networks. The main idea of this method is to cast the uncertainty relative to the uncertain evidence E on some $virtual$ sure event η: the uncertainty regarding E is specified as the likelihood of η in the context of E. In Pearl's method of virtual evidence the beliefs are encoded with a Bayesian network over a set of variables $\{A_1, .., A_n\}$. Assume that the observation regarding a variable A_i is uncertain (for instance, because of a sensor unreliability). Pearl's virtual evidence method deals with this issue by adding for each uncertain observation variable A_i a variable Z_i with an arc from A_i to Z_i. The uncertainty relative to A_i is then cast as the likelihoods of $Z_i = z_i$ in the context of A_i. Then the uncertain inputs are taken into account by observing the sure evidence $Z_i = z_i$. Doing this way, it is clear that the conditional probability of any event ϕ given A_i is the same in the old and revised distribution, namely $\forall \phi \subseteq \Omega$, $p(\phi|A_i) = p'(\phi|A_i)$. It is the d-separation[3] criterion that ensures this property. In this method, the uncertainty bears on a set of exhaustive and mutually exclusive events $a_1,..,a_n$ (forming the domain of variable A_i). Let $\gamma_1 :..: \gamma_n$ denote the



[3]The d-separation property states that two disjoint variable subsets X and Y are d-separated if there exists a third variable sub-set Z such that X and Y are independent given Z.

likelihood ratios encoding the new inputs. Such ratios should satisfy the following condition:

$$\gamma_1 : .. : \gamma_n = \frac{P'(a_1)}{P(a_1)} : .. : \frac{P'(a_n)}{P(a_n)} \quad (7)$$

Note that there are many solutions for the values of $\gamma_1, .. , \gamma_n$ satisfying the condition of Equation 7 (one possible solution for encoding the inputs within the network is to set $p(z|a_i)$ to γ_i=$\frac{p'(a_i)}{p(a_i)}$). It is worth to mention that contrary to Jeffrey's rule where the inputs α_1,..,α_n are the revised belief degrees once the revision performed, in Pearl's methods, the inputs are likelihood ratios γ_1,..,γ_n satisfying Equation 7 and they don't form a probability distribution.

Example 3. *Assume that the current beliefs about a given problem are encoded by the Bayesian network G of Figure 2 over two binary variables A and B. The joint probability distribution encoded by this network is given by the joint probability distribution $p(AB)$ of Figure 2.*

z	a_2	2

Figure 3: Bayesian network G': Bayesian network G of Figure 2 augmented with node Z to encode the new inputs.

Let us mention that the conditional probability table of node Z in order to encode the new inputs don't need to be normalized (it can easily be normalized but this is not needed to revise the old beliefs encoded by the initial network). Another solution satisfying Equation 7 is γ_{a_1}:γ_{a_2} = .2:.7 (since $\frac{.57}{2}$=$\frac{.2}{.7}$). The revised beliefs are given in Table 1.

A	B	$p(AB\|z)$
a_1	b_1	0.34
a_2	b_1	0.3
a_1	b_2	0.06
a_2	b_2	0.3

Table 1: The conditional distribution $p_{G'}(.|z)$ representing the revised distribution encoded by the network of Figure 2.

It is easy to check that the revised distribution p'=$p_{G'}(.|z)$ fully integrates the inputs.

Virtual evidence method

The virtual evidence method generalizes Pearl's method of virtual evidence and applies directly on joint probability distributions as in Jeffrey's rule.

1. **Specifying the uncertain inputs:** The new information is in the form of a set of likelihood ratios γ_1,..,γ_n such that γ_i=$P(\eta|\lambda_i)$ and
$$\gamma_1 : .. : \gamma_n = \frac{P'(\lambda_1)}{P(\lambda_1)} : .. : \frac{P'(\lambda_n)}{P(\lambda_n)},$$
where λ_1,..,λ_n denote the exhaustive and mutually exclusive set of events on which bears the uncertainty. Moreover, as a consequence of the d-separation criterion in Bayesian networks, we have the following property:
$$\forall \phi \subseteq \Omega, \forall i = 1..n, P'(\eta|\lambda_i, \phi) = P'(\eta|\lambda_i),$$
where η denotes the virtual event.
2. **Computing the revised beliefs:** The revised probability distribution p' is simply equivalent to $p(.|\eta)$ and it is computed as follows (Chan and Darwiche 2005):
$$\forall \phi \subseteq \Omega, P'(\phi) = P(\phi|\eta) = \frac{\sum_{i=1}^{n}(\gamma_i * P(\lambda_i, \phi))}{\sum_{j=1}^{n}(\gamma_j * P(\lambda_j))}. \quad (8)$$

Example 4. *Let us reuse the joint probability distribution of the example of Figure 2. Let also the likelihood ratios be γ_1=$\frac{P'(a_1)}{P(a_1)}$=.57 and γ_2=$\frac{P'(a_2)}{P(a_2)}$=2. The revised distribution p' is computed using Equation 8.*

A	B	$p(AB)$
a_1	b_1	0.6
a_2	b_1	0.15
a_1	b_2	0.1
a_2	b_2	0.15

A	B	$p(AB\|\eta)$
a_1	b_1	0.34
a_2	b_1	0.3
a_1	b_2	0.06
a_2	b_2	0.3

Table 2: Example of initial probability distribution p and the revised distribution $p(.|\eta)$.

From the results of Table 1 and Table 2, it is clear that the revised distributions are equivalent.

Jeffrey's rule and Pearl's methods differ only in the way they specify the inputs and the way the revised beliefs are computed (Chan and Darwiche 2005). In Jeffrey's rule, the inputs are seen as the result or the effect of the revision operation while in the virtual evidence method, the inputs only denote the relative difference between the old beliefs and the revised ones specified in terms of likelihood ratios.
In the following, we compare the two methods presented in this section in a possibilistic framework.

Reasoning with uncertain inputs in the quantitative possibilistic setting

Jeffrey's rule of conditioning in the quantitative possibilistic setting

In the possibilistic setting, given the initial beliefs encoded by a possibility distribution π and a set of inputs in the form of (α_i, λ_i) such that $\Pi'(\lambda_i)$=α_i and α_i∈[0, 1] meaning that

after revising π, the new possibility degree of λ_i is α_i. The revised possibility distribution π' according to Jeffrey's rule must satisfy the following conditions:

C1: $\forall\lambda_i, \Pi'(\lambda_i)=\alpha_i$.

C2: $\forall\lambda_i\subset\Omega, \forall\phi\subseteq\Omega, \Pi'(\phi|\lambda_i)=\Pi(\phi|\lambda_i)$.

As in the probabilistic setting, revising a possibility distribution π into π' according to the possibilistic counterpart of Jeffrey's rule must fully accept the inputs (condition C1) and preserve the fact that the uncertainty about the events λ_i must not alter the conditional possibility degree of any event $\phi\subseteq\Omega$ given any uncertain event λ_i (condition C2). The revision based on the possibilistic counterpart of Jeffrey's rule in the product-based possibilistic setting is performed as follows (Dubois and Prade 1997):

Definition 1. *Let π be a possibility distribution and (λ_1, α_1),..,(λ_n, α_n) be a set of exhaustive and mutually exclusive events where the uncertainty is of the form $\Pi'(\lambda_i)=\alpha_i$ for i=1..n. The revised possibility degree of any arbitrary event $\phi\subseteq\Omega$ is computed as follows (we assume that $\Pi(\phi)>0$):*

$$\forall\phi\subseteq\Omega, \Pi'(\phi)=\max_{\lambda_i}(\alpha_i * \frac{\Pi(\phi,\lambda_i)}{\Pi(\lambda_i)}). \quad (9)$$

It follows from Equation 9 that the revised possibility degree of any interpretation $\omega_j\in\Omega$ is computed as follows:

$$\forall\omega_j\in\lambda_i, \pi'(w_j)=\alpha_i * \frac{\pi(w_j)}{\Pi(\lambda_i)}.$$

It is shown in (Benferhat, Tabia, and Sedki 2011) that the revised possibility distribution π' computed according to Definition 1 always exists and it is unique.

Example 5. *In this example, we assume that we have beliefs over two binary variables A and B. The possibility distribution $\pi(AB)$ encodes the current beliefs. Table 3 gives the distribution π, the marginal distribution of A (namely, $\pi(A)$), the one of B (namely, $\pi(B)$) and the conditional distribution of B given A (namely, $\pi(B|A)$).*

A	B	$\pi(AB)$
a_1	b_1	1
a_2	b_1	0.4
a_1	b_2	0.1
a_2	b_2	0.4

A	$\pi(A)$
a_1	1
a_2	0.4

B	$\pi(B)$
b_1	1
b_2	0.4

A	B	$\pi(B\|A)$
a_1	b_1	1
a_2	b_1	1
a_1	b_2	0.1
a_2	b_2	1

Table 3: Example of initial possibility distribution π and the underlying marginal and conditional distributions.

Now assume that we have new beliefs in the form (a_1, .4) and (a_2, 1). The revised distribution using Jeffrey's rule of Equation 9 is given by π' of Table 4.

According to Tables 3 and 4, it is clear that the input beliefs are fully accepted (see the marginal distribution $\pi'(A)$) and that $\forall a_i\in D_A$, $\forall b_j\in D_B$, $\Pi(b_j|a_i)=\Pi'(b_j|a_i)$.

Pearl's method of virtual evidence in the quantitative possibilistic setting

In Pearl's virtual evidence method, the new information is a set of likelihood ratios γ_1,..,γ_n and satisfies the following condition:

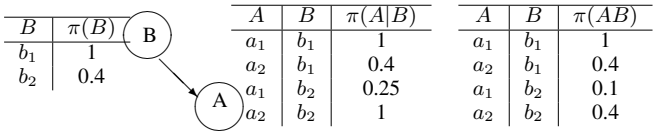
A	B	$\pi'(AB)$
a_1	b_1	0.4
a_2	b_1	1
a_1	b_2	0.04
a_2	b_2	1

A	$\pi'(A)$
a_1	**0.4**
a_2	**1**

B	$\pi'(B)$
b_1	1
b_2	1

A	B	$\pi'(B\|A)$
a_1	b_1	1
a_2	b_1	1
a_1	b_2	0.1
a_2	b_2	1

Table 4: Revised beliefs of the initial distribution given in Table 3 using Jeffrey's rule of Equation 9.



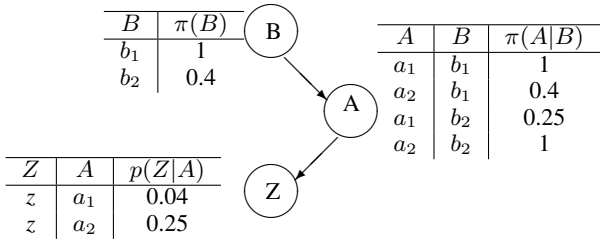
C3: γ_1:..:γ_n= $\Pi(\eta|\lambda_1)$:..:$\Pi(\eta|\lambda_n)$=$\frac{\Pi(\lambda_1|\eta)}{\Pi(\lambda_1)}$:..:$\frac{\Pi(\lambda_n|\eta)}{\Pi(\lambda_n)}$.

Pearl's virtual evidence method guarantees that the uncertainty bears only on the events λ_1,..,λ_n and does not concern the other events. Formally,

C4: $\forall\phi\subseteq\Omega, \Pi(\eta|\lambda_i,\phi)=\Pi(\eta|\lambda_i)$.

Pearl's method of virtual evidence applies in a quite straightforward way for quantitative possibilistic networks. Indeed, once the new inputs specified, they are integrated into the network G encoding the current beliefs in the form of a new node Z with a conditional possibility table designed in such a way that conditioning on the node Z, the conditional distribution $\pi_G(.|z)$ provides the revised joint distribution.

Example 6. *Let G be a possibilistic network over two binary variables A and B. The network G encodes the same possibility distribution as the distribution π of Table 3.*



B	$\pi(B)$
b_1	1
b_2	0.4

A	B	$\pi(A\|B)$
a_1	b_1	1
a_2	b_1	0.4
a_1	b_2	0.25
a_2	b_2	1

A	B	$\pi(AB)$
a_1	b_1	1
a_2	b_1	0.4
a_1	b_2	0.1
a_2	b_2	0.4

Figure 4: Example of a possibilistic network G and the joint distribution $\pi(AB)$ encoded by G.

Let us assume now that new information says that γ_{a_1}:γ_{a_2}=.4:2.5. One solution satisfying this ratio is γ_{a_1}=.04 and γ_{a_2}=.25. Let us then add a new node Z to integrate γ_{a_1} and γ_{a_2}.

B	$\pi(B)$
b_1	1
b_2	0.4

A	B	$\pi(A\|B)$
a_1	b_1	1
a_2	b_1	0.4
a_1	b_2	0.25
a_2	b_2	1

Z	A	$p(Z\|A)$
z	a_1	0.04
z	a_2	0.25

Figure 5: G': The possibilistic network G of Figure 4 augmented with the node Z.

The revised beliefs are given in Table 5.

One can easily check that the revised distribution of Table 5 using Pearl's method of virtual evidence is exactly the same as the distribution π' obtained using Jeffrey's rule given in Table 4. It is also easy to check that conditions C3 and C4 are satisfied.

A	B	$\pi(AB\|z)$
a_1	b_1	0.4
a_2	b_1	1
a_1	b_2	0.04
a_2	b_2	1

Table 5: The conditional possibility distribution $\pi_{G'}(.|z)$ representing the revised distribution of the initial beliefs encoded by the network of Figure 4.

After addressing Pearl's method of virtual evidence in the quantitative possibilistic setting, let us see its generalization.

Virtual evidence method in the quantitative possibilistic setting

Here, the virtual evidence method applies on any possibility distribution exactly as Jeffrey's rule. The revised beliefs are computed according to the following definition.

Definition 2. *Let the initial beliefs be encoded by π and the new inputs be $\gamma_1,..,\gamma_n$. The revised possibility degree $\Pi'(\phi)$ of any event $\phi \subseteq \Omega$ is computed as follows:*

$$\forall \phi \subseteq \Omega, \Pi'(\phi) = \Pi(\phi|\eta) = \frac{\max_{i=1}^{n} \gamma_i * \Pi(\phi, \lambda_i)}{\max_{j=1}^{n} \gamma_j * \Pi(\lambda_j)}. \quad (10)$$

It is straightforward that revising the possibility degree of individual events $\omega_k \in \Omega$ is done as follows:

$$\forall \omega_k \in \lambda_i, \pi'(\omega_k) = \pi(\omega_k|\eta) = \frac{\gamma_i * \pi(\omega_k)}{\max_{j=1}^{n} \gamma_j * \Pi(\lambda_j)}. \quad (11)$$

Example 7. *Let the initial beliefs be encoded by the possibility distribution π of Table 6. Let also the likelihood ratios be $\gamma_1 = \frac{\Pi'(a_1)}{\Pi(a_1)} = .4$ and $\gamma_2 = \frac{\Pi'(a_2)}{\Pi(a_2)} = 2.5$ as in the example of Table 5. The revised distribution π' is computed using Equation 10.*

A	B	$\pi(AB)$
a_1	b_1	1
a_2	b_1	0.4
a_1	b_2	0.1
a_2	b_2	0.4

A	B	$\pi(AB\|\eta)$
a_1	b_1	0.4
a_2	b_1	1
a_1	b_2	0.04
a_2	b_2	1

Table 6: Example of initial possibility distribution π and the revised distribution $\pi(.|\eta)$.

The distribution π' computed using Equation 11 always exists and it is unique according the following proposition.

Proposition 1. *Let π be the possibility distribution encoding the initial beliefs. Let also $\gamma_1,..,\gamma_n$ be the likelihood ratios corresponding to the new inputs regarding the exhaustive and mutually exclusive set of events $\lambda_1,..,\lambda_n$. Then the revised possibility distribution π' computed using the formula of Equation 10 always exists and it is unique.*

Proof. Let π be the possibility distribution encoding the initial beliefs and let $\gamma_1,..,\gamma_n$ be the likelihood ratios regarding the events $\lambda_1,..,\lambda_n$.

1. Let us first show that the revised possibility distribution π' computed using the formula of Equation 10 satisfies the conditions **(C3)** and **(C4)**. Let us start proving that condition **(C3)** is satisfied.

$\Pi(\eta|\lambda_1) :..: \Pi(\eta|\lambda_n) = \frac{\Pi(\eta,\lambda_1)}{\Pi(\lambda_1)} :..: \frac{\Pi(\eta,\lambda_n)}{\Pi(\lambda_n)}$

$= \frac{\Pi(\lambda_1|\eta)*\Pi(\eta)}{\Pi(\lambda_n)} :..: \frac{\Pi(\lambda_n|\eta)*\Pi(\eta)}{\Pi(\lambda_n)}$

$= \frac{\frac{\gamma_1*\Pi(\lambda_1)}{\max_j(\gamma_j*\Pi(\lambda_j))}*\Pi(\eta)}{\Pi(\lambda_n)} :..: \frac{\frac{\gamma_n*\Pi(\lambda_n)}{\max_j(\gamma_j*\Pi(\lambda_j))}*\Pi(\eta)}{\Pi(\lambda_n)}$

$= \gamma_1 * \frac{\Pi(\eta)}{\max_j(\gamma_j*\Pi(\lambda_j))} :..: \gamma_n * \frac{\Pi(\eta)}{\max_j(\gamma_j*\Pi(\lambda_j))}$

$= \gamma_1 :..: \gamma_n$ □

Let us now prove that condition **(C4)** is satisfied.

$\forall \phi \subseteq \Omega, \Pi(\eta|\lambda_i, \phi) = \frac{\Pi(\eta,\lambda_i,\phi)}{\Pi(\lambda_i,\phi)}$

$= \frac{\Pi(\lambda_i,\phi|\eta)*\Pi(\eta)}{\Pi(\lambda_i,\phi)} = \frac{\frac{\gamma_i*\Pi(\lambda_i,\phi)}{\max_j(\gamma_j*\Pi(\lambda_j))}*\Pi(\eta)}{\Pi(\lambda_i,\phi)}$

$= \frac{\gamma_i*\Pi(\eta)}{\max_j(\gamma_j*\Pi(\lambda_j))} = \frac{\gamma_i*\frac{\Pi(\lambda_i,\eta)}{\Pi(\lambda_i|\eta)}}{\max_j(\gamma_j*\Pi(\lambda_j))}$

$= \frac{\gamma_i*\frac{\Pi(\lambda_i,\eta)}{\gamma_i*\Pi(\lambda_i)}}{\frac{\max_j(\gamma_j*\Pi(\lambda_j))}{\max_j(\gamma_j*\Pi(\lambda_j))}}$

$= \frac{\Pi(\lambda_i,\eta)}{\Pi(\lambda_i)} = \Pi(\eta|\lambda_i)$ □

2. Now let us provide the proof that if a distribution π' satisfies the conditions **(C3)** and **(C4)** then π' is computed using Equation 10.

$\forall \phi \subseteq \Omega, \Pi'(\phi) = \Pi(\phi|\eta) = \frac{\Pi(\phi,\eta)}{\Pi(\eta)}$

$= \frac{\max_{i=1}^{n}(\Pi(\phi,\lambda_i,\eta))}{\max_{j=1}^{n}(\Pi(\lambda_j,\eta))}$

$= \frac{\max_{i=1}^{n}(\Pi(\eta|\phi,\lambda_i)*\Pi(\phi,\lambda_i))}{\max_{j=1}^{n}(\Pi(\eta|\lambda_j)*\Pi(\lambda_j))}$

$= \frac{\max_{i=1}^{n}(\Pi(\eta|\lambda_i)*\Pi(\phi,\lambda_i))}{\max_{j=1}^{n}(\Pi(\eta|\lambda_j)*\Pi(\lambda_j))}$

$= \frac{\max_{i=1}^{n}(\gamma_i*\Pi(\phi,\lambda_i))}{\max_{j=1}^{n}(\gamma_j*\Pi(\lambda_j))}$ □

In the following, we provide the transformations from Jeffrey's rule to the virtual evidence method and vice versa.

From Jeffrey's rule to the virtual evidence method in a quantitative possibilistic setting

The following transformations are the possibilistic counterparts of the corresponding ones proposed in the probabilistic framework in (Chan and Darwiche 2005):

Proposition 2. *Let π be a possibility distribution encoding the initial beliefs and let also $\lambda_1,..,\lambda_n$ be an exhaustive and mutually exclusive set of events and new information in the form of (α_i, λ_i) such that for $i=1..n$, $\Pi'(\lambda_i)=\alpha_i$. Let $\gamma_1,..,\gamma_n$ be likelihood ratios such that*

$$\gamma_1 : .. : \gamma_n = \frac{\alpha_1}{\Pi(\lambda_1)} : .. : \frac{\alpha_n}{\Pi(\lambda_n)},$$

then the revised possibility distribution π'_J computed using Jeffrey's rule of Equation 9 and the revised possibility distribution π'_P computed using the virtual evidence method of Equation 10 are equivalent. Namely, $\forall\omega\in\Omega$, $\pi'_J(\omega)=\pi'_P(\omega)$.

Proof sketch. The proof is direct. Just set in the virtual evidence method of Equation 10 $\gamma_i=\frac{\alpha_i}{\Pi(\lambda_i)}$ for i=1..n, and the obtained distribution π'_P satisfies conditions C1 and C2 of Jeffrey's rule and since the revised distribution with Jeffrey's rule is unique then π'_P equals π'_J. □

From the virtual evidence method to Jeffrey's rule in a quantitative possibilistic setting

We show now how to obtain the new beliefs α_1,..,α_n needed in Jeffrey's rule from the available set of likelihood ratios:

Proposition 3. *Let π be a possibility distribution encoding the initial beliefs. Let also λ_1,..,λ_n be an exhaustive and mutually exclusive set of events and new information in the form of likelihood ratios γ_1,..,γ_n. For i=1..n, let $\alpha_i=\gamma_i*\Pi(\lambda_i)$. Then the revised possibility distribution π'_J computed using Jeffrey's rule of Equation 9 and the revised possibility distribution π'_P computed using the virtual evidence method of Equation 10 are equivalent. Namely, $\forall\omega\in\Omega$, $\pi'_J(\omega)=\pi'_P(\omega)$.*

Proof sketch. The proof is similar to the proof of Proposition 2. Using Jeffrey's rule of Equation 9 with the inputs (λ_i, α_i) for i=1..n such that $\alpha_i=\gamma_i*\Pi(\lambda_i)$ and the obtained distribution π'_J satisfies conditions C3 and C4 of the virtual evidence method and since the revised distribution is also unique then π'_J equals π'_P. □

Reasoning with uncertain inputs in the qualitative possibilistic setting

Jeffrey's rule in the qualitative possibilistic setting

In the qualitative setting, the revision according to Jeffrey's rule is performed as follows (Dubois and Prade 1997):

Definition 3. *Let π be a possibility distribution and λ_1,..,λ_n be a set of exhaustive and mutually exclusive events. The revised possibility degree of any arbitrary event $\phi\subseteq\Omega$ is computed using the following formula:*

$$\forall\phi\subseteq\Omega, \Pi'(\phi)=\max_{\lambda_i}(\min(\Pi(\phi|\lambda_i),\alpha_i)). \quad (12)$$

It is straightforward that for elementary events ω_j, the revised beliefs are computed according the following formula:

$$\forall w_j\in\lambda_i, \pi'(w_j)=\begin{cases}\alpha_i & \text{if } \pi(w_j)\geq\alpha_i \text{ or } \pi(w_j)=\Pi(\lambda_i);\\ \pi(w_j) & \text{otherwise.}\end{cases}$$

Contrary to the probabilistic and quantitative possibilistic settings, there exist situations where the revision according to Equation 12 does not guarantee the existence of a solution satisfying conditions C1 and C2 (Benferhat, Tabia, and Sedki 2011).

Example 8. *Assume that we have beliefs in the form of a possibility distribution $\pi(AB)$ over two binary variables A and B (we have the same beliefs as in Table 3). In Table 7, we have the joint distribution $\pi(AB)$, the marginal distributions $\pi(A)$ and $\pi(B)$) and the conditional one $\pi(B|A)$.*

A	B	$\pi(AB)$
a_1	b_1	1

a_2	b_2	1

Table 8: Revised beliefs of the initial distribution given in Table 7 using Jeffrey's rule of Equation 12.

According to the results of Table 7 and 8, it is clear that in this example conditions C1 and C2 are fulfilled.

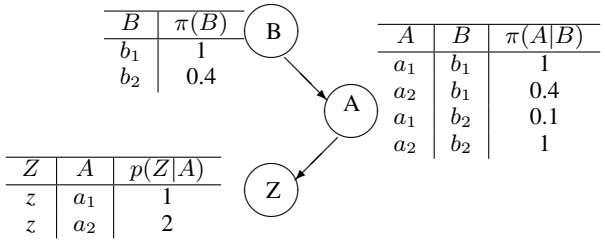
Pearl's method of virtual evidence in the qualitative possibilistic setting

As in the quantitative setting, the inputs are specified in the same way. Namely, the uncertainty bears on an exhaustive and mutually exclusive set of events λ_1,..,λ_n and the new information is specified as likelihood ratios γ_1:..:γ_n according to condition C3. As shown in the following example, unlike the probabilistic and quantitative possibilistic settings, it is not enough for the parameters γ_1,..,γ_n to satisfy condition C3 to be directly integrated into the conditional possibility table of the new node Z.

Example 9. *Let G be the possibilistic network of Figure 6 and the corresponding joint distribution π_G.*

B	$\pi(B)$
b_1	1
b_2	0.4

B → A



A	B	$\pi(A\|B)$

a_1	b_2	0.1
a_2	b_2	0.4

Figure 6: Example of a possibilistic network G and the joint distribution $\pi_G(AB)$ encoded by G in the qualitative setting.

Let us assume now that we want to revise the distribution π_G encoded by the network G of Figure 6 into a new distribution π'_G such that γ_{a_1}=1 and γ_{a_2}=2 meaning that the initial belief degree of a_1 is not changed while the degree of a_2 is to be doubled. The augmented network G' encoding the new inputs is shown in Figure 7.

The revised beliefs are given in Table 9.

B	$\pi(B)$
b_1	1
b_2	0.4

A	B	$\pi(A\|B)$
a_1	b_1	1
a_2	b_1	0.4
a_1	b_2	0.1
a_2	b_2	1

Z	A	$p(Z\|A)$
z	a_1	1
z	a_2	2

Figure 7: The possibilistic network G' obtained by augmenting G of Figure 6 with the node Z.

A	B	$\pi_{G'}(AB\|z)$
a_1	b_1	1
a_2	b_1	.4
a_1	b_2	.1
a_2	b_2	.4

Table 9: The conditional distribution $\pi_{G'}(.|z)$ representing the revised distribution of the initial beliefs of Figure 6.

One can notice from the results of Table 9 that condition C3 is not satisfied since $\frac{\Pi_{G'}(a_2|z)}{\Pi_G(a_2)}=\frac{.4}{.4}\neq\gamma_{a_2}=2$.

Hence, instead of using only the inputs $\gamma_1,..,\gamma_n$, the conditional possibility table of the new node Z must be set for each uncertain event λ_i directly to $\Pi'(\lambda_i)=\gamma_i*\Pi(\lambda_i)$ as in Jeffrey's rule. This is imposed by the min-based operator and the definition of conditioning in the qualitative possibilistic setting (see Equations 3 and 4). Clearly, if a parameter $\pi_{G'}(z|a_i)>1$ then it is not taken into account (note that in the probabilistic and quantitative possibilistic settings, the values of γ_i are not necessarily in the interval [0, 1] and they are always taken into account thanks to the definition of conditioning in these settings). Now, even when replacing γ_i by $\gamma_i*\Pi(\lambda_i)$ for i=1..n, it is impossible with Pearl's method of virtual evidence to increase the plausibility of an event as stated in the following proposition.

Proposition 4. *Let G be a* min*-based network and let π_G be the possibility distribution encoded by G. Let also $\gamma_1,..,\gamma_n$ be the likelihood ratios corresponding to the new inputs regarding the exhaustive and mutually exclusive set of events $a_1,..,a_n$. Let G' be the augmented possibilistic network with the virtual node Z to encode $\gamma_1,..,\gamma_n$ such that for i=1..n, $\pi_{G'}(Z=z|a_i)=\Pi_G(a_i)*\gamma_i$. Then we have two cases:*

- *If $\forall i$=1..n, $\gamma_i\leq 1$, then conditions C3 and C4 are satisfied.*
- *Otherwise if $\exists\gamma_i>1$ then the revised possibility degree $\Pi_{G'}(a_i|z)=\Pi_G(a_i)$ implying that C3 is not satisfied while C4 is always satisfied.*

Proposition 4 states that associating with an uncertain event a_i a possibility degree of $\Pi_G(a_i)*\gamma_i$ in the augmented network G', the posterior possibility degree $\Pi_{G'}(a_i|z)$ equals $\Pi_G(a_i)$ (unless $\Pi_{G'}(a_i|z)$ is the greatest one in the context of z in which case $\Pi(a_i|z)$=1 because of normalization). As a consequence of Proposition 4, it is impossible to augment the possibility degree of an event a_i unless $\Pi(a_i)\geq\Pi(a_j)$ for any $j\neq i$ meaning that condition C3 is not satisfied. Indeed, because of the idempotency of the min-based operator used in the min-based chain rule of Equation 4 and the definition of the min-based conditioning of Equation 3, applying directly Pearl's method of virtual evidence does not guarantee that condition C3 will be satisfied. However, condition C4 is always satisfied as it is implied by a graphical property.

Proof sketch. The proof follows from the min-based chain rule and the augmented network G'. Indeed,
$\Pi'_G(a_i|z)=\Pi(a_i,z)=\max_{A_1..a_i..A_n}(\Pi(A_1..a_i..A_n,z))$
$=\max_{A_1..a_i..A_n}(\min(\pi(A_1|U_1),..,\pi(a_i|U_i),..,\pi(A_n|U_n),\pi(z|a_i))$
$\leq\pi(z|a_i)=\gamma_i*\Pi_G(a_i)$ □
However, one can show that due to the encoding of the inputs by means of augmenting the network, for every event ϕ, $\forall a_i\in D_i$, $\Pi(z|a_i,\phi)=\Pi(z|a_i)$ (due to d-separation) meaning that condition C4 is always satisfied since it is a graphical property of the augmented network G'. □

Virtual evidence method in the qualitative possibilistic setting

The min-based counterpart of the quantitative possibilistic virtual evidence method of Definition 2 is defined as follows:

Definition 4. *Let the initial beliefs be encoded by π and the new inputs be $\gamma_1,..,\gamma_n$ specified as likelihood ratios $\gamma_1:..:\gamma_n$ such that $\gamma_i=\Pi(\eta|\lambda_i)=\frac{\Pi(\lambda_i|\eta)}{\Pi(\lambda_i)}$. The revised possibility degree $\Pi'(\phi)$ of any event $\phi\subseteq\omega$ is computed as follows:*

$$\forall\phi\subseteq\Omega,\Pi(\phi|\eta)=\max_{i=1}^{n}(\min(\Pi(\phi|\lambda_i),\gamma_i*\Pi(\lambda_i)) \quad (13)$$

For single interpretations $\omega_k\in\Omega$, the revised degrees are computed as follows:

$$\forall\omega_k\in\lambda_i,\pi'(\omega_k)=\min(\Pi(\omega_k|\lambda_i),\gamma_i*\Pi(\lambda_i)) \quad (14)$$

Example 10. *Let us reuse the beliefs given Table 7 as initial beliefs. Assume now that we want to revise π of Table 7 into π' such $\gamma_{a_1}=\frac{\pi'(a_1)}{\pi(a_1)}$=.75 and $\gamma_{a_2}=\frac{\pi'(a_2)}{\pi(a_2)}$=2.5. The revised distribution using the qualitative counterpart of the virtual evidence method of Equation 13 is given by π' Table 10.*

A	B	$\pi'(AB)$
a_1	b_1	0.75
a_2	b_1	1
a_1	b_2	0.1
a_2	b_2	1

A	$\pi'(A)$
a_1	0.75
a_2	1

γ_{a_1}	.75
γ_{a_2}	2.5

Table 10: Revised beliefs of the initial distribution given in Table 7 using the virtual evidence method of Equation 13.

From the results of Table 7 and 10, one can easily check that the conditions C3 and C4 are satisfied.

The distribution π' computed using Equation 13 always satisfy conditions C3 and C4 as stated in Proposition 5.

Proposition 5. *Let π be the possibility distribution encoding the initial beliefs. Let also $\gamma_1,..,\gamma_n$ be the likelihood ratios corresponding to the new inputs regarding the exhaustive and mutually exclusive set of events $\lambda_1,..,\lambda_n$. Then the revised possibility distribution π' computed using the formula of Equation 13 always satisfy conditions C3 and C4.*

Proof sketch. Let π be the possibility distribution encoding the initial beliefs and let γ_1,..,γ_n be the likelihood ratios corresponding to the new inputs regarding the set of exhaustive and mutually exclusive set of events λ_1,..,λ_n such that for i=1..n, γ_i=$\frac{\Pi'(\lambda_i)}{\Pi(\lambda_i)}$. Let us first show that the revised possibility distribution π' computed using the formula of Equation 13 satisfies condition **(C3)**.

$\Pi(\eta|\lambda_1)$:..: $\Pi(\eta|\lambda_n) = \Pi(\lambda_1, \eta)$:..: $\Pi(\lambda_n|\eta)$
$=\min(\Pi(\lambda_1|\eta), \Pi(\eta))$:..: $\min(\Pi(\lambda_n|\eta), \Pi(\eta))$
$=\min(\max_i(\Pi(\lambda_1|\lambda_i), \gamma_i * \Pi(\lambda_i)))$:..:$\min(\max_i(\Pi(\lambda_n|\lambda_i), \gamma_i * \Pi(\lambda_i)))$
$=\min(\Pi(\lambda_1|\lambda_1), \gamma_1 * \Pi(\lambda_1))$:..:$\min(\Pi(\lambda_n|\lambda_n), \gamma_n * \Pi(\lambda_n))$
$=\gamma_1 * \Pi(\lambda_1)$:..:$\gamma_n * \Pi(\lambda_n)$. □

The proof that π' satisfies condition C4 is similar to the proof of Proposition 1. Let us now provide the proof that if a distribution π' satisfies the conditions **(C3)** and **(C4)** then π' is computed using Equation 13.

$\forall\phi\subseteq\Omega$, $\Pi'(\phi)$= $\Pi(\phi|\eta)$=$\max_{\lambda_i}(\Pi(\phi|\eta, \lambda_i))$
$= \max_{\lambda_i}(\min(\Pi(\phi|\lambda_i), \Pi(\lambda_i|\eta))$
$= \max_{\lambda_i}(\min(\Pi(\phi|\lambda_i), \gamma_i * \Pi(\lambda_i))$ □

Relating the virtual evidence method with Jeffrey's rule in the qualitative possibilistic setting

As in the quantitative setting, it is straightforward to move from Jeffrey's rule to the virtual evidence method and vice versa (because of space limitation, we provide only basic results, the propositions and their proofs are similar to the corresponding transformations in the quantitative setting).

1. *From the virtual evidence method to Jeffrey's rule*: Just set the inputs α_i=γ_i*$\Pi(\lambda_i)$ for i=1..n and use Jeffrey's rule of Equation 12 will give exactly the same revised distribution π' as the distribution $\pi(.|\eta)$ obtained by the min-based possibilistic counterpart of the virtual evidence method of Equation 13.
2. *From Jeffrey's rule to the virtual evidence method* : Here, it is enough to set the inputs γ_i=α_i/$\Pi(\lambda_i)$ for i=1..n then use the virtual evidence method of Equation 13 to obtain $\pi(.|\eta)$ which is equivalent to π' obtained using Jeffrey's rule of Equation 12.

Discussions and concluding remarks

In order to revise the beliefs encoded by means of a possibility distribution one can either use Jeffrey's rule or the virtual evidence method which are shown equivalent in both the quantitative and qualitative settings. However, revising a whole distribution is very costly while Pearl's method of virtual evidence allows to integrate the inputs and compute any possibility degree of interest directly from the network without revising the whole distribution. Moreover, the existing inference algorithms in graphical models (e.g. Junction tree) can be used directly to compute the revised beliefs.

This paper addressed reasoning with uncertain inputs in possibilistic networks. We provided possibilistic counterparts for Pearl's methods and compared them with the well-known Jeffrey's rule of conditioning. In Jeffrey's rule, the inputs (α_i, λ_i) are seen as constraints that should be satisfied leading to fully accepting the new beliefs. The way Jeffrey's method revises the old distribution π in order to fully accept the inputs (α_i, λ_i) complies with the probability kinematics principle (see condition C2) aiming to minimize belief change. In spite of the fact that Pearl's methods specify the inputs differently, the way the new inputs are graphically taken into account (see condition C4) complies with the probability kinematics principle hence minimizing also belief change. Regarding accepting the inputs, it is clear that even specified differently, the inputs to both methods are fully accepted (see conditions C1 and C3).

Regarding iterative revisions, it is well-known that Jeffrey's rule is no commutative (since the new inputs are fully accepted, then revising first with (λ_i, α_i) then with (λ_i, α'_i) will be different from first revising with (λ_i, α'_i) then with (λ_i, α_i)). However in the virtual evidence method, due to the commutativity of multiplication and the definition of the quantitative counterpart of this revision rule, it is easy to show that revising with a set of likelihood ratios γ_1,..,γ_n then revising the resulted beliefs with other new inputs γ'_1,..,γ'_n will give exactly the same results as revising first with γ'_1,..,γ'_n followed by revision with γ_1,..,γ_n. Revision using the qualitative virtual evidence method is not commutative because the inputs are no more likelihood ratios γ_1,..,γ_n but the new beliefs which are fully accepted as in Jeffrey's rule.

To sum up, the contributions of the paper are:

1. Providing counterparts to Pearl's method of virtual evidence and its generalization in the quantitative and qualitative settings. We showed that contrary to the probabilistic and quantitative possibilistic settings, the inputs for the qualitative counterparts of Pearl's methods should be possibility degrees satisfying condition C3. This is due to the fact that in possibilistic networks, we deal with local tables combined with the min-based operator which is idempotent and because of the definition of the qualitative conditioning. We showed also that it is impossible to enhance the possibility degree of an event using Pearl's method of virtual evidence in qualitative networks.
2. Analyzing the existence and uniqueness of the solutions using the proposed possibilistic counterparts of Pearl's methods. In the quantitative setting, the paper showed that the solution always exists and it is unique. In the min-based setting however, depending on the inputs, the solution is not guaranteed to satisfy conditions C3 using Pearl's method of virtual evidence while using the virtual evidence method the solution always exists and it is unique and satisfies conditions C3 and C4.
3. Providing transformations from Jeffrey's rule to the virtual evidence method and comparisons of these methods in both the quantitative and qualitative settings. We provided precise conditions where the methods are equivalent. Finally, we tried to relate the criteria underlying Jeffrey's rule and Pearl's methods and highlighted many related issues like iterated revisions in these formalisms.

Abstract

Logistic regression is a commonly used representation for aggregators in Bayesian belief networks when a child has multiple parents. In this paper we consider extending logistic regression to relational models, where we want to model varying populations and interactions among parents. In this paper, we first examine the representational problems caused by population variation. We show how these problems arise even in simple cases with a single parametrized parent, and propose a linear relational logistic regression which we show can represent arbitrary linear (in population size) decision thresholds, whereas the traditional logistic regression cannot. Then we examine representing interactions among the parents of a child node, and representing non-linear dependency on population size. We propose a multi-parent relational logistic regression which can represent interactions among parents and arbitrary polynomial decision thresholds. Finally, we show how other well-known aggregators can be represented using this relational logistic regression.

Introduction

Relational probabilistic models are models where there are probabilities about relations among individuals that can be specified independently of the actual individuals, and where the individuals are exchangeable; before we know anything about the individuals, they are treated identically. One of the features of relational probabilistic models is that the predictions of the model may depend on the number of individuals (the population size) (Poole et al. 2012). Sometimes, this dependence is desirable; in other cases, model weights may need to change (Jian, Bernhard, and Beetz 2007; Jian, Barthels, and Beetz 2009). In either case, it is important to understand how the predictions change with population size.

Varying population sizes are quite common. They can appear in a number of ways including:

- The actual population may be arbitrary. For example, in considering the probability of someone committing a crime (which depends on how many other people could have committed the crime) (Poole 2003) we could consider the population to be the population of the neighbourhood, the population of the city, the population of the country, or the population of the whole world. It would be good to have a model that does not depend on this arbitrary decision. We would like to be able to compare models which involve different choices.
- The population can change. For example, the number of people in a neighbourhood or in a school class may change. We would like a model to make reasonable predictions as the population changes. We would also like to be able to apply a model learned at one or a number of population sizes to different population sizes. For example, models from drug studies are acquired from very limited populations but are applied much more generally.
- The relevant populations can be different for each individual. For example, the happiness of a person may depend on how many of her friends are kind (and how many are not kind). The set of friends is different for each individual. We would like a model that makes reasonable predictions for diverse numbers of friends.

In this paper, we consider applying standard logistic regression to relational domains and tasks and investigate how varying populations can cause a problem for logistic regression. Then we propose *single-parent linear relational logistic regression* which solves this problem with standard logistic regression by taking the population growth into account. This representation is, however, only able to model linear function dependencies of the child on its parents' population sizes. Also when used for multiple parents, it cannot model the interactions among the parents. We examine these two limitations and propose a general relational logistic regression which we prove can represent arbitrary Boolean formulae among the parents as well as every polynomial dependency of the child node on its parents' population sizes. We also show how other well-known aggregators can be represented using our polynomial relational logistic regression.

Our model assumes all the parent variables are categorical and the child variable is Boolean. Extending the model to multi-valued child variables and continuous parent variables (as done by Mitchell (2010) for non-relational models) is left as a future work.

Background

Bayesian Belief Networks

Suppose we have a set of random variables $\{X_1,\ldots,X_n\}$. A **Bayesian network (BN)** or **belief network** (Pearl 1988) is an acyclic directed graph where the random variables are the nodes, and the arcs represent interdependence between the random variables. Each variable is independent of its non-descendants given values for its parents. Thus, if X_i is not an ancestor of X_j, then $P(X_i \mid parents(X_i), X_j) = P(X_i \mid parents(X_i))$. The joint probability of the random variables can be factorized as:

$$P(X_1,X_2,...,X_n) = \prod_{i=1}^{n} P(X_i \mid parents(X_i))$$

One way to represent a conditional probability distribution $P(X_i \mid parents(X_i))$ is in terms of a table. Such a tabular representation for a random variable increases exponentially in size with the number of parents. For instance, a Boolean child having 10 Boolean parents requires $2^{10} = 1024$ numbers to specify the conditional probability. A compact alternative to a table is an **aggregation** operator, or aggregator, that specifies a function of how the distribution of a variable depends on the values of its parents. Examples for common aggregators include OR, AND, as well as "noisy-OR" and "noisy-AND". These can be specified much more compactly than as a table.

Logistic Regression

Suppose a Boolean random variable Q is a child of the numerical random variables $\{X_1,X_2,\ldots,X_n\}$. Logistic regression is an aggregation operator defined as:

$$P(q \mid X_1,\ldots,X_n) = \text{sigmoid}(w_0 + \sum_i w_i X_i) \qquad (1)$$

where $q \equiv$ "$Q = True$" and $\text{sigmoid}(x) = 1/(1+e^{-x})$. It follows that $P(q \mid X_1,\ldots,X_n) > 0.5$ iff $w_0 + \sum_i w_i X_i > 0$.

The space of assignments to the w's so that $w_0 + \sum_i w_i X_i = 0$ is called the **decision threshold**, as it is the boundary of where $P(q \mid X_1,\ldots,X_n)$ changes between being closer to 0 and being closer to 1. Logistic regression provides a soft threshold, in that it changes from close to 0 to close to 1 in a continuous manner. How fast it changes can be adjusted by multiplying all weights by a positive constant.

The Factorization Perspective

A simple and general formulation of logistic regression can be defined using a multiplicative factorization of the conditional probability. (1) then becomes a special case, which is equivalent to the general case when variables are binary and probabilities are positive (non-zero).

We define a **general logistic regression** for Q with parents $X_1,\ldots,X_n$ (all variables here may be discrete or continuous) to be when $P(Q \mid X_1,\ldots,X_n)$ can be factored into a product of non-negative pairwise factors and a non-negative factor for Q:

$$P(Q \mid X_1,\ldots,X_n) \propto f_0(Q) \prod_{i=1}^{n} f_i(Q,X_i)$$

where $\propto$ *(proportional-to)* means it is normalized separately for each assignment to the parents. This differs from the normalization for joint distributions (as used in undirected models), where there is a single normalizing constant. Here the constraint that causes the normalization is $\forall X_1,\ldots,X_n : \sum_Q P(Q \mid X_1,\ldots,X_n) = 1$, whereas for joint distributions, the normalization is to satisfy the constraint $\sum_{Q,X_1,\ldots,X_n} P(Q,X_1,\ldots,X_n) = 1$.

If Q is binary, then:

$$P(q \mid X_1,\ldots,X_n) = \frac{f_0(q)\prod_{i=1}^{n} f_i(q,X_i)}{f_0(q)\prod_{i=1}^{n} f_i(q,X_i) + f_0(\neg q)\prod_{i=1}^{n} f_i(\neg q,X_i)}$$

If all factors are positive, we can divide and then use the identity $y = e^{\ln y}$:

$$\begin{aligned} P(q \mid X_1,\ldots,X_n) &= \frac{1}{1 + \frac{f_0(\neg q)}{f_0(\ \ q)} \prod_{i=1}^{n} \frac{f_i(\neg q,X_i)}{f_i(\ \ q,X_i)}} \\ &= \frac{1}{1 + exp\left(\ln \frac{f_0(\neg q)}{f_0(\ \ q)} + \sum_{i=1}^{n} \ln \frac{f_i(\neg q,X_i)}{f_i(\ \ q,X_i)}\right)} \\ &= \text{sigmoid}\left(\ln \frac{f_0(\ \ q)}{f_0(\neg q)} + \sum_{i=1}^{n} \ln \frac{f_i(\ \ q,X_i)}{f_i(\neg q,X_i)}\right). \end{aligned}$$

When the $\ln \frac{f_i(\ \ q,X_i)}{f_i(\neg q,X_i)}$ are linear functions w.r.t. X_i, it is possible to find values for all w's such that this can be represented by Eq. (1). This is always possible when the parents are binary.

The idea of *relational* logistic regression is to extend logistic regression to relational models, by allowing weighted logical formulae to represent the factors in the factorization of a conditional probability.

Relational Models

Relational probabilistic models (Getoor and Taskar 2007) or template based models (Koller and Friedman 2009) extend Bayesian or Markov networks by adding the concepts of individuals (objects, entities, things), relations among individuals (including properties, which are relations of a single individual) and by allowing for probabilistic dependencies among these relations. In these models, individuals about which we have the same information are exchangeable, meaning that, given no evidence to distinguish them, they should be treated identically. We provide some basic definitions and terminologies in these models which are used in the rest of the paper.

A **population** is a set of **individuals**. A population corresponds to a domain in logic. The **population size** is the cardinality of the population which can be any non-negative integer.

A **logical variable** is written in lower case. Each logical variable is typed with a population; we use $|x|$ for the size of the population associated with a logical variable x. Constants, denoting individuals, start with an upper case letter.

A **parametrized random variable (PRV)** is of the form $F(t_1,\ldots,t_k)$ where F is a k-ary functor (a function symbol or a predicate) and each t_i is a logical variable or a constant. Each functor has a range, which is $\{True, False\}$ for predicate symbols. A PRV represents a set of random variables,

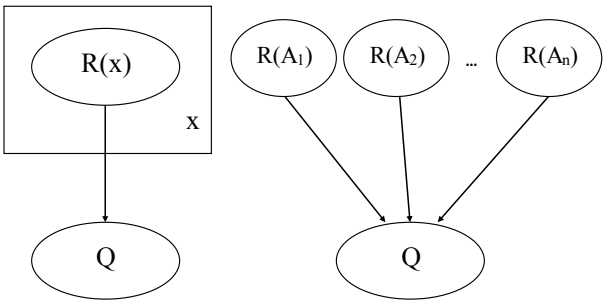

Figure 1: logistic regression (with i.i.d. priors for the $R(x)$). The left side is the relational model in plate notation and on the right is the groundings for the population $\{A_1, A_2, \ldots, A_n\}$.

one for each assignment of individuals to its logical variables. The range of the functor becomes the range of each random variable.

A **relational belief network** is an acyclic directed graph where the nodes are PRVs. A **grounding** of a relational belief network with respect to a population for each logical variable is a belief network created by replacing each PRV with the set of random variables it represents, while preserving the structure.

A **formula** is made up of assignments of values to PRVs with logical connectives. For a Boolean PRV $R(x)$, we represent $R(x) = \mathit{True}$ by $R(x)$ and $R(x) = \mathit{False}$ by $\neg R(x)$.

When using a single population, we write the population as $A_1 \ldots A_n$, where n is the population size, and use $R_1 \ldots R_n$ as short for $R(A_1) \ldots R(A_n)$. We also use n_{val} for the number of individuals x for which $R(x) = val$. When $R(x)$ is binary, we use the shortened $n_T = n_{\mathit{True}}$ and $n_F = n_{\mathit{False}}$.

Relational Logistic Regression

While aggregation is optional in non-relational models, it is necessary in directed relational models whenever the parent of a PRV contains extra logical variables. For example, suppose Boolean PRV Q is a child of the Boolean PRV $R(x)$, which contains an extra logical variable, x, as in Figure 1. In the grounding, Q is connected to n instances of $R(x)$, where n is the population size of x. For the model to be defined before n is known, it needs to be applicable for all values of n.

Common ways to aggregate the parents in relational domains, e.g. (Horsch and Poole 1990; Friedman et al. 1999; Neville et al. 2005; Perlish and Provost 2006; Kisynski and Poole 2009; Natarajan et al. 2010), include logical operators such as *OR*, *AND*, *noisy-OR*, *noisy-AND*, as well as ways to combine probabilities.

Logistic regression, as described above, may also be used for relational models. Since the individuals in a relational model are exchangeable, w_i must be identical for all parents R_i (this is known as parameter-sharing or weight-tying), so Eq. (1) becomes:

$$P(q \mid R_1, \ldots, R_n) = \text{sigmoid}(w_0 + w_1 \sum_i R_i). \qquad (2)$$

Consider what happens with a relational model when n is not fixed.

Example 1. Suppose we want to represent "Q is True if and only if R is True for 5 or more individuals", i.e., $q \equiv \left(|\{i : R_i = \mathit{True}\}| \geq 5\right)$ or $q \equiv (n_T \geq 5)$, using a logistic regression model $(P(q) \geq 0.5) \equiv (w_0 + w_1 \sum_i R_i \geq 0)$, which we fit for a population of 10. Consider what this model represents when the population size is 20.

If $R = \mathit{False}$ is represented by 0 and $R = \mathit{True}$ by 1, this model will have $Q = \mathit{True}$ when R is true for 5 or more individuals out of the 20. It is easy to see this, as $\sum_i R_i$ only depends on the number of individuals for which R is *True*.

However, if $R = \mathit{False}$ is represented by -1 and $R = \mathit{True}$ by 1, this model will have $Q = \mathit{True}$ when R is *True* for 10 or more individuals out of the 20. The sum $\sum_i R_i$ depends on how many more individuals have *R True* than have *R False*.

If $R = \mathit{True}$ is represented by 0 and $R = \mathit{False}$ by any other value, this model will have $Q = \mathit{True}$ when R is *True* for 15 or more individuals out of the 20. The sum $\sum_i R_i$ depends on how many individuals have *R False*.

While the choice of representation for *True* and *False* was arbitrary in the non-relational case, in the relational case different parametrizations can result in different decision thresholds as a function of the population. The following table gives five numerical representations for *False* and *True*, with corresponding parameter settings (w_0 and w_1), such that all regressions represent the same conditional distribution for $n = 10$. However, for $n = 20$, the predictions are different:

False	True	w_0	w_1	Prediction for n = 20
0	1	-4.5	1	$Q \equiv (n_T \geq 5)$
-1	1	0.5	0.5	$Q \equiv (n_T \geq 10)$
-1	0	5.5	1	$Q \equiv (n_T \geq 15)$
-1	2	$-\frac{7}{6}$	$\frac{1}{3}$	$Q \equiv (n_T \geq 8)$
1	2	-14.5	1	$Q \equiv (n_T \geq 0)$

The decision thresholds in all of these are linear functions of population size. It is straightforward to prove the following proposition:

Proposition 1. *Let $R = \mathit{False}$ be represented by the number α and $R = \mathit{True}$ by $\beta \neq \alpha$. Then, for fixed w_0 and w_1 (e.g., learned for one specific population size), the decision threshold for a population of size n is*

$$\frac{w_0}{w_1(\alpha - \beta)} + \frac{\alpha}{\alpha - \beta} n.$$

What is important about this proposition is that the way the decision threshold changes with the population size n, i.e., the coefficient $\frac{\alpha}{\alpha - \beta}$, does not depend on data (which affects the weights w_0 and w_1), but only on the arbitrary choice of the numerical representation of R.

Thus, Eq. (2) with a specific numeric representation of *True* and *False* is only able to model one of the dependencies

of how predictions depend on population size, and so cannot properly fit data that does not adhere to that dependence.

We need an additional degree of freedom to get a relational model that can model any linear dependency on n, regardless of the numerical representation chosen.

Definition 1. Let Q be a Boolean PRV with a single parent $R(x)$, where x is the set of logical variables in R that are not in Q (so we need to aggregate over x). A (single-parent, linear) **relational logistic regression (RLR)** for Q with parents $R(x)$ is of the form:

$$P(q \mid R(A_1),\ldots,R(A_n)) = \text{sigmoid}\left(w_0 + w_1 \sum_i R_i + w_2 \sum_i (1-R_i)\right) \quad (3)$$

where R_i is short for $R(A_i)$, and is treated as 1 when it is *True* and 0 when it is *False*. Note that $\sum_i R_i$ is the number of individuals for which R is *True* ($= n_T$) and $\sum_i (1-R_i)$ is the number of individuals for which R is *False* ($= n_F$).

An alternative but equivalent parametrization is:

$$P(q \mid R(A_1),\ldots,R(A_n)) = \text{sigmoid}(w_0 + w_2 \sum_i 1 + w_3 \sum_i R_i) \quad (4)$$

where 1 is a function that has value 1 for every individual, so $\sum_i 1 = n$. The mapping between these parametrizations is $w_3 = w_1 - w_2$; w_0 and w_2 are the same.

Proposition 2. *Let $R = False$ be represented by α and $R = True$ by $\beta \neq \alpha$. Then, for fixed w_0, w_2 and w_3 in Eq. (4), the decision threshold for a population of size n is*

$$\frac{w_0}{w_3(\alpha-\beta)} + \frac{\alpha + w_2/w_3}{\alpha-\beta} n.$$

Proposition 2 implies that the way the decision threshold in a single-parent linear RLR grows with the population size n, i.e. the coefficient $\frac{\alpha+w_2/w_3}{\alpha-\beta}$, depends on the weights. Moreover, for fixed α and β, any linear function of population can be modeled by varying the weights. This was not true for the traditional logistic regression.

For the rest of this paper, when we embed logical formulae in arithmetic expressions, we take *True* formulae to represent 1, and *False* formulae to represent 0. Thus $\sum_L F$ is the number of assignments to the variables L for which formula F is *True*.

Interactions Among Parents

The RLR proposed in Definition 1 can be extended to multiple (parametrized) parents by having a different pair of weights ((w_1,w_2) or (w_2,w_3)) for each parent PRV. This is similar to the non-relational logistic regression, where each parent has a (single) different weight. However, there are cases where we want to model the interactions among the parents.

Example 2. Suppose we want to model whether someone being happy depends on the number of their friends that are kind. We assume the variable $Happy(x)$ has as parents $Friend(y,x)$ and $Kind(y)$. Note that the number of friends for each person can be different.

Consider the following hypotheses:

(a) A person is happy as long as they have 5 or more friends who are kind.

$$happy(x) \equiv |\{y : Friend(y,x) \wedge Kind(y)\}| \geq 5$$

(b) A person is happy if half or more of their friends are kind.

$$happy(x) \equiv |\{y : Friend(y,x) \wedge Kind(y)\}| \geq |\{y : Friend(y,x) \wedge \neg Kind(y)\}|$$

(c) A person is happy as long as fewer than 5 of their friends are not kind.

$$happy(x) \equiv |\{y : Friend(y,x) \wedge \neg Kind(y)\}| < 5$$

These three hypotheses coincide for people with 10 friends, but make different predictions for people with 20 friends.

All three hypotheses are based on the interaction between the two parents. Linear RLR considers each parent separately from the others, and so cannot model these interactions without introducing new relations. In order to model such aggregators, we need to be able to count the number of instances of a formula that are *True* in an assignment to the parents. We can use the following extended RLR to model these cases:

$$P(happy(x) \mid \Pi) = \text{sigmoid}\Big(w_0 + w_1 \sum_y Friend(y,x) \wedge \quad Kind(y) + w_2 \sum_y Friend(y,x) \wedge \neg Kind(y) \Big) \quad (5)$$

where Π is a complete assignment of *friend* and *kind* to the individuals, and the right hand side is summing over the propositions in Π for each individual. To model each of the above three cases, we can set w_0, w_1, and w_2 in Eq. (5) as follows:

(a) Let $w_0 = -4.5$, $w_1 = 1$, $w_2 = 0$
(b) Let $w_0 = 0.5$, $w_1 = 1$, $w_2 = -1$
(c) Let $w_0 = 5.5$, $w_1 = 0$, $w_2 = -1$

Going from Eq. (3) to Eq. (4) allowed us to only model the positive cases in linear single-parent RLR. We can use a similar construction for more general cases:

Example 3. Suppose a PRV Q is a child of PRVs $R(x)$ and $S(x)$. We want to represent "Q is *True* if and only if there are more than t individuals for x for which $R(x) \wedge \neg S(x)$." As in Example 2, we need to count the number of instances of a formula that are *True* in an assignment to the parents. It turns out that in this case $R(x) \wedge S(x)$ is the only non-atomic formula required to model the interactions between the two parents, because other conjunctive interactions can be represented using this count as follows:

$$\sum_x R(x) \wedge \neg S(x) = \sum_x R(x) - \sum_x R(x) \wedge S(x)$$
$$\sum_x \neg R(x) \wedge S(x) = \sum_x S(x) - \sum_x R(x) \wedge S(x)$$
$$\sum_x \neg R(x) \wedge \neg S(x) = |x| - \sum_x R(x) - \sum_x S(x) + \sum_x R(x) \wedge S(x)$$

with $|x| = \sum_x True$.

Example 3 shows that the positive conjunction of the interacting parents is the only formula required to compute arbitrary conjunctions of the two parents. In more complicated cases, however, subtle changes to the representation may be required.

Example 4. Suppose a PRV Q is a child of PRVs $R(x,y)$ and $S(x,z)$. Suppose we want to represent "Q is *True* if and only if we have $R(x,y) \wedge \neg S(x,z)$ for more than 5 triples $\langle x,y,z \rangle$". If we only count the number of instances of $(R \wedge T)(x,y,z)$ that are *True* given the assignment to the parents and do the same as in Example 3, we would only count the number of pairs $\langle x,y \rangle$ for which $R(x,y)$ is *True*. However, we need the number of triples $\langle x,y,z \rangle$ for which $R(x,y)$ is *True*. We thus need to use $\sum_{x,y,z} R(x,y)$ as the number of assignments to x, y and z, for which $R(x,y)$ is *True*, as follows:

$$\sum_{x,y,z} R(x,y) \wedge \neg S(x,z) = \sum_{x,y,z} R(x,y) - \sum_{x,y,z} R(x,y) \wedge S(x,y,z)$$

So as part of the representation, we need to incude the set of logical variables, and not just a weighted formula.

Non-Linear Decision Thresholds

Examples 3 and 4 suggest how to model interactions among the parents. Now consider the case where the child PRV is a non-linear function of its parents' population sizes. For instance, if the individuals are the nodes in a dense graph, some properties of arcs grow with the square of the population of nodes.

Markov logic networks (MLNs) (Richardson and Domingos 2006; Domingos et al. 2008) define probability distributions over worlds (complete assignments to the ground model) in terms of weighted formulae. The probability of a world is proportional to the exponential of the sum of the weights of the instances of the formulae that are *True* in the world. The probability of any formula is obtained by summing over the worlds in which the formula is *True*. MLNs can also be adapted to define conditional distributions. The following example shows a case where a non-linear conditional distribution is modeled by MLNs.

Example 5. Consider the MLN for PRVs Q and $R(x)$, consisting of a single formula $Q \wedge R(x) \wedge R(y)$ with weight w, where y represents the same population as x. The probability of q given observations of $R(A_i)$ for all A_i has a quadratic decision threshold:

$$P(q \mid R(A_1), \ldots, R(A_n)) = \text{sigmoid}(w\, {n_T}^2).$$

A similar method can be used by RLR to model non-linear decision thresholds. Consider the following example:

Example 6. Suppose a PRV Q is a child of the PRV $R(x)$, and we want to represent "Q is *True* if and only if ${n_T}^2 > n_F$". This dependency can be represented using the single-parent linear RLR by introducing a new logical variable x' with the same population as x and treating $R(x')$ as if it were a separate parent of Q. Then we can use the interaction between $R(x)$ and $R(x')$ to represent the model in this example as:

$$\sum_{x,x'} R(x) \wedge R(x') - \sum_{x} \mathit{True} + \sum_{x} R(x).$$

General Relational Logistic Regression (RLR)

The previous examples show the potential for using RLR as an aggregator for relational models. We need a language for representing aggregation in relational models in which we can address the problems mentioned. We propose a generalized form of RLR which works for multi-parent cases and can model polynomial decision thresholds.

Definition 2. A **weighted parent formula (WPF)** for a PRV $Q(x)$, where x is a set of logical variables, is a triple $\langle L, F, w \rangle$ where L is a set of logical variables for which $L \cap x = \{\}$, F is a Boolean formula of parent PRVs of Q such that each logical variable in F either appears in Q or is in L, and w is a weight. Only those logical variables that do not appear in Q are allowed to be substituted in F.

Definition 3. Let $Q(x)$ be a Boolean PRV with parents $R_i(x_i)$, where x_i is the set of logical variables in R_i. A (multi-parent, polynomial) **relational logistic regression (RLR)** for Q with parents $R_i(x_i)$ is defined using a set of WPFs as:

$$P(q(X) \mid \Pi) = \text{sigmoid}\Big(\sum_{\langle L,F,w \rangle} w \sum_{L} F_{\Pi, x \to X} \Big)$$

where Π represents the assigned values to parents of Q, X represents an assignment of an individual to each logical variable in x, and $F_{\Pi, x \to X}$ is formula F with each logical variable x in it being replaced according to X, and evaluated in Π. (The first summation is over the set of WPFs; the second summation is over the tuples of L. Note that $\sum_{\{\}}$ sums over a single instance.)

Since the logical variables that appear in $Q(x)$ are fixed in the formulae and not allowed to be substituted according to Definition 2, in the rest of the paper we only focus on those logical variables of the parents that do not appear in $Q(x)$.

The single-parent linear RLR (Definition 1) is a subset of Definition 3, because the terms of Eq. (4) can be modeled by WPFs:

- w_0 can be represented by $\langle \{\}, \mathit{True}, w_0 \rangle$
- $w_2 \sum_i 1$ can be represented by $\langle \{x\}, \mathit{True}, w_2 \rangle$
- $w_3 \sum_i R_i$ can be represented by $\langle \{x\}, R(x), w_3 \rangle$

RLR then sums these WPFs, resulting in:

$$\begin{aligned} P(q \mid \Pi) &= \text{sigmoid}\Big(w_0 \sum_{\{\}} \mathit{True} + w_1 \sum_{\{x\}} \mathit{True} + w_2 \sum_{\{x\}} R(x)\Big) \\ &= \text{sigmoid}\Big(w_0 + w_2 n + w_3 \sum_i R_i\Big). \end{aligned}$$

Example 7. Consider the problem introduced in Example 4. Using general RLR (Definition 3), we can model the conditional probability of Q using the following WPFs:

$$\langle \{\}, \mathit{True}, w_0 \rangle$$
$$\langle \{x,y,z\}, R(x,y) \wedge \neg S(y,z), w_1 \rangle$$

Or alternatively:

$$\langle \{\}, \mathit{True}, w_0 \rangle$$
$$\langle \{x,y,z\}, R(x,y), w_1 \rangle$$
$$\langle \{x,y,z\}, R(x,y) \wedge S(y,z), -w_1 \rangle$$

Canonical Forms for RLR

While in Definition 2 we allow for any Boolean formula of parents, we can prove that a positive conjunctive form is sufficient to model all the Boolean interactions among parents. A Boolean interaction is one that can be expressed in terms of logical connectives of values to the parents.

Proposition 3. *Let Q be a Boolean PRV with parents $R_i(x_i)$, where x_i is a set of logical variables in R_i which are not in Q. Using only positive conjunctive form formulae in the WPFs for Q, all Boolean interactions between the parents can be modeled by RLR.*

Proof. We show how to model every conjunctive form interaction between the parents. Other interactions (such as a disjunctive interaction) can be modeled by a set of conjunctives.

For a subset M of parents of Q, we prove by induction on the number of negations $j \leq |M|$, that every conjunctive form interaction between the parents having j negations can be modeled by a set of WPFs.

For $j = 0$, the formula F is in a positive conjunction form and the proposition holds (even if $M = \{\}$). Assume the proposition holds for $j < |M|$. For $j+1$, let $R_i(x_i)$ be one of the negated parents. Removing $\neg R_i(x_i)$ from the formula F gives a new formula F_1 with j negated parents. According to our assumption for j negations, there exists a set S_1 of WPFs that models F_1. Replacing $\neg R_i(x_i)$ in F by $R_i(x_i)$ gives a new formula F_2 with j negated parents, which can be modeled by some set S_2 of WPFs. Let S_1' represent the WPFs in S_1 where each set of logical variables L in each WPFs is replaced by $L \cup x_i$. F can then be modeled by combining S_1' and S_2 and negating the weights associated with S_2. The reason why this is correct can be seen in Example 4. □

Proposition 3 suggests using only positive conjunctive formuale in WPFs. Proposition 4 proves that positive disjunctive RLR has the same representational power as positive conjunctive RLR. Therefore, all propositions proved for positive conjunctive RLR in the rest of the paper also hold for positive disjunctive RLR.

Proposition 4. *A conditional distribution $P(Q \mid R_i(x_i))$ can be expressed by a positive disjunctive RLR if and only if it can be expressed by a positive conjunctive RLR.*

Proof. First, suppose $P(Q \mid R_i(x_i))$ can be expressed by a positive disjunctive RLR. We can write a disjunctive formula as a negated conjunctive formula. So we change all the disjunctive formulae in the WPFs for $P(Q \mid R_i(x_i))$ to negated conjunctive formulae. A negated conjunctive formula in WPF $\langle L, \neg F, w \rangle$ can be modeled by two conjunctive WPFs $\langle L, T, w \rangle$ and $\langle L, F, -w \rangle$. The latter WPF consists of negated parents but we know from Proposition 3 that we can model it by a set of positive conjunctive WPFs. Consequently, $P(Q \mid R_i(x_i))$ can be also expressed by a positive conjunctive RLR.

Now, suppose the conditional distribution can be expressed by a positive conjunctive RLR definition of $P(Q \mid R_i(x_i))$. While Proposition 3 is written for positive conjunctive RLR, it is straight forward to see that it also holds for negative conjunctive RLR. This means that we can express Q by WPFs having negative conjunctive formulae. We can represent each of these formulae in a negated positive disjunctive form. We also mentioned that a negated WPF $\langle L, \neg F, w \rangle$ can be expressed by two WPFs $\langle L, T, w \rangle$ and $\langle L, F, -w \rangle$. The former does not contain any parent and the latter is in positive disjunctive form. Consequently, $P(Q \mid R_i(x_i))$ can be also expressed by a positive disjunctive RLR. □

Buchman et al. (2012) looked at canonical representations for probability distributions with binary variables in the non-relational case. Our positive conjunctive canonical form corresponds to their "canonical parametrization" with a "reference state" *True* (i.e., in which all variables are assigned *True*), and our positive disjunctive canonical form has a connection to using a "reference state" *False*. Their "spectral representation" would correspond to a third positive canonical form for RLR, in terms of **XORs** (i.e., parity functions).

Polynomial Decision Thresholds

We can also model polynomial decision thresholds using RLR. The following example is a case where the child PRV depends on $|x|^2$.

Example 8. Suppose Q is a Boolean PRV with a parent $R(x)$, where x is a set of logical variables in R which are not in Q. By having a WPF $\langle \{x, x'\}, R(x) \wedge R(x'), w \rangle$ for Q where x' is typed with the same population as x, the conditional probability of Q depends on the square of the number of assignments to x for which $R(x)$ is *True*.

Example 8 represents a case where the conditional probability of a child PRV is a non-linear function of its parent's population size. We can prove that by using only positive conjunctive formulae in the WPFs of a child PRV, we can model any polynomial decision threshold. First we prove this for the single-parent case and then for the general case of multi-parents. We assume in the following propositions that Q is a Boolean PRV and $R_i(x_i)$ are its parents where x_i is the set of logical variables in R_i which are not in Q. We also use x_i' to refer to a new logical variable typed with the same population as x_i.

Proposition 5. *A positive conjunctive RLR definition of $P(Q \mid R(x))$ (single-parent case) can represent any decision threshold that is a polynomial of terms each indicating a number of (tuples of) individuals for which R(x) is True or False.*

Proof. Based on Proposition 3 we know that a WPF having any Boolean formula can be written as a set of WPFs each having a positive conjunctive formula. Therefore, in this proof we disregard using only positive conjunctives. The final set of WPFs can be then represented by a set of positive conjunctive WPFs using Proposition 3.

Each term of the polynomial in the single-parent case is of the form $w(\prod_i |y_i|^{d_i}) {n_T}^{\alpha} {n_F}^{\beta}$, where n_T and n_F denote the number of individuals for which $R(x)$ is *True* or *False* respectively, $y_i \in x$ represents the logical variables in x, α, β and d_is are non-negative integers, and w is the weight of the

term. First we prove by induction that for any j, there is a WPF that can build the term ${n_T}^{\alpha}{n_F}^{\beta}$ where $\alpha+\beta=j$, $\alpha \geq 0$ and $\beta \geq 0$.

For $j=0$, ${n_T}^{\alpha}{n_F}^{\beta}=1$. We can trivially build this by WPF $\langle\{\},True,w\rangle$. Assuming it is correct for j, we prove it for $j+1$. For $j+1$, either $\alpha>0$ or $\beta>0$. If $\alpha>0$, using our assumption for j, we can have a WPF $\langle L,F,w\rangle$ which builds the term ${n_T}^{\alpha-1}{n_F}^{\beta}$. So the WPF $\langle L\cup x',F\wedge R(x'),w\rangle$ builds the term ${n_T}^{\alpha}{n_F}^{\beta}$ because the first WPF was *True* ${n_T}^{\alpha-1}{n_F}^{\beta}$ times and now we count it n_T more times because $R(x')$ is *True* n_T times.

If $\alpha=0$ and $\beta>0$, we can have a WPF $\langle L,F,w\rangle$ which builds the term ${n_T}^{\alpha}{n_F}^{\beta-1}$. By the same reasoning as in previous case, we can see that the WPF $\langle L\cup\{x'\},F\wedge\neg R(x'),w\rangle$ produces the term ${n_T}^{\alpha}{n_F}^{\beta}$.

In order to include the population size of logical variables y_i, where $y_i \in x$, and generate the term $(\prod_i |y_i|^{d_i}){n_T}^{\alpha}{n_F}^{\beta}$, we only add d_i extra logical variables y_i' to the set of logical variables of the WPF that generates ${n_T}^{\alpha}{n_F}^{\beta}$. Then we set the weight of this WPF to w to generate the desired term. □

Conclusion. We can conclude from this proposition that a term $w(\prod_i |y_i|^{d_i}){n_T}^{\alpha}{n_F}^{\beta}$ can be generated by having a WPF with its formula consisting of n_T instances of $R(x')$ and n_F instances of $\neg R(x')$, adding d_i of each logical variable y_i to the set of logical variables, and setting the weight of WPF to w. We will use this conclusion for proving the proposition in multi-parent case.

Example 9. Suppose we want to model the case where Q is *True* if ${n_T}^2 \geq 2n_F+5$. In this case, we need to model the sigmoid of the polynomial ${n_T}^2-2n_F-4.5$. The reason for using 4.5 instead of 5 is to make the polynomial positive when ${n_T}^2=2n_F+5$. The following WPFs are used by RLR to model this polynomial. The first one generates the term ${n_T}^2$, the second one generate $-2n_F$ and the third one generates -4.5.

$$\langle\{x,x'\},R(x)\wedge R(x'),1\rangle$$
$$\langle\{x\},\neg R(x),-2\rangle$$
$$\langle\{\},True,-4.5\rangle$$

Note that the second WPF above can be written in positive form by using the following two WPFs:

$$\langle\{x\},True,-2\rangle$$
$$\langle\{x\},R(x),2\rangle$$

Using the conclusion following Proposition 5, we now extend Proposition 5 to the multi-parent case:

Proposition 6. *A positive conjunctive RLR definition of $P(Q \mid R_i(x_i))$ (multi-parent case) can represent any decision threshold that is a polynomial of terms each indicating the number of (tuples of) individuals for which a Boolean function of parents hold.*

Proof. Let $G_1,G_2,\ldots,G_t$ represent the desired Boolean functions of parents for our model. Also let $n_{(i)}$ denote the number of individuals for which G_i is *True*. Each term of the polynomial in the multi-parent case is then of the form: *w * (a polynomial of population sizes) ** $n_{(1)}^{\alpha_1}n_{(2)}^{\alpha_2}\ldots n_{(t)}^{\alpha_t}$. We demonstrate how we can generate any term $n_{(1)}^{\alpha_1}n_{(2)}^{\alpha_2}\ldots n_{(t)}^{\alpha_t}$. The inclusion of population size of logical variables and the weight w for each term is the same as in Proposition 5.

The conclusion of Proposition 5 can be easily generalized to work for any Boolean formula G_i instead of R. We only need to include a conjunction of α_i instances of G_i with different logical variables representing the same population in each instance. We use this generalization in our proof.

For each $n_{(i)}^{\alpha_i}$, we can use the generalization of conclusion of the Proposition 5 to come up with a WPF $\langle L_i,F_i,1\rangle$ which generates this term. Similar to the reasoning for single-parent case, we can see that the WPF $\left\langle\{\cup_{i=1}^{t}L_i,F_1\wedge F_2\wedge\cdots\wedge F_t,w\right\rangle$ generates the term $n_{(1)}^{\alpha_1}n_{(2)}^{\alpha_2}\ldots n_{(t)}^{\alpha_t}$. We can then use Proposition 3 to write this WPF using only positive conjunctive WPFs. □

Example 10. Suppose we want to model the case where Q is *True* if the square of number of individuals for which $R_1(x_1)=True$ multiplied by the number of individuals for which $R_2(x_2)=True$ is less than five times the whole number of *False* individuals in $R_1(x_1)$ and $R_2(x_2)$. In this case, we define $G_1=\neg R_1(x_1)$, $G_2=\neg R_2(x_2)$ and $G_3=R_1(x_1)\wedge R_1(x_1')\wedge R_2(x_2)$ we need to model the sigmoid of the polynomial $5n_{(1)}+5n_{(2)}-n_{(3)}-0.5$. The reason why we use -0.5 in the polynomial is that we want the polynomial to be negative when $5n_{(1)}+5n_{(2)}=n_{(3)}$. The following WPFs are used by RLR to model this polynomial where the first formula generates the term $5n_{(1)}$, the second generates $5n_{(2)}$, the third generates $-n_{(3)}$ and the fourth generates -0.5.

$$\langle\{x_1\},\neg R_1(x_1),5\rangle$$
$$\langle\{x_2\},\neg R_2(x_2),5\rangle$$
$$\langle\{x_1,x_1',x_2\},R_1(x_1)\wedge R_1(x_1')\wedge R_2(x_2),-1\rangle$$
$$\langle\{\},True,-0.5\rangle$$

Note that the first and second WPF above can be written in positive form in the same way as in Example 9.

Proposition 7 proves the converse of Proposition 6:

Proposition 7. *Any decision threshold that can be represented by a positive conjunctive RLR definition of $P(Q \mid R_i(x_i))$ is a polynomial of terms each indicating the number of (tuples of) individuals for which a Boolean function of parents hold.*

Proof. We prove that every WPF for Q can only generate a term of the polynomial. Since RLR sums over these terms, it will always represent the polynomial of these terms.

Similar to Proposition 6, let $G_1,G_2,\ldots,G_t$ represent the desired Boolean functions of parents and let $k_{(i)}$ denote the number of individuals for which G_i is *True*. A positive conjunctive formula in a WPF can consist of α_1 instances of G_1, α_2 instances of G_2, …, α_t instances of G_t. Based on Proposition 6, we know that this formula is *True* $k_{(1)}^{\alpha_1}k_{(2)}^{\alpha_2}\ldots k_{(t)}^{\alpha_t}$ times. The WPF can contain more logical variables in its set of logical variables than the ones in its formula. This, however, will only cause the above term to be multiplied by the

population size of the logical variable generating a term of the polynomial described in Proposition 6. Therefore, each of the WPFs can only generate a term of the polynomial which means that positive conjunctive RLR can only represent the sigmoid of this polynomial. □

Approximating Other Aggregators Using RLR

We can model other well-known aggregators using positive conjunctive RLR. In most cases, however, this is only an approximation because the sigmoid function reaches 0 or 1 only asymptotically and we cannot choose infinitely large numbers. We can, however, get arbitrarily close to 0 or 1 by choosing arbitrarily large weights. In the rest of this section, we use M to refer to a number which can be set sufficiently large to receive the desired level of approximation. n_{val} is the number of individuals x for which $R(x) = val$, when R is not Boolean.

OR. To model OR in RLR, we use the WPFs:

$$\langle\{\}, True, -M\rangle$$
$$\langle\{x\}, S(x), 2M\rangle$$

for which $P(q \mid S(x)) = \text{sigmoid}(-M + 2Mk)$. We can see that if none of the individuals are *True* (i.e. $n_T = 0$), the value inside the sigmoid is $-M$ which is a negative number thus the probability is close to 0. If even one individual is *True* (i.e. $n_T \geq 1$), the value inside the sigmoid becomes positive and the probability becomes closer to 1. In both cases, the value inside the sigmoid is a linear function of M. Increasing M pushes the probability closer to 0 or to 1 and the approximation becomes more accurate.

AND. AND can be modeled similarly to OR, but with the WPFs

$$\langle\{\}, True, M\rangle$$
$$\langle\{x\}, True, -2M\rangle$$
$$\langle\{x\}, S(x), 2M\rangle$$

for which $P(q \mid S(x)) = \text{sigmoid}(M - 2Mn_F)$. When $n_F = 0$, the value inside the sigmoid is $M > 0$, so the probability is closer to 1. When $n_F \geq 1$, the value inside the sigmoid becomes negative and the probability becomes closer to 0. Like OR, accuracy increases with M. Note that the number of WPFs for representing *OR* and *AND* is fixed.

Noisy-OR and noisy-AND. Figure 2 (a) represents how noisy-OR and noisy-AND can be modeled for the network in Figure 1. In this figure, $R(x)$ represents the values of the individuals being combined and $N(x)$ represents the noise probability. For noisy-OR, $S(x) \equiv R(x) \wedge N(x)$, and Q is the OR aggregator of $S(x)$. For noisy-AND, $S(x) \equiv R(x) \vee N(x)$, and Q is the AND aggregator of $S(x)$.

Mean $>$ t. We can model "Q is *True* if $\text{mean}(R(x)) > t$" using the following WPFs (*val* and t are numeric constants):

$$\langle\{\}, True, -M\rangle$$
$$\langle\{x\}, R(x) = val, M^2(val - t)\rangle \quad \text{for each } val \in \text{range}(R)$$

for which

$$P(q \mid R(x)) = \text{sigmoid}(-M + M^2 \sum_{val \in \text{range}(R)} n_{val}(val - t))$$
$$= \text{sigmoid}(-M + M^2(sum - nt))$$

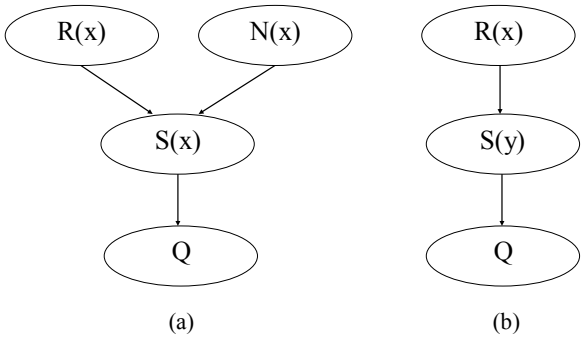

Figure 2: (a) The model for the noisy-OR and noisy-AND aggregators (b) The model for the mode aggregator

where $n = |x|$ and *sum* represents the sum of the values of the individuals. When $mean = \frac{sum}{n} > t$, the value inside the sigmoid is positive and the probability is close to 1. Otherwise, the value inside the sigmoid is negative and the probability is close to 0. Note that M should be greater than $|\frac{1}{sum - nt}|$ to generate a number greater than 1 when multiplied by $(sum - nt)$. Otherwise, it may occur that $sum - nt > 0$ but $M^2(sum - nt) \leq M$ which makes the sigmoid produce a number close to 0. Also note that the number of required WPFs grows with the number of values that the parent can take.

More than t *True*s. "Q is *True* if R is *True* for more than t individuals" can be modeled using the WPFs:

$$\langle\{\}, True, -2Mt - M\rangle$$
$$\langle\{x\}, R(x), 2M\rangle$$

giving $P(q \mid R(x)) = \text{sigmoid}(-2Mt - M + 2Mn_T)$ and the value inside the sigmoid is positive if $n_T > t$. The number of WPFs required is fixed.

More than t% *True*s. "Q is *True* if R is *True* for more than t percent of the individuals" is a special case of the aggregator "mean $> \frac{t}{100}$" when we treat *False* values as 0 and *True* values as 1. This directly provides the WPFs:

$$\langle\{\}, True, -M\rangle$$
$$\left\langle\{x\}, \neg R(x), M^2(0 - \tfrac{t}{100})\right\rangle$$
$$\left\langle\{x\}, \quad R(x), M^2(1 - \tfrac{t}{100})\right\rangle$$

while requiring $M > |\frac{1}{n_T - nt/100}|$, where n is the populations size of x. Note that we can use Proposition 3 to replace the second WPF with two WPFs having positive conjunctive formulae. Unlike the aggregator "mean $> \ldots$", here the number of WPFs is fixed.

Max $>$ t. We can model "Q is *True* if $\max(R(x)) > t$" using the following WPFs:

$$\langle\{\}, True, -M\rangle$$
$$\langle\{x\}, R(x) = val, 2M\rangle \quad \text{for each } val > t,\ val \in \text{range}(R)$$

thus $P(q \mid R(x)) = \text{sigmoid}(-M + 2M \sum_{val > t \in \text{range}(R)} n_{val})$. The value inside the sigmoid is positive if there is an individual having a value greater then t (i.e. $\exists val > t \in \text{range}(R)$:

$n_{val} > 0$). Note that the number of WPFs required grows with the number of values greater than t that the parents can take.

Max. For binary parents, the "max" aggregator is identical to "OR". Otherwise, $\text{range}(Q) = \text{range}(R(x))$. The "max" aggregator can be modeled using a 2-level structure. First, for every $t \in \text{range}(R(x))$, create a separate "max $\geq t$" aggregator, with $R(x)$ as its parents. Then, define the child Q, with all the "max $\geq t$" aggregators as its parents. Q can compute $\max R(x)$ given its parents. Note that while $|parents(Q)| = |\text{range}(R(x))|$ may be arbitrarily large, $|parents(Q)|$ does not change with population size, hence it is possible to use non-relational constructs (e.g., a table) for its implementation.

Mode = t. To model "Q is *True* if $\text{mode}(R(x)) = t$", we first add another PRV $S(y)$ to the network as in Figure 2 (b) where y represents the range of the values for $R(x)$. Then for each individual $S(C)$ of $S(y)$, we use the following WPFs for which $P(s(C) \mid R(x)) = \text{sigmoid}(M - 2M(n_C - n_t))$ and the value inside the sigmoid is positive if $n_t \geq n_C$. Note that the number of WPFs required grows with the number of values that the parent can take.

$$\langle \{\}, True, M \rangle$$
$$\langle \{x\}, R(x) = C, -2M \rangle$$
$$\langle \{x\}, R(x) = t, 2M \rangle$$

Then Q must be *True* if all the individuals in S are *True*. This is because a *False* value for an individual of S means that this individual has occurred more than t and t is not the mode. Therefore, we can use WPFs similar to the ones we used for AND:

$$\langle \{\}, True, M \rangle$$
$$\langle \{y\}, True, -2M \rangle$$
$$\langle \{y\}, S(y), 2M \rangle$$

Mode & Majority. For binary parents, the "mode" aggregator is also called "majority", and can be modeled with the "more than t% Trues" aggregator, with $t = 50$. Otherwise, $\text{range}(Q) = \text{range}(R(x))$, and we can use the same approach as for "max", by having $|\text{range}(R(x))|$ separate "mode $= t$" aggregators, with Q as their child.

Beyond Polynomial Decision Thresholds

Proposition 7 showed that any conditional probability that can be expressed using a positive conjunctive RLR definition of $P(Q \mid R_i(x_i))$ is the sigmoid of a polynomial of the number of *True* and *False* individuals in each parent $R_i(x_i)$. However, given that the decision thresholds are only defined for integral counts, some of the apparently non-polynomial decision thresholds are equivalent to a polynomial and so can be modeled using RLR.

Example 11. Suppose we want to model $Q \equiv \left(\left\lceil \sqrt{n_T} \right\rceil < n_F \right)$. This is a non-polynomial decision threshold, but since n_T and n_F are integers, it is equivalent to the polynomial decision threshold $n_T - (n_F - 1)^2 \leq 0$ which can be formulated using RLR.

Example 12. Suppose we want to model $Q \equiv (2^{n_T} > 3^{n_F})$. This is, however, equivalent to the polynomial form $Q \equiv (n_T \log 2 - n_F \log 3 > 0)$ and can be formulated in positive conjunctive RLR using the WPFs:

$$\langle \{x\}, True, -\log 3 \rangle$$
$$\langle \{x\}, R(x), \quad \log 3 + \log 2 \rangle$$

There are, however, non-polynomial decision thresholds that cannot be converted into a polynomial one and RLR is not able to formulate them.

Example 13. Suppose we want to model $Q \equiv (2^{n_T} > n_F)$. This cannot be converted to a polynomial form and RLR cannot formulate it.

Finding a parametrization that allows to model any non-polynomial decision threshold remains an open problem.

Conclusion

Today's data and models are complex, composed of objects and relations, and noisy. Hence it is not surprising that relational probabilistic knowledge representation currently receives a lot of attention. However, relational probabilistic modeling is not an easy task and raises several novel issues when it comes to knowledge representation:

- What assumptions are we making? Why should we choose one representation over another?
- We may learn a model for some population size(s), and want to apply it to other population sizes. We want to make assumptions explicit and know the consequences of these assumptions.
- If one model fits some data, it is important to understand why it fits the data better.

In this paper, we provided answers to these questions for the case of the logistic regression model. The introduction of the relational logistic regression (RLR) family from first principle is already a major contribution. Based on it, we have investigated the dependence on population size for different variants and have demonstrated that already for simple and well-understood (at the non-relational level) models, there are complex interactions of the parameters with population size. Future work includes inference and learning for these models and understanding the relationship to other models such as undirected models like MLNs. Exploring these directions is important since determining which models to use is more than fitting the models to data; we need to understand what we are representing.

Abstract

We propose the Probabilistic Sentential Decision Diagram (PSDD): A complete and canonical representation of probability distributions defined over the models of a given propositional theory. Each parameter of a PSDD can be viewed as the (conditional) probability of making a decision in a corresponding Sentential Decision Diagram (SDD). The SDD itself is a recently proposed complete and canonical representation of propositional theories. We explore a number of interesting properties of PSDDs, including the independencies that underlie them. We show that the PSDD is a tractable representation. We further show how the parameters of a PSDD can be efficiently estimated, in closed form, from complete data. We empirically evaluate the quality of PSDDs learned from data, when we have knowledge, a priori, of the domain logical constraints.

Introduction

The interplay between logic and probability has been of great interest throughout the history of AI. One of the earliest proposals in this direction is Nilsson's (1986) probabilistic logic, which aimed at augmenting first-order logic with probabilities. This has prompted similar approaches, including, for example, Halpern (1990). The focus of these approaches, however, was mainly semantical, yielding no effective schemes for realizing them computationally. More recently, the area of lifted probabilistic inference has tackled this interplay, while employing a different compromise (Poole 2003). In these efforts, the focus has been mostly on restricted forms of first-order logic (e.g., function-free and finite domain), but with the added advantage of efficient inference (e.g., algorithms whose complexity is polynomial in the domain size).

On the propositional side, the thrust of the interplay has been largely computational. An influential development in this direction has been the realization that enforcing certain properties on propositional representations, such as decomposability and determinism, provides one with the power to answer probabilistic queries efficiently. This development was actually based on two technical observations. First, that decomposable and deterministic representations allow one to perform weighted model counting efficiently. Second, that probabilistic reasoning can be reduced to weighted model counting. This development, which has its first roots in Darwiche (2002), has been underlying an increasing number of probabilistic reasoning systems in the last decade. This is especially true for representations that employ both logical and probabilistic elements (e.g., Chavira, Darwiche, and Jaeger (2006) and Fierens et al. (2011)). Moreover, the technique has been extended recently to certain first-order representations as well (Van den Broeck et al. 2011).

This paper is concerned with an orthogonal contribution to this interplay between propositional logic and probability theory. The problem we tackle here is that of developing a representation of probability distributions in the presence of massive, logical constraints. That is, given a propositional logic theory which represents domain constraints, our goal is to develop a representation that induces a unique probability distribution over the models of the given theory. Moreover, the proposed representation should satisfy requirements that are sometimes viewed as necessary for the practical employment of such representations. These include a clear semantics of the representation parameters; an ability to reason with the representation efficiently; and an ability to learn its parameters from data, also efficiently.

Our proposal is called a *Probabilistic Sentential Decision Diagram (PSDD).* It is based on the recently proposed *Sentential Decision Diagram (SDD)* for representing propositional theories (Darwiche 2011; Xue, Choi, and Darwiche 2012; Choi and Darwiche 2013). While the SDD is comprised of *logical* decision nodes, the PSDD is comprised of *probabilistic* decision nodes, which are induced by supplying a distribution over the branches of a logical decision node. Similar to SDDs, the PSDD is a canonical representation, but under somewhat more interesting conditions. Moreover, computing the probability of a term can be done in time linear in the PSDD size. In fact, the probability of each and every literal can be computed in only two passes over the PSDD. It is particularly notable that the local parameters of a PSDD have clear semantics with respect to the global distribution induced by the PSDD. We will also show that these parameters can be learned efficiently from complete data.

This paper is structured as follows. We start by a concrete discussion on some of the applications that have driven the development of PSDDs and follow by an intuitive expo-

sure of PSDDs and their salient features. We next provide a formal treatment of the syntax, semantics and properties of PSDDs. This allows us to present the main inference algorithm for PSDDs and the one for learning PSDD parameters from complete data. The paper concludes with some experimental results showing the promise of PSDDs in learning probability distributions under logical constraints. Proofs of theorems are delegated to the full version of the paper due to space limitations.

Motivation

PSDDs were inspired by the need to learn probability distributions that are subject to domain constraints. Take for example a computer science department that organizes four courses: Logic (L), Knowledge Representation (K), Probability (P), and Artificial Intelligence (A). Students are asked to enroll for these courses under the following restrictions:

– A student must take at least one of Probability or Logic.

– Probability is a prerequisite for AI.

– The prerequisite for KR is either AI or Logic.

The department may have data on student enrollments, as in Table 1, and may wish to learn a probabilistic model for reasoning about student preferences. For example, the department may need to know whether students are more likely to satisfy the prerequisite of KR using AI or using Logic.

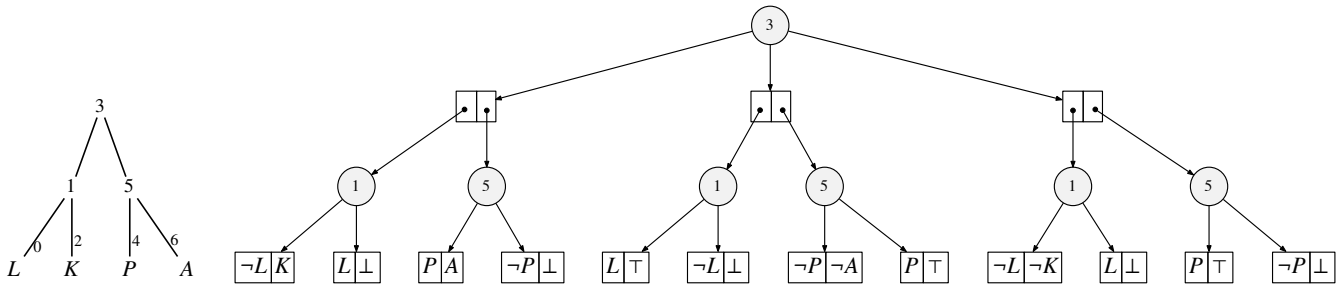
A mainstream approach for addressing this problem is to learn a probabilistic graphical model, such as a Bayesian network. In this case, a network structure is constructed manually or learned from data. The structure is then turned into a Bayesian network by learning its parameters from the data. Other graphical models can also be used. This includes, for example, Markov networks or their variations.

What is common among all these approaches is that they lack a principled and effective method for accommodating the domain constraints into the learning process—that is, ensuring, for example, that a student with a profile $A \wedge K \wedge L \wedge \neg P$, or a profile $\neg A \wedge K \wedge \neg L \wedge P$, has zero probability in the learned model. In principle, the zero parameters of a graphical model can capture logical constraints, although a fixed model structure will not in general accommodate arbitrary logical constraints. We could introduce additional structure into the model to capture such constraints, using, e.g., the method of virtual evidence (Pearl 1988; Mateescu and Dechter 2008). However, incorporating constraints in this manner will in general lead to a highly-connected network, making inference intractable. Even if inference remained tractable, such an approach is not ideal as we now have to learn a distribution that is conditioned on the constraints. This would require new learning algorithms (e.g., gradient methods) for performing parameter estimation as traditional methods may no longer be applicable. For example, in Bayesian networks, the closed-form parameter estimation algorithm under complete data will no longer be valid in this case.

The domain constraints of our example can be expressed using the following CNF.

$$\begin{aligned} P \vee L \\ A \Rightarrow P \\ K \Rightarrow A \vee L \end{aligned} \tag{1}$$

Even though there are 16 combinations of courses, the CNF says that only 9 of them are valid choices. An approach that observes this information must learn a probability distribution that assigns a zero probability to every combination that is not allowed by these constraints.



None of the standard learning approaches we are familiar with has been posed to address this problem. The complication here is not strictly with the learning approaches, but with the probabilistic models that are amenable to being learned under these circumstances. In particular, these models are not meant to induce probability distributions that respect a given set of logical constraints.

The simple problem we posed in this section is exemplary of many real-world applications. We mention in particular *configuration* problems that arise when purchasing products, such as cars and computers. These applications give users the option to configure products, but subject to certain constraints. Data is abundant for these applications and there is a clear economic interest in learning probabilistic models under the given constraints. We also mention *reasoning about physical systems,* which includes verification and diagnosis applications. Here, propositional logic is typically used to encode some system functionality, while leaving out some system behaviors which may have a non-deterministic nature (e.g., component failures and probabilistic transitions). There is also an interest here to learn probabilistic models of these systems, subject to the given constraints.

Our goal in this paper is to introduce the PSDD representation for addressing this particular need. We will start by an intuitive (and somewhat informal) introduction to PSDDs, followed by a more formal treatment of their syntax, semantics and the associated reasoning and learning algorithms.

PSDDs

We will refer to domain constraints as the *base* of a probability distribution. Our proposed approach starts by representing this base as a *Sentential Decision Diagram (SDD)* as in Figure 1 (Darwiche 2011; Xue, Choi, and Darwiche 2012; Choi and Darwiche 2013). An SDD is determined by a *vtree,* which is a full binary tree with leaves corresponding to the domain variables (Pipatsrisawat and Darwiche 2008). The choice of a particular SDD can then be thought of as a choice of a particular vtree. We will later discuss the impact of this

(a) Vtree (b) SDD

Figure 1: A vtree and SDD for the student enrollment problem. Numbers in circles correspond to vtree nodes.

choice on the represented distribution. For now, however, we will develop some further understanding of SDDs as they are the backbones of our probability distributions.

SDDs. An SDD is either a *decision node* or a *terminal node.* A terminal node is a literal, the constant $\top$ (true) or the constant $\bot$ (false). A decision node is a disjunction of the form $(p_1 \wedge s_1) \vee \ldots \vee (p_n \wedge s_n)$, where each pair (p_i, s_i) is called an *element.* A decision node is depicted by a circle and its elements are depicted by paired boxes. Here, $p_1, \ldots, p_n$ are called *primes* and $s_1, \ldots, s_n$ are called *subs.* Primes and subs are themselves SDDs. Moreover, the primes of a decision node are always consistent, mutually exclusive and exhaustive. The SDD in Figure 1 has seven decision nodes. The decision node to the far left has two elements $(\neg L, K)$ and $(L, \bot)$. It represents $(\neg L \wedge K) \vee (L \wedge \bot)$, which is equivalent to $\neg L \wedge K$. There are two primes for this node $\neg L$ and L. The two corresponding subs are K and $\bot$.

Structure. An SDD can be viewed as a *structure* that induces infinitely many probability distributions (all having the same base). By *parameterizing* an SDD, one obtains a PSDD that induces a particular probability distribution.

Parameters. Figure 2 depicts a PSDD which is obtained by parameterizing the SDD in Figure 1. Both decision and terminal SDD nodes are parameterized, but we focus here on decision nodes. Let n be a decision node having elements $(p_1, s_1), \ldots, (p_n, s_n)$. To parameterize node n is to provide a distribution $\theta_1, \ldots, \theta_n$. Intuitively, θ_i is the probability of prime p_i given that the decision of node n has been implied. We will formalize and prove this semantics later. We will also provide an efficient procedure for learning the parameters of a PSDD from complete data. The PSDD parameters in Figure 2 were learned using this procedure from the data in Table 2. The table also depicts the probability distribution induced by the learned PSDD.

Independence. The PSDD structure is analogous to a Bayesian network structure in the following sense. The latter can be parameterized in infinitely many ways, with each parameterization inducing a particular probability distribution. Moreover, all the induced distributions satisfy certain independences that can be inferred from the underlying Bayesian network structure. The same is true for PSDDs. Each parameterization of a PSDD structure yields a unique probability distribution. Moreover, all the induced distributions satisfy independences that can be inferred from the PSDD structure.

L	K	P	A	Students	Learned PSDD Distribution	
0	0	1	0	6	$0.6 \cdot 0.1$	6.0%
0	0	1	1	54	$0.6 \cdot 0.9$	54.0%
0	1	1	1	10	0.1	10.0%
1	0	0	0	5	$0.3 \cdot 0.2 \cdot 0.6$	3.6%
1	0	1	0	1	$0.3 \cdot 0.2 \cdot 0.4 \cdot 0.75$	1.8%
1	0	1	1	0	$0.3 \cdot 0.2 \cdot 0.4 \cdot 0.25$	0.6%
1	1	0	0	13	$0.3 \cdot 0.8 \cdot 0.6$	14.4%
1	1	1	0	8	$0.3 \cdot 0.8 \cdot 0.4 \cdot 0.75$	7.2%
1	1	1	1	3	$0.3 \cdot 0.8 \cdot 0.4 \cdot 0.25$	2.4%

Table 2: Student enrollment data and learned distribution.

We will show, however, that PSDD independence is more refined than Bayesian network independence as it allows one to express more qualified independence statements.

The Syntax and Semantics of PSDDs

PSDDs are based on *normalized* SDDs in which every node n is associated with (normalized for) a vtree node v according to the following rules (Darwiche 2011).

- If n is a terminal node, then v is a leaf node which contains the variable of n (if any).
- If n is a decision node, then its primes (subs) are normalized for the left (right) child of v.
- If n is the root SDD node, then v is the root vtree node.

The SDD in Figure 1 is normalized. Each decision node in this SDD is labeled with the vtree node it is normalized for. We are now ready to define the syntax of a PSDD.

Definition 1 (PSDD Syntax) *A PSDD is a normalized SDD with the following parameters.*

- *For each decision node $(p_1, s_1), \ldots, (p_k, s_k)$ and prime p_i, a positive parameter θ_i is supplied such that $\theta_1 + \ldots + \theta_k = 1$ and $\theta_i = 0$ iff $s_i = \bot$.*
- *For each terminal node $\top$, a positive parameter θ is supplied such that $0 < \theta < 1$.*

A terminal node $\top$ with parameter θ will be denoted by $X : \theta$, where X is the variable of leaf vtree node that $\top$ is normalized for. Other terminal nodes (i.e., $\bot$, X and $\neg X$) have fixed, implicit parameters (discussed later) and will be denoted as is. A decision PSDD node will be denoted by

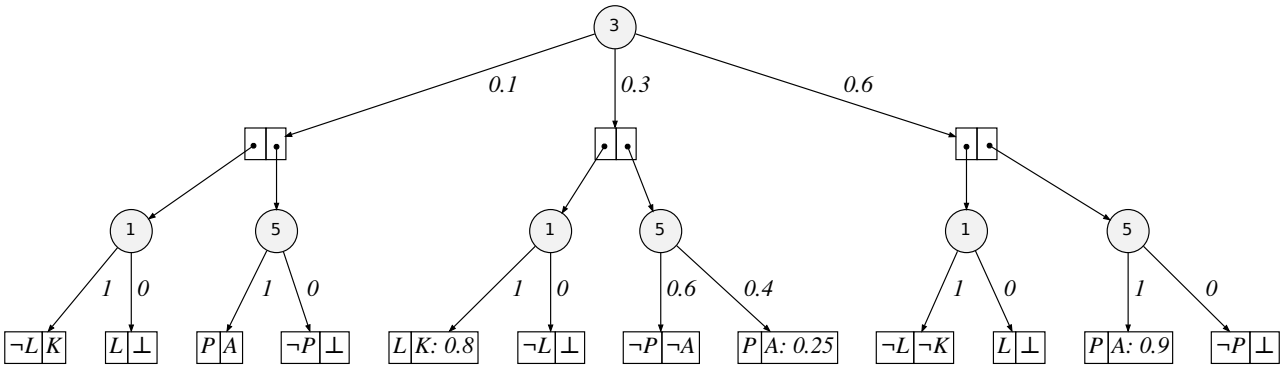


Figure 2: A PSDD for the student enrollment problem, which results from parameterizing the SDD in Figure 1. The parameters were learned from the dataset in Table 1 (also shown in Table 2).

$(p_1, s_1, \theta_1), \ldots, (p_k, s_k, \theta_k)$. Graphically, we will just annotate the edge into element (p_i, s_i) with the parameter θ_i. Figure 2 provides examples of this notation.

We next define the distribution of a PSDD, inductively. That is, we first define the distribution induced by a terminal node. We then define the distribution of a decision node in terms of the distributions induced by its primes and subs.

Definition 2 (PSDD Distribution) *Let n be a PSDD node that is normalized for vtree node v. Node n defines a distribution Pr_n over the variables of vtree v as follows.*

– *If n is a terminal node, and v has variable X, then*

n	$\mathsf{Pr}_n(X)$	$\mathsf{Pr}_n(\neg X)$
$X : \theta$	θ	$1-\theta$
$\bot$	0	0
X	1	0
$\neg X$	0	1

– *If n is a decision node $(p_1, s_1, \theta_1), \ldots, (p_k, s_k, \theta_k)$ and v has left variables $\mathbf{X}$ and right variables $\mathbf{Y}$, then*

$$\mathsf{Pr}_n(\mathbf{xy}) \stackrel{def}{=} \mathsf{Pr}_{p_i}(\mathbf{x}) \cdot \mathsf{Pr}_{s_i}(\mathbf{y}) \cdot \theta_i \quad \textit{for } i \textit{ where } \mathbf{x} \models p_i.$$

Applying this definition to the PSDD of Figure 2 leads to the distribution in Table 2 for its root node. The following table depicts the distribution induced by a non-root node in this PSDD, which appears in the middle of Figure 2.

$\mathbf{x}$	$\mathbf{y}$	$\mathsf{Pr}_{p_i}(\mathbf{x})$	$\mathsf{Pr}_{s_i}(\mathbf{y})$	θ_i	$\mathsf{Pr}_n(\mathbf{xy})$
P	A	1	0.25	0.4	0.1
P	$\neg A$	1	0.75	0.4	0.3
$\neg P$	A	1	0	0.6	0.0
$\neg P$	$\neg A$	1	1	0.6	0.6

Table 3: Distribution of node $n = (\neg P, \neg A)(P, \top)$.

The SDD node associated with a PSDD node n is called the *base* of n and is denoted by $[n]$. When there is no ambiguity, we will often not distinguish between a PSDD node n and its base $[n]$.

A PSDD assigns a strictly positive probability to a variable instantiation iff the instantiation satisfies its base. This can be seen, for example, in Table 3. This is also the first key property of PSDDs.

Theorem 1 (Base) *Consider a PSDD node n that is normalized for vtree node v. If $\mathbf{Z}$ are the variables of vtree v, then $\mathsf{Pr}_n(\mathbf{z}) > 0$ iff $\mathbf{z} \models [n]$.*

We will now discuss the second key property of PSDDs, which reveals the *local* semantics of PSDD parameters.

Theorem 2 (Parameter Semantics) *Let n be a decision node $(p_1, s_1, \theta_1), \ldots, (p_k, s_k, \theta_k)$. We have $\theta_i = \mathsf{Pr}_n([p_i])$.*

Consider the PSDD in Figure 2 and its decision node n in Table 3. Prime $\neg P$ of this node has parameter 0.6. According to Theorem 2, we must then have $\mathsf{Pr}_n(\neg P) = 0.6$, which can be verified in Table 3. Similarly, $\mathsf{Pr}_n(P) = 0.4$.

The third key property of PSDDs is the relationship between the local distributions induced by its various nodes (node distributions) and the global distribution induced by its root node (PSDD distribution)—for example, the relationship between the distribution of node n in Table 3 and the PSDD distribution given in Table 2.

Node distributions are linked to the PSDD distribution by the notion of *context.*

Definition 3 (Context) *Let $(p_1, s_1), \ldots, (p_k, s_k)$ be the elements appearing on some path from the SDD root to node n.*[1] *Then $p_1 \wedge \ldots \wedge p_k$ is called a sub-context for node n and is feasible iff $s_i \neq \bot$. The context is a disjunction of all sub-contexts and is feasible iff some sub-context is feasible.*

Consider Figure 1. The three decision nodes normalized for vtree node $v = 5$ have the contexts $\neg L \wedge K$, L and $\neg L \wedge \neg K$. Moreover, the terminal nodes normalized for vtree $v = 6$ have the contexts:

– A: $\neg L \wedge K \wedge P$

– $\neg A$: $L \wedge \neg P$

– $\bot$: $(\neg L \wedge K \wedge \neg P) \vee (\neg L \wedge \neg K \wedge \neg P) = (\neg L \wedge \neg P)$

– $\top$: $(L \wedge P) \vee (\neg L \wedge \neg K \wedge P) = (L \vee \neg K) \wedge P$.

Contexts satisfy interesting properties.

[1] That is, $n = p_k$ or $n = s_k$.

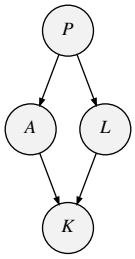

Figure 3: A Bayesian network structure.

Theorem 3 (Context) *A node is implied by its context and the underlying SDD. Nodes normalized for the same vtree node have mutually exclusive and exhaustive contexts. The sub-contexts of a node are mutually exclusive. A context/sub-context is feasible iff it has a strictly positive probability.*

Contexts give a global interpretation to node distributions.

Theorem 4 (Node Distribution) *Consider a PSDD r and let n be one of its nodes. If γ_n is a feasible sub-context or feasible context of node n, then $\mathsf{Pr}_n(.) = \mathsf{Pr}_r(. \mid \gamma_n)$.*

Contexts also give a *global* interpretation to parameters.

Corollary 1 (Parameter Semantics) *Consider a PSDD r and node n with feasible sub-context or feasible context γ_n.*

- *If n is a terminal node $X:\theta$, then $\theta = \mathsf{Pr}_r(X \mid \gamma_n)$.*
- *If n is a decision node $(p_1, s_1, \theta_1), \ldots, (p_k, s_k, \theta_k)$, then $\theta_i = \mathsf{Pr}_r([p_i] \mid \gamma_n)$ for $i = 1, \ldots, k$.*

This corollary says that the parameters of a node are conditional probabilities of the PSDD distribution.

We show in the Appendix that PSDDs are *complete* as they are capable of representing any probability distribution. We also show that PSDDs are *canonical* under a condition known as compression. More precisely, we show that there is a unique compressed PSDD for each distribution and vtree. This is particularly important for learning PSDDs (structure and parameters) as it reduces the problem of searching for a PSDD into the problem of searching for a vtree.

PSDD Independence

Consider the Bayesian network structure in Figure 3, which corresponds to our earlier example. This structure encodes a number of probabilistic independences that hold in any distribution it induces (i.e., regardless of its parameters). These independences are

- A and L are independent given P.
- K and P are independent given AL.

These independences are conditioned on variables. That is, "given AL" reads "given any state of variables A and L." The second independence can therefore be expanded into $2 \times 2 \times 4$ statements of the form "α is independent of β given γ," where α, β and γ are propositional sentences (e.g., $\neg K$ is independent of P given $A \wedge \neg L$).

The structure of a PSDD also encodes independences that hold in every induced distribution. These independences fall into two major categories, the first coming from Theorem 4.

Corollary 2 (Independence I) *Consider a PSDD r and a node n with context γ_n and feasible sub-context β_n.*

- *If n is a terminal node $X:\theta$, then*

$$\mathsf{Pr}_r(X \mid \gamma_n, \beta_n) = \mathsf{Pr}_r(X \mid \gamma_n) = \mathsf{Pr}_r(X \mid \beta_n) = \theta.$$

- *If n is a decision node $(p_1, s_1, \theta_1), \ldots, (p_k, s_k, \theta_k)$, then*

$$\mathsf{Pr}_r([p_i] \mid \gamma_n, \beta_n) = \mathsf{Pr}_r([p_i] \mid \gamma_n) = \mathsf{Pr}_r([p_i] \mid \beta_n) = \theta_i$$

for $i = 1, \ldots, k$.

That is, the probability of a prime is independent of a sub-context once the context is known. This is also true for the probability of a terminal sub. Moreover, which specific sub-context we know is irrelevant. All are equivalent as far as defining the semantics of parameters is concerned.

The second category of independences is as follows.

Theorem 5 (Independence II) *Let γ_v be a feasible context for a PSDD node normalized for vtree node v. Variables inside v are independent of those outside v given context γ_v.*

To read the independences characterized by this theorem, one iterates over each vtree node v, identifying its corresponding, feasible contexts γ_v. Consider the PSDD in Figure 2. There are three decision nodes which are normalized for vtree node $v = 5$, with contexts $\neg L \wedge K$, L and $\neg L \wedge \neg K$. Using the second context, we get

variables PA and LK are independent given context L.

This reads as "If we know that someone took Logic, then whether they took KR has no bearing on whether they took Probability or AI."

PSDD independences are conditioned on propositional sentences (contexts) instead of variables. This kind of independence is known to be more expressive and is usually called *context-specific independence* (Boutilier et al. 1996). This kind of independence is beyond the scope of probabilistic graphical models, which can only condition independence statements on variables. Consider the example statement we discussed above. If we were to condition on the variable L instead of the propositional sentence L, we would also get "If we know that someone *did not take* Logic, then whether they took KR has no bearing on whether they took Probability or AI." This is actually contradicted by the logical constraints for this problem ($K \Rightarrow A \vee L$). If someone did not take Logic, but took KR, they must have taken AI.

Reasoning with PSDDs

We now present the main algorithms for reasoning with PSDDs. In particular, given a PSDD r and an instantiation $\mathbf{e}$ of some variables (*evidence*), we provide an algorithm for computing the probability of this evidence $\mathsf{Pr}_r(\mathbf{e})$. We also present an algorithm for computing the conditional probability $\mathsf{Pr}_r(X \mid \mathbf{e})$ for every variable X. Both algorithms run in time which is linear in the PSDD size.

We start with the first algorithm. For variable instantiation $\mathbf{e}$ and vtree node v, we will use $\mathbf{e}_v$ to denote the subset of instantiation $\mathbf{e}$ that pertains to the variables of vtree v, and $\mathbf{e}_{\bar{v}}$ to denote the subset of $\mathbf{e}$ that pertains to variables outside v. The first algorithm is based on the following result.

Algorithm 1: Probability of Evidence

Input: PSDD r and evidence $\mathbf{e}$

$evd(n) \leftarrow 0$ for every node n
// visit children before parents
foreach *node n in the PSDD* **do**
  if *n is a terminal node* **then**
    $v \leftarrow$ leaf vtree node that n is normalized for
    $evd(n) \leftarrow \mathsf{Pr}_n(\mathbf{e}_v)$
  else
    foreach *element (p_i, s_i, θ_i) of node n* **do**
      $evd(n) \leftarrow evd(n) + evd(p_i) \cdot evd(s_i) \cdot \theta_i$

Theorem 6 *Consider a decision node $n = (p_1, s_1, \theta_1), \ldots, (p_k, s_k, \theta_k)$ that is normalized for vtree node v, with left child l and right child r. For evidence $\mathbf{e}$, we have*

$$\mathsf{Pr}_n(\mathbf{e}_v) = \sum_{i=1}^{k} \mathsf{Pr}_{p_i}(\mathbf{e}_l) \cdot \mathsf{Pr}_{s_i}(\mathbf{e}_r) \cdot \theta_i$$

When n is a terminal node, v is a leaf vtree node and $\mathbf{e}_v$ is either a literal or the empty instantiation. In this case, we can just look up the value of $\mathsf{Pr}_n(\mathbf{e}_v)$ from the distribution induced by the terminal node n (from Definition 2).

Theorem 6 leads to Algorithm 1, which traverses the PSDD bottom-up, computing $\mathsf{Pr}_n(\mathbf{e}_v)$ for each node n and storing the result in $evd(n)$. The probability of evidence is then $evd(r)$, where r is the PSDD root.

We now turn to computing the probability $\mathsf{Pr}_r(X, \mathbf{e})$ for each variable X. One can use Algorithm 1 to perform this computation, but the algorithm would need to be called once for each variable X. However, with the following theorem, we can compute all of these node marginals using a single, second pass on the PSDD, assuming that Algorithm 1 did the first pass.

Theorem 7 *Consider a PSDD r, variable X, and its leaf vtree node v. Let $n_1, \ldots, n_k$ be all the terminal nodes normalized for v and let $\gamma_{n_1}, \ldots, \gamma_{n_k}$ be their corresponding contexts. For evidence $\mathbf{e}$, we have*

$$\mathsf{Pr}_r(X, \mathbf{e}_{\bar{v}}) = \sum_{i=1}^{k} \mathsf{Pr}_{n_i}(X) \cdot \mathsf{Pr}_r(\gamma_{n_i}, \mathbf{e}_{\bar{v}}).$$

If $\mathbf{e} \models \neg X$, then $\mathsf{Pr}_r(X, \mathbf{e}) = 0$. Otherwise, $X, \mathbf{e}_{\bar{v}} = X, \mathbf{e}$ and $\mathsf{Pr}_r(X, \mathbf{e}) = \mathsf{Pr}_r(X, \mathbf{e}_{\bar{v}})$.

The term $\mathsf{Pr}_{n_i}(X)$ in Theorem 7 is immediately available. Algorithm 2 computes $\mathsf{Pr}_r(\gamma_n, \mathbf{e}_{\bar{v}})$ for every PSDD node n that has context γ_n and is normalized for vtree node v. The algorithm traverses the PSDD top-down, computing this probability for each visited node n, storing it in $ctx(n)$. If n is a terminal node, the algorithm also computes $\mathsf{Pr}_r(X, \mathbf{e}_{\bar{v}})$ and $\mathsf{Pr}_r(\neg X, \mathbf{e}_{\bar{v}})$, storing them in $mrg(X)$ and $mrg(\neg X)$.

The simplicity of Algorithm 2 is due to the following. The probability of a sub-context can be computed by multiplying the parameters appearing on its corresponding path. Since sub-contexts are mutually exclusive, their probabilities can be added to obtain the context probability. Algorithm 2 does precisely this except that it accounts for evidence as well using quantities computed by Algorithm 1.

Algorithm 2: Probability of Contexts

Input: PSDD r

$ctx(n) \leftarrow 0$ for nodes $n \neq r$ and $ctx(r) \leftarrow 1$
$mrg(X) \leftarrow 0$ and $mrg(\neg X) \leftarrow 0$ for every variable X
// visit parents before children
foreach *node n in the PSDD* **do**
  if *n is a terminal node* **then**
    $X \leftarrow$ variable of node n
    $mrg(X) \leftarrow mrg(X) + ctx(n) \cdot \mathsf{Pr}_n(X)$
    $mrg(\neg X) \leftarrow mrg(\neg X) + ctx(n) \cdot \mathsf{Pr}_n(\neg X)$
  else
    foreach *element (p_i, s_i, θ_i) of node n* **do**
      $ctx(p_i) \leftarrow ctx(p_i) + \theta_i \cdot evd(s_i) \cdot ctx(n)$
      $ctx(s_i) \leftarrow ctx(s_i) + \theta_i \cdot evd(p_i) \cdot ctx(n)$

Learning with PSDDs

We now present an algorithm for learning the parameters of a PSDD from a *complete* dataset. We start first with some basic definitions. An instantiation of all variables is called an *example*. There are 2^n distinct examples over n propositional variables. A complete dataset is a multi-set of examples.[2] That is, an example may appear multiple times in a dataset. Given a PSDD structure (a normalized SDD), and a complete dataset, our goal is to learn the value of each PSDD parameter. More precisely, we wish to learn *maximum likelihood* parameters: ones that maximize the probability of examples in the dataset.

We will use Pr_θ to denote the distribution induced by the PSDD structure and parameters θ. The *likelihood* of these parameters given dataset $\mathbf{D}$ is defined as

$$L(\theta|\mathbf{D}) = \prod_{i=1}^{N} \mathsf{Pr}_\theta(\mathbf{d}_i),$$

where $\mathbf{d}_i$ ranges over all N examples in dataset $\mathbf{D}$. Our goal is then to find the maximum likelihood parameters

$$\theta^{ml} = \operatorname*{argmax}_\theta L(\theta|\mathbf{D}).$$

We will use $\mathbf{D}\#(\alpha)$ to denote the number of examples in dataset $\mathbf{D}$ that satisfy propositional sentence α. For a decision node $n = (p_1, s_1, \theta_1), ..., (p_k, s_k, \theta_k)$ with context γ_n, we propose the following estimate for parameter θ_i:

$$\theta_i^{ml} = \frac{\mathbf{D}\#(p_i, \gamma_n)}{\mathbf{D}\#(\gamma_n)}. \quad (2)$$

For terminal node $n = X{:}\theta$ with context γ_n, we propose the following estimate for parameter θ:

$$\theta^{ml} = \frac{\mathbf{D}\#(X, \gamma_n)}{\mathbf{D}\#(\gamma_n)}. \quad (3)$$

[2] In an *incomplete* dataset, an example corresponds to an instantiation of some variables (not necessarily all).

We can now show the following.

Theorem 8 *The parameter estimates of Equations 2 and 3 are the only estimates that maximize the likelihood function.*

Our parameter estimates admit a *closed-form*, in terms of the counts $\mathbf{D}\#(\alpha)$ in the data. One can compute these estimates using a single pass through the examples of a dataset. Moreover, each distinct example can be processed in time linear in the PSDD size.[3] These are very desirable properties for a parameter learning algorithm. These properties are shared with Bayesian network representations, but are missing from many others, including Markov networks.

When learning probabilistic graphical models, one makes a key distinction between learning structures versus learning parameters (the former being harder in general). While learning PSDD structures is beyond the scope of this paper, the experimental results we present next do use a basic method for learning structures. In particular, since we compile logical constraints into an SDD (i.e., a PSDD structure), the compilation technique we use is effectively "learning" a structure. We used the publicly available SDD package for this purpose (*http://reasoning.cs.ucla.edu/sdd/*). The SDD package tries to dynamically minimize the size of the compiled SDD and, as a result, tries to minimize the number of PSDD parameters.

Preliminary Experimental Results

In this Section, we empirically evaluate our parameter estimation algorithm for PSDDs. First, we illustrate how our algorithm can effectively recover the parameters of a PSDD from data, assuming that the dataset was indeed generated by the distribution of a PSDD. Second, we highlight how knowing the logical constraints underlying a given dataset can impact the accuracy of learned models.

In our first set of experiments, using synthetic data, we show how we can recover the true parameters that generated a dataset, given that the logical constraints are known. As we will be simulating datasets from a known PSDD, we shall use the KL-divergence to compare the original PSDD distribution $\Pr(\mathbf{Z})$, and the PSDD distribution $\Pr'(\mathbf{Z})$ that we learned from the data:

$$KL(\Pr, \Pr') = \sum_{\mathbf{z}} \Pr(\mathbf{z}) \log \frac{\Pr(\mathbf{z})}{\Pr'(\mathbf{z})}.$$

Note that the KL-divergence is non-negative, and zero iff the two distributions are equivalent.[4]

[3] A dataset may not include every example that is consistent with the domain constraints. If this is the case, a parameter θ for prime p may be estimated to zero, even though its sub s may not be $\bot$; see Theorem 1. To address this, one can assume a pseudo-count for each distinct example, which can be thought of as providing a prior distribution on parameters. In our experiments, we assumed a pseudo-count of $1/\mathsf{mc}$ for each distinct example, where mc is the model count of the SDD. This corresponds to a very weak prior since, in aggregate, these pseudo-counts contribute a total count that is equivalent to one real example in the dataset.

[4] The KL–divergence between two PSDDs can be computed efficiently if they share the same structure.

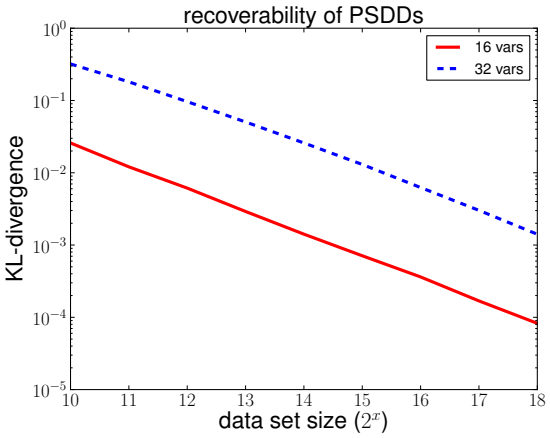

Figure 4: We observe how our parameter estimation algorithm can recover the original PSDD as we increase the size of the training dataset (x-axis), measured by the KL-divergence (y-axis, where lower is better).

Consider Figure 4, where each point in the plot represents an average of 100 randomly generated PSDDs. We generated 10 random PSDD structures by compiling random 3-CNFs into SDDs (the used clause to variable ratio is 3). For each SDD, we randomly generated 10 different parameterizations, giving us $10 \times 10 = 100$ PSDDs total. The SDDs were compiled using dynamic minimization, which reduces the size of the SDD, and hence, the number of parameters in the corresponding PSDD. We evaluated PSDDs over 16 variables and 32 variables (one curve each).

As we go right on the x-axis, we increase the size of the dataset that we are learning our PSDD from. We clearly see that as more data becomes available, the parameters that we learn more closely match the true parameters of the original PSDD (measured using the KL-divergence, on the y-axis). Indeed, both curves are steadily tending to zero. The PSDDs over 16 variables converge faster than those over 32 variables. The PSDDs over 16 variables have fewer parameters, roughly, a tenth as many.

Our final experiment tries to put PSDD learning in the context of learning probabilistic graphical models. It is hard to make a direct comparison here since existing approaches do not factor domain constraints into the learning process. Hence, there are no available systems that tackle the learning problem we posed in this paper, nor are there reported experimental results that are directly relevant. Still, we conceived an experiment that is revealing in this regard, which we explain next.

A standard experiment for evaluating a learning approach goes as follows. The dataset is divided into a *training* portion and *testing* one. The learning algorithm is then given the training dataset and asked to find a probabilistic model. The quality of the model is then measured by computing the likelihood of learned parameters, but using the testing dataset. The literature contains many experiments of this form (e.g., Table 4). The question we posed is this: What if the dataset embedded the domain constraints, in that any example that

Table 4: Log Likelihoods of Testing Datasets. A question mark indicates the unavailability of likelihood for the corresponding approach/dataset.

does not appear in the dataset (training or testing) is an impossible example? Under this assumption, the domain constraints correspond to a sentence which is obtained by disjoining all examples in the dataset. This is indeed what we did in our last experiment. We compiled the mentioned disjunction (which is a DNF) into an SDD, learned its parameters using the training dataset, and measured the quality of learned PSDD using the testing dataset.

We compared the obtained results on the corpus in Table 4; see, e.g., (Davis and Domingos 2010) for more statistics on these datasets. These real-world datasets are commonly used to evaluate algorithms for learning probabilistic graphical models as we just discussed.[5] Here, ACMN are Arithmetic Circuits for Bayesian networks, ACBN are Arithmetic Circuits for Markov networks, LTM are Latent Tree Models, and CLT are Chow-Liu trees. Each algorithm learns its corresponding model using the training dataset, and evaluates it using the testing dataset. The likelihoods of learned models are given in Table 4; these likelihoods can also be found in (Lowd and Rooshenas 2013). For the two datasets over a small number of variables, our PSDDs obtain competitive likelihoods (smaller magnitude is better). In datasets over a larger number of variables, the PSDDs obtain better, and often significantly better, likelihoods than other learned models.

While this experiment is contrary to what is usual, it is both revealing and suggestive. First, it highlights the potential impact of accommodating logical constraints into the learning process. Second, it begs the question: What if the data was indeed indicative of the domain constraints? For example, when the dataset is large enough, and the domain is known to be constrained enough, it is not unreasonable to assume that the dataset is indicative of domain constraints. Moreover, theoretically, this assumption does hold in the limit. As far as we know, there is no existing approach that can exploit this assumption as done by this work. In fact, this observation and the need to address it is what prompted us to develop PSDDs in the first place.

[5]The models that were learned in Table 4 correspond to restricted Bayesian or Markov networks (they have a corresponding arithmetic circuit (AC) or have a tree structure). These restrictions are meant to allow one to compute likelihoods efficiently.

Related Work

The PSDD can be viewed from two angles: As a knowledge representation and reasoning formalism, and as a learning formalism. We next discuss related work across both angles.

As a KR formalism, the PSDD is related to work on extending Binary Decision Diagrams (BDDs) to represent real-valued functions. The relationship between SDDs (which underly PSDDs) and BDDs is known (Darwiche 2011; Xue, Choi, and Darwiche 2012; Choi and Darwiche 2013). In sum though, BDDs branch on literals, instead of sentences, which leads to limitations that are inherited by their extensions (Xue, Choi, and Darwiche 2012). Algebraic Decision Diagrams (ADDs) (R.I. Bahar et al. 1993) in particular are often used to represent joint probability distributions. However, they are not factorized representations and, as such, they need to explicitly represent every distinct probability in a distribution. Affine ADDs (Sanner and McAllester 2005) and Edge-valued Binary Decision Diagrams (Lai and Sastry 1992) do offer a factorized representation, but their parameters are not interpretable as in PSDDs (i.e., as probabilities of the global distribution).

There is also a body of work on facilitating the representation of logical constraints in the context of probabilistic representations. This includes Richardson and Domingos (2006), who facilitate the representation of logical constraints in Markov networks. Additionally, Mateescu and Dechter (2008) separate an unconstrained probabilistic model (e.g., Bayesian network) from the logical constraints and define the target distribution as the former conditioned on the latter. Hence, individual parameters in their framework have no local semantics in the target distribution. Several more first-order probabilistic languages can directly express logical dependencies (De Raedt et al. 2008; Getoor and Taskar 2007). Within these representations, there has been considerable interest in probabilistic reasoning in the presence of logical constraints. See for example Poon and Domingos (2006) and Gogate and Dechter (2007).

Perhaps the most strongly related formalism is the probabilistic decision graph (Bozga and Maler 1999; Jaeger 2004). These circuits are governed by a variable forest instead of a vtree. Their parameters represent contextual conditional probabilities. However, for a fixed variable forest, probabilistic decision graphs are not a complete representation. There are distributions that cannot be represented because the variable forest already encodes certain conditional independencies. Hence, these representations are canonical only in a weaker sense although they have been learned from data (Jaeger, Nielsen, and Silander 2006). As a logical representation, they are situated in between BDDs and SDDs:

They provide stronger decompositions than BDDs but still branch over single variables instead of sentences.

Viewing PSDDs as a learning formalism brings up two potential connections to existing work. First, as a formalism that aims at learning *generative* probabilistic models with well defined bases (i.e., logical constraints), the PSDD is somewhat unique as this learning problem has not been posed this explicitly before. The only possible exception is (Chang et al. 2008), which learns a *discriminative* probabilistic model given logical constraints (they propose a generalization of linear models called Constrained Conditional Models).[6] Second, as a formalism that aims at learning *tractable* representations of distributions, the PSDD falls into the recent body of work on *deep learning*. The closest connection here is to the sum-product network (Poon and Domingos 2011), which is a new (but also tractable) class of deep architectures. These networks represent probability distributions as a (deep) hierarchy of mixtures (essentially, an arithmetic circuit with latent variables). However, they do not take logical constraints as an input. Moreover, even though they provide a less constrained representation of distributions, compared to the PSDD, the implication is that learning becomes harder (e.g., there is no closed form for parameter learning under complete data).

Conclusion

We presented the PSDD as a representation of probability distributions that respect a given propositional theory. The PSDD is a complete and canonical representation, with parameters that are interpretable as conditional probabilities. The PSDD encodes context-specific independences, which can be derived from its structure. The PSDD is a tractable representation, allowing one to compute the probability of any term in time linear in its size. The PSDD has unique maximum likelihood parameters under complete data, which can be learned efficiently using a closed form. Preliminary experimental results suggest that the PSDD can be quite effective in learning distributions under domain constraints.

Appendix

Completeness and Canonicity of PSDDs

We will now address two connected questions with regards to the representational power of PSDDs. The first question asks whether every distribution can be represented by a PSDD. The second question asks whether the PSDD representation is canonical (given a vtree). The answers to both questions rely on the notion of *probabilistic* $\mathbf{XY}$*-partitions,* which are based on the $\mathbf{XY}$-partitions underlying SDDs.

We review the latter notion first. Consider a propositional sentence α over disjoint variables $\mathbf{X}$ and $\mathbf{Y}$. One can always express this sentence as

$$\alpha = (p_1 \wedge s_1) \vee \ldots \vee (p_k \wedge s_k) \tag{4}$$

where $p_1, \ldots, p_k$ mention only variables $\mathbf{X}$ and $s_1, \ldots, s_k$ mention only variables $\mathbf{Y}$. One can also always ensure that each p_i is consistent, that $p_i \wedge p_j$ is inconsistent for $i \neq j$, and that $p_1 \vee \ldots \vee p_k$ is valid. Under these conditions, the form in (4) is called an $\mathbf{XY}$-partition of α (Darwiche 2011). One obtains an SDD for some sentence α by recursively decomposing it into $\mathbf{XY}$-partitions (Darwiche 2011). A parallel notion exists for distributions.

Definition 4 *Let* $\mathsf{Pr}(\mathbf{XY})$ *be a distribution with base* α*. A probabilistic* $\mathbf{XY}$*-partition of this distribution has the form*

$$(\mathsf{Pr}_{p_1}(\mathbf{X}), \mathsf{Pr}_{s_1}(\mathbf{Y}), \theta_1), \ldots, (\mathsf{Pr}_{p_k}(\mathbf{X}), \mathsf{Pr}_{s_k}(\mathbf{Y}), \theta_k)$$

such that

- $(p_1 \wedge s_1) \vee \ldots \vee (p_k \wedge s_k)$ *is an* $\mathbf{XY}$*-partition of base* α*.*
- *Each* Pr_{p_i} *is a (prime) distribution with base* p_i*.*
- *Each* Pr_{s_i} *is a (sub) distribution with base* s_i*.*
- $\theta_i \geq 0$*,* $\theta_i = 0$ *iff* $s_i = \bot$*, and* $\theta_1 + \cdots + \theta_k = 1$*.*
- $\mathsf{Pr}(\mathbf{xy}) = \mathsf{Pr}_{p_i}(\mathbf{x}) \cdot \mathsf{Pr}_{s_i}(\mathbf{y}) \cdot \theta_i$ *where* p_i *satisfies* $\mathbf{x} \models p_i$*.*

The above definition shows how one can decompose a distribution $\mathsf{Pr}(\mathbf{XY})$ into a number of smaller distributions $\mathsf{Pr}(\mathbf{X})$ and $\mathsf{Pr}(\mathbf{Y})$. More importantly though, the bases of these smaller distributions correspond to a decomposition of the base for distribution $\mathsf{Pr}(\mathbf{XY})$.

One can always decompose a distribution this way.

Theorem 9 *Let* Pr *be a probability distribution and suppose that its variables are partitioned into* $\mathbf{X}$ *and* $\mathbf{Y}$*. There must exist a probabilistic* $\mathbf{XY}$*-partition of distribution* Pr*.*

Corollary 3 *Every probability distribution can be represented by a PSDD.*

Let v be a vtree over the distribution variables. The root of this vtree partitions the variables into $\mathbf{X}$ (variables in left subtree of v) and $\mathbf{Y}$ (variables in right subtree of v). By Theorem 9, we can construct a probabilistic $\mathbf{XY}$-partition of the distribution, which defines the root PSDD node. By repeating the process recursively, we can construct PSDDs for the prime and sub distributions of each constructed $\mathbf{XY}$-partition, until we reach distributions over single variables.

A distribution may have multiple (or even many) probabilistic $\mathbf{XY}$-partitions for the same sets of variables $\mathbf{X}$ and $\mathbf{Y}$. However, exactly one of these is *compressed.*

Theorem 10 *A probabilistic* $\mathbf{XY}$*-partition is compressed iff its sub distributions are distinct. A distribution has a unique compressed* $\mathbf{XY}$*-partition for each* $\mathbf{X}$ *and* $\mathbf{Y}$*.*[7]

[6] Generative learning is concerned with learning a distribution that is optimized for generating the data, yet is not connected to any particular reasoning task. Discriminative learning is concerned with learning a distribution that is optimized for a classification task (i.e., a probabilistic classifier).

[7] Consider a prime distribution Pr_{p_i} where sub $s_i = \bot$. Since $\theta_i = 0$ in this case, the non-zero probabilities of the prime distribution Pr_{p_i} are irrelevant to the distribution represented by the probabilistic $\mathbf{XY}$-partition. The uniqueness claimed in this theorem is modulo such prime distributions.

A decision PSDD node is compressed iff its subs (not their bases) are distinct. A PSDD is compressed iff all its decision nodes are compressed. We now have our canonicity result.

Corollary 4 *Every distribution is induced by a unique, compressed PSDD (given a vtree).*

We close this section by stressing the following point. The notion of compression in PSDDs generalizes a corresponding notion of compression for SDDs (Darwiche 2011). In particular, an SDD is said to be compressed if every decision node has distinct subs. The main observation here is that the SDD of a compressed PSDD may itself be uncompressed. That is, a compressed PSDD may have two distinct sub distributions with equal bases.[8] In fact, the PSDD representation is complete only if one allows the underlying SDDs to be uncompressed.

Linear Programs for Measuring Inconsistency in Probabilistic Logics

Nico Potyka
Department of Computer Science
FernUniversität in Hagen,
Germany

Abstract

Inconsistency measures help analyzing contradictory knowledge bases and resolving inconsistencies. In recent years several measures with desirable properties have been proposed, but often these measures correspond to combinatorial or non-convex optimization problems that are hard to solve in practice. In this paper, I study a new family of inconsistency measures for probabilistic knowledge bases. All members satisfy many desirable properties and can be computed by means of convex optimization techniques. For two members, I present linear programs whose computation is barely harder than a probabilistic satisfiability test.

1 Introduction

A central problem in the design of expert systems is to assure consistency of the knowledge base. The represented knowledge may originate from several experts or different sources of statistical data, which might be incompatible with each other. Even for a single expert designing a consistent knowledge base can be difficult.

This work focuses on probabilistic knowledge bases. Some heuristic approaches have been developed to resolve inconsistencies by adapting probabilities or deleting parts of the knowledge base (Rödder and Xu 1999; Finthammer, Kern-Isberner, and Ritterskamp 2007), but such methods do not help understanding possible causes for contradictions and lack a well-founded methodology. Inconsistency measures evaluate the degree of inconsistency (Knight 2002; Grant and Hunter 2008; Thimm 2013) and in this way can complement and guide heuristic approaches; however, many existing measures rely on combinatorial or non-convex optimization problems that can be hard to solve in practice.

In this paper, I study a new family of inconsistency measures that correspond to convex optimization problems. As opposed to non-convex problems, they lack (non-global) local minima and therefore are significantly easier to compute. Two members can be computed by particularly efficient linear programming techniques. The measures are based on the fact that a probabilistic knowledge base is satisfiable if and only if a corresponding system of linear equations can be solved. If the equation system is unsolvable, we can search for a vector that violates the system in a minimal way. The overall violation can be measured with respect to some norm like the euclidean norm. If the violation value is zero, the knowledge base is consistent. Otherwise, the value increases continuously with the degree of violation. This is the basic idea of the family of *minimal violation measures*.

Inconsistency Measures for Probabilistic Logics

In recent years various approaches have been developed to measure the degree to which knowledge bases are inconsistent, see, e.g., (Knight 2002; Grant and Hunter 2008; Doder et al. 2010). A short overview of measures for classical logics can be found in (Hunter and Konieczny 2006). Extensions and new measures for probabilistic logics are summarized in (Thimm 2013). I quickly sketch some examples that will be referred to in the following.

The easiest measure one can possibly think of is the *drastic measure* (Hunter and Konieczny 2006; Thimm 2013) that yields 0 if the knowledge base is consistent and 1 otherwise.

A class of measures that is interesting for both classical and probabilistic knowledge bases relies on *minimal inconsistent sets* (Hunter and Konieczny 2008; Thimm 2013). A subset of a knowledge base is called a minimal inconsistent set, if it is inconsistent and removing a single rule renders the set consistent. Hence, the contained rules are in conflict with each other and the conflict can be resolved by removing a single rule. Interesting measures can be defined by counting the minimal inconsistent sets, or by combining the numbers of minimal inconsistent sets that contain certain rules (Hunter and Konieczny 2008; Thimm 2013).

A particularly interesting class of measures derives from the idea of *minimally changing* the knowledge base to a consistent one. In (Thimm 2009), the probabilities of the rules are changed and an inconsistency measure is defined by the minimal sum of all absolute changes. In (Picado-Muiño 2011) the probabilities are relaxed to probability intervals. The corresponding inconsistency measure is defined by arranging the size of these intervals in a vector and measuring the vector's size with respect to a norm. Both measures are particularly interesting because they yield an *optimal repair* for a knowledge base, that is, a consistent knowledge base that is obtained from an inconsistent one by minimal changes.

Computational Aspects: The drastic measure corresponds to a satisfiability test and can be regarded as the measure that is most easily computable, because each reasonable measure should distinguish consistent from inconsistent sets. Deciding whether a probabilistic knowledge base is inconsistent is NP-hard in general (Georgakopoulos, Kavvadias, and Papadimitriou 1988). Still, for knowledge bases containing more than one hundred propositional variables and several hundred rules satisfiability can be tested by linear programming techniques in reasonable time (Jaumard, Hansen, and Poggi 1991; Hansen and Perron 2008).

Measures based on minimal inconsistent sets correspond to combinatorial optimization problems. There has been some progress in implementing such measures efficiently for classical logics (Konieczny and Roussel 2013), but the key idea is that a classical knowledge base can be regarded as a single formula in conjunctive normal form. This, however, does not apply to probabilistic knowledge bases. As the number of subsets of a knowledge base is exponential in the size of the knowledge base, the vital problems are efficiently enumerating candidates for minimal inconsistent sets and testing their satisfiability.

Minimal change measures like in (Thimm 2009) and (Picado-Muiño 2011) correspond to non-convex optimization problems that suffer from (non-global) local optima. Therefore, computing these measures can be hard in practice.

Overview of the Paper

The logical framework and some notations are explained in Section 2. In Section 3, I introduce the family of minimal violation measures and demonstrate in some examples how they differ from other measures and how they can be used to analyze and to resolve inconsistencies. In Section 4, I show that minimal violation measures satisfy several desirable properties that have been considered in the literature (Knight 2003; Hunter and Konieczny 2006; Thimm 2013). Section 5 deals with computational issues. I present linear programs for two minimal violation measures and compare their performance to other measures using prototypical implementations. Subsequently, I summarize some empirical estimates for the performance of typical optimization algorithms (Boyd and Vandenberghe 2004; Matousek and Gärtner 2007) and use them to provide some rough estimates for the performance of different measures when applying general purpose algorithms.

2 Preliminaries

Consider a propositional language $\mathcal{L}_\Sigma$ built up over a finite set of propositional variables Σ using logical connectives like conjunction and disjunction in the usual way. For formulas $\mathcal{F}, \mathcal{G} \in \mathcal{L}_\Sigma$, negation $\neg\mathcal{F}$ is abbreviated by an overbar $\overline{\mathcal{F}}$ and conjunction $\mathcal{F} \wedge \mathcal{G}$ by juxtaposition $\mathcal{F}\mathcal{G}$. A *possible world* is a classical logical interpretation $\omega : \Sigma \to \{0,1\}$ assigning a truth value to each propositional variable. Let Ω denote the set of all possible worlds. An atom $\mathfrak{a}$ is satisfied by ω iff $\omega(\mathfrak{a}) = 1$. The definition is extended to complex formulas in the usual way. The *classical models* $\mathrm{Mod}(\mathcal{G})$ of a formula $\mathcal{G}$ are the possible worlds $\omega \in \Omega$ that satisfy $\mathcal{G}$. $\mathcal{F}, \mathcal{G} \in \mathcal{L}_\Sigma$ are called equivalent, $\mathcal{F} \equiv \mathcal{G}$, iff $\mathrm{Mod}(\mathcal{F}) = \mathrm{Mod}(\mathcal{G})$.

Consider the probabilistic conditional language $(\mathcal{L}_\Sigma|\mathcal{L}_\Sigma) := \{(\mathcal{G}|\mathcal{F})[\rho] \,|\, \mathcal{G}, \mathcal{F} \in \mathcal{L}_\Sigma, \rho \in [0,1]\}$ over Σ (Lukasiewicz 1999). Intuitively, a conditional $(\mathcal{G}|\mathcal{F})[\rho]$ expresses that our belief in $\mathcal{G}$ given that $\mathcal{F}$ holds is ρ. Unconditioned probabilistic formulas are obtained for the special case $(\mathcal{G} \,|\, \top)[\rho]$, where $\top$ denotes a tautological formula. $(\mathcal{G} \,|\, \top)[\rho]$ is abbreviated by $(\mathcal{G})[\rho]$.

Probabilistic interpretations $\mathcal{P} : \Omega \to [0,1]$ are probability functions over possible worlds. For a formula $\mathcal{G} \in \mathcal{L}_\Sigma$ let $\mathcal{P}(\mathcal{G}) = \sum_{\omega \in \mathrm{Mod}(\mathcal{G})} \mathcal{P}(\omega)$. A probabilistic interpretation $\mathcal{P}$ satisfies a conditional $(\mathcal{G}|\mathcal{F})[\rho]$ iff $\mathcal{P}(\mathcal{G}\mathcal{F}) = \rho \cdot \mathcal{P}(\mathcal{F})$. If $\mathcal{P}(\mathcal{F}) > 0$ this definition corresponds to the definition of conditional probability $\mathcal{P}(\mathcal{G} \,|\, \mathcal{F}) = \frac{\mathcal{P}(\mathcal{G}\mathcal{F})}{\mathcal{P}(\mathcal{F})} = \rho$. As often done (Paris and Vencovská 1989; Lukasiewicz 1999; Thimm 2013), I do not demand $\mathcal{P}(\mathcal{F}) > 0$.

A *probabilistic knowledge base* $\mathcal{R} \subset (\mathcal{L}_\Sigma|\mathcal{L}_\Sigma)$ is a finite set of conditionals. A probabilistic interpretation $\mathcal{P}$ satisfies $\mathcal{R}$ iff it satisfies each $c \in \mathcal{R}$. Let $\mathrm{Mod}(\mathcal{R})$ denote the set of probabilistic models of $\mathcal{R}$, i.e., the set of probabilistic interpretations over Ω that satisfy $\mathcal{R}$.

Two conditionals $c_1, c_2 \in (\mathcal{L}_\Sigma|\mathcal{L}_\Sigma)$ are called *equivalent*, $c_1 \equiv c_2$, iff $\mathrm{Mod}(c_1) = \mathrm{Mod}(c_2)$. Following (Thimm 2013), two knowledge bases $\mathcal{R}_1, \mathcal{R}_2$ over $(\mathcal{L}_\Sigma|\mathcal{L}_\Sigma)$ are called *(semi-extensionally) equivalent*, $\mathcal{R}_1 \equiv \mathcal{R}_2$, iff there is a bijection $B : \mathcal{R}_1 \to \mathcal{R}_2$ such that $c_1 \equiv B(c_1)$ for each $c_1 \in \mathcal{R}_1$. That is, both knowledge bases contain the same number of conditionals and these conditionals differ only in their syntactical representation. If both $\mathcal{G}\mathcal{F}$ and $\overline{\mathcal{G}}\mathcal{F}$ are satisfiable, $(\mathcal{G}|\mathcal{F})[\rho]$ is called a *normal conditional*. The following lemma states an intermediate result that was obtained in (Thimm 2013) in the proof of Theorem 2, (4).

Lemma 2.1. *(Thimm 2013) Let $c_1, c_2 \in \mathcal{R}$ be normal, $c_i = (\mathcal{G}_i \,|\, \mathcal{F}_i)[\rho_i]$. If $c_1 \equiv c_2$, then $\mathcal{F}_1 \equiv \mathcal{F}_2$ and either*

- *$\mathcal{G}_1\mathcal{F}_1 \equiv \mathcal{G}_2\mathcal{F}_2$ and $\rho_1 = \rho_2$, or*
- *$\mathcal{G}_1\mathcal{F}_1 \equiv \overline{\mathcal{G}_2}\mathcal{F}_2$ and $\rho_1 = 1 - \rho_2$.*

As done in (Thimm 2013), I will assume that knowledge bases contain only normal conditionals.

If $\mathrm{Mod}(\mathcal{R}) \neq \emptyset$, $\mathcal{R}$ is called consistent. Given a consistent knowledge base, we can draw probabilistic conclusions in different ways. For example, we can consider the whole set $\mathrm{Mod}(\mathcal{R})$ and compute probability intervals for arbitrary formulas, see, e.g., (Nilsson 1986; Jaumard, Hansen, and Poggi 1991). Another possible way is to select a single best model from $\mathrm{Mod}(\mathcal{R})$ with respect to some evaluation function and to use it to compute point probabilities for arbitrary (conditional) formulas, see, e.g., (Paris and Vencovská 1989; Kern-Isberner 2001).

An inconsistency measure assigns a nonnegative inconsistency value to each knowledge base.

Definition 2.2. *An* inconsistency measure Inc *is a function* $\mathrm{Inc} : 2^{(\mathcal{L}_\Sigma|\mathcal{L}_\Sigma)} \to \mathbb{R}_{\geq 0}$ *such that* $\mathrm{Inc}(\mathcal{R}) = 0$ *if and only if* $\mathcal{R}$ *is consistent.*

Several interesting properties have been considered in the literature to motivate and to compare different inconsistency measures, see, e.g., (Knight 2002; Hunter and Konieczny 2006; Picado-Muiño 2011). An overview of inconsistency measures for probabilistic logics and a comparison of some of their properties can be found in (Thimm 2013).

Matrix representation of knowledge bases

Sometimes it is more convenient to represent the conditional satisfaction constraints in matrix notation (Nilsson 1986; Jaumard, Hansen, and Poggi 1991). Suppose that the possible worlds in Ω are ordered in an arbitrary but fixed sequence $\omega_1, \ldots, \omega_n$, $n = |\Omega|$, so that each probabilistic interpretation $\mathcal{P}$ can be identified with a column vector $\vec{\pi} = (\mathcal{P}(\omega_1) \ldots \mathcal{P}(\omega_n))^\mathsf{T}$, where the symbol $^\mathsf{T}$ denotes transposition of vectors. The set of all probabilistic interpretations of $(\mathcal{L}_\Sigma|\mathcal{L}_\Sigma)$ corresponds to the set $\Pi_n = \{\vec{\pi} \in \mathbb{R}^n \mid \vec{\pi} \geq \vec{0} \text{ and } \sum_{i=1}^n \vec{\pi}_i = 1\}$, where $\geq$ denotes componentwise inequality.

To compare vectors, we can consider different norms on $\mathbb{R}^n$. A p-norm is a function $\|.\|_p : \mathbb{R}^n \to \mathbb{R}$, which is defined by $\|\vec{\pi}\|_p = \sqrt[p]{\sum_{i=1}^n |\vec{\pi}_i|^p}$. The best known special cases are the 1-*norm* $\|\vec{\pi}\|_1 = \sum_{i=1}^n |\vec{\pi}_i|$, the *euclidean norm* $\|\vec{\pi}\|_2 = \sqrt[2]{\sum_{i=1}^n \vec{\pi}_i^2}$ and the limit for $p \to \infty$, the *maximum norm* $\|\vec{\pi}\|_\infty = \max\{|\vec{\pi}_i| \mid 1 \leq i \leq n\}$.

Recall that a probabilistic model of c satisfies the equation $\mathcal{P}(\mathcal{GF}) = \rho \cdot \mathcal{P}(\mathcal{F})$. Subtracting $\rho \cdot \mathcal{P}(\mathcal{F})$ yields

$$\begin{aligned}
0 &= \mathcal{P}(\mathcal{GF}) - \rho \cdot \mathcal{P}(\mathcal{F}) \\
&= \mathcal{P}(\mathcal{GF}) - \rho \cdot (\mathcal{P}(\mathcal{GF}) + \mathcal{P}(\overline{\mathcal{G}}\mathcal{F})) \\
&= (1-\rho) \cdot \mathcal{P}(\mathcal{GF}) - \rho \cdot \mathcal{P}(\overline{\mathcal{G}}\mathcal{F}) \\
&= \sum_{\omega \in \mathrm{Mod}(\mathcal{GF})} \mathcal{P}(\omega) \cdot (1-\rho) - \sum_{\omega \in \mathrm{Mod}(\overline{\mathcal{G}}\mathcal{F})} \mathcal{P}(\omega) \cdot \rho \\
&= \sum_{\omega \in \Omega} \mathcal{P}(\omega) \cdot (1_{\{\mathcal{GF}\}}(\omega) \cdot (1-\rho) - 1_{\{\overline{\mathcal{G}}\mathcal{F}\}}(\omega) \cdot \rho),
\end{aligned}$$

where for a formula F the indicator function $1_{\{F\}}(\omega)$ maps to 1 iff $\omega \models_{\mathcal{L}_\Sigma} F$ and to 0 otherwise. In vector notation this equation becomes

$$\vec{a}_c^\mathsf{T} \vec{\pi} = 0,$$

where $\vec{a}_c^\mathsf{T}$ is the transpose of the vector

$$(1_{\{\mathcal{GF}\}}(\omega_j) \cdot (1-\rho) - 1_{\{\overline{\mathcal{G}}\mathcal{F}\}}(\omega_j) \cdot \rho)_{1 \leq j \leq n}.$$

That is, the j-th component of $\vec{a}^\mathsf{T}$ is either $1-\rho$, $-\rho$ or 0 dependent on whether the conditional is verified ($1_{\{\mathcal{GF}\}}(\omega_j) = 1$), falsified ($1_{\{\overline{\mathcal{G}}\mathcal{F}\}}(\omega_j) = 1$) or not applicable ($\omega_j \models_{\mathcal{L}_\Sigma} \overline{\mathcal{F}}$) in the j-th world.

Given a knowledge base $\mathcal{R}$, suppose that the conditionals in $\mathcal{R}$ are ordered in an arbitrary but fixed sequence $c_1, \ldots, c_m$, $m = |\mathcal{R}|$, so that we can identify the i-th conditional with a row vector $\vec{a}_i^\mathsf{T}$. Then we can associate $\mathcal{R}$ with the $(m \times n)$-matrix

$$A_\mathcal{R} = \begin{pmatrix} \vec{a}_1^\mathsf{T} \\ \ldots \\ \vec{a}_m^\mathsf{T} \end{pmatrix}.$$

Using the introduced notations, the question whether $\mathcal{R}$ is consistent becomes the question whether the linear equation system $A_\mathcal{R} x = 0$ can be solved by a probability vector $\vec{\pi} \in \Pi_n$ (Nilsson 1986; Jaumard, Hansen, and Poggi 1991).

3 Minimal Violation Measures

Given a knowledge base $\mathcal{R}$ over $(\mathcal{L}_\Sigma|\mathcal{L}_\Sigma)$, the corresponding matrix $A_\mathcal{R}$ and some p-norm $\|.\|_p$ as explained in Section 2, we consider the following optimization problem:

$$\begin{aligned}
\min_{\vec{\pi} \in \mathbb{R}^n} \quad & \|A_\mathcal{R} \vec{\pi}\|_p \qquad (1) \\
\textit{subject to} \quad & \sum_{i=1}^n \vec{\pi}_i = 1 \\
& \vec{\pi} \geq 0.
\end{aligned}$$

The constraints just guarantee that the solution is a probabilistic interpretation in Π_n. The objective $\|A_\mathcal{R} \vec{\pi}\|_p$ measures to which degree $\vec{\pi}$ violates $\mathcal{R}$ with respect to the p-norm. The choice of p depends on the application. For $p = 1$ a lower total violation might be obtained but the violation can be rather extreme. As p grows, higher violations are penalized more heavily. The following example illustrates this behavior for the extreme cases $p = 1$ and $p = \infty$.

Example 3.1. *Consider the vectors $v_1 = (\frac{1}{4}\ \frac{1}{4}\ \frac{1}{4}\ \frac{1}{4})^\mathsf{T}$, $v_2 = (0\ 0\ 0\ \frac{1}{2})^\mathsf{T}$ in $\mathbb{R}^4$. v_1 corresponds to a violation of $\frac{1}{4}$ for four conditionals. In v_2 no conditional but the last one is violated. We have $\|v_1\|_1 = 1$, $\|v_2\|_1 = \frac{1}{2}$. Hence v_2 is preferable to v_1 with respect to $\|.\|_1$, because the overall error is lower. In contrast, $\|v_1\|_\infty = \frac{1}{4}$, $\|v_2\|_\infty = \frac{1}{2}$. Hence v_1 is preferable to v_2 with respect to $\|.\|_\infty$, because the highest error is lower. Which behavior is more desirable, depends on the specific application.*

The *minimal violation inconsistency measures* are defined by means of optimization problem (1). A vector $\vec{\pi} \in \Pi_n$ minimizing optimization problem (1) will be called *minimal violating* in the following. If $\mathcal{R}$ is consistent, the minimal violating $\vec{\pi}$ are the models of $\mathcal{R}$. For inconsistent $\mathcal{R}$, they can be regarded to be as close to a model as possible.

Definition 3.2. *For $p \in \mathbb{N} \cup \{\infty\}$ the* minimal violation p-inconsistency measure $\mathrm{Inc}_\Pi^p : 2^{(\mathcal{L}_\Sigma|\mathcal{L}_\Sigma)} \to \mathbb{R}$ *is defined by $\mathrm{Inc}_\Pi^p(\mathcal{R}) = \epsilon$, where ϵ is the solution of optimization problem* (1)*.*

Proposition 3.3. Inc_Π^p *is an inconsistency measure.*

Proof. To begin with, we convince ourselves that Inc_Π^p is well-defined. That is, there always exists a unique minimum for optimization problem (1). The objective is the composition of a p-norm and the linear function induced by the constraint matrix $A_\mathcal{R}$ and therefore continuous and convex. The feasible region of optimization problem (1) is the convex and compact probability simplex. As each continuous function on a compact set takes on its minimum, the minimum exists. It is also unique, because the minimum for each convex function on a convex set is unique.

It remains to show that Inc_Π^p is an inconsistency measure as defined in Definition 2.2. By definition of optimization

problem (1), it holds $\mathrm{Inc}^p_\Pi(\mathcal{R}) \geq 0$. $\mathcal{R}$ is consistent if and only if there is a $\vec{\pi} \in \Pi_n$ such that $A_\mathcal{R}\vec{\pi} = 0$. Hence, by definiteness of norms, it follows $\mathrm{Inc}^p_\Pi(\mathcal{R}) = 0$ if and only if $\mathcal{R}$ is consistent. □

Before investigating general properties of Inc^p_Π, we consider some simple examples and explore differences between Inc^p_Π and the drastic measure (Hunter and Konieczny 2006; Thimm 2013), measures based on minimal inconsistent sets (Hunter and Konieczny 2008; Thimm 2013) as well as minimal change measures (Thimm 2009; Picado-Muiño 2011) that have been explained in Section 1.

Example 3.4. *Consider $\Sigma = \{A\}$ and the knowledge base $\mathcal{R}_\rho = \{(A)[\rho], (A)[1-\rho]\}$ over Σ for $0 \leq \rho \leq 0.5$. For instance, $\mathcal{R}_{0.5} = \{(A)[0.5], (A)[0.5]\} = \{(A)[0.5]\}$ is consistent and $\mathcal{R}_0 = \{(A)[0], (A)[1]\}$ is inconsistent. Intuitively, the degree of inconsistency of $\mathcal{R}_\rho$ should increase as ρ decreases from 0.5 to 0. The following table shows some inconsistency values of $\mathcal{R}_\rho$ with respect to Inc^p_Π.*

	$\mathcal{R}_{0.5}$	$\mathcal{R}_{0.49}$	$\mathcal{R}_{0.4}$	$\mathcal{R}_{0.2}$	$\mathcal{R}_0$
Inc^1_Π	0	0.02	0.2	0.6	1
Inc^∞_Π	0	0.01	0.1	0.3	0.5

Minimal change measures also capture this intuitive increase of inconsistency. In contrast, the drastic measure and inconsistency measures based on minimal inconsistent sets cannot distinguish the knowledge bases $\mathcal{R}_\rho$ for $0 \leq \rho < 0.5$, because all these $\mathcal{R}_\rho$ are inconsistent and in each case the only minimal inconsistent set is $\mathcal{R}_\rho$ itself.

Example 3.5. *Consider $\Sigma = \{A, B\}$ and the knowledge base $\mathcal{R} = \{(A)[0.8], (B)[0.6], (B \mid A)[0.9]\}$. We find*

$$\mathrm{Inc}^1_\Pi(\mathcal{R}) \approx 0.120 \text{ and } \mathrm{Inc}^\infty_\Pi(\mathcal{R}) \approx 0.041.$$

Intuitively, we can conjecture that decreasing the probability of A, increasing the probability of B or decreasing the probability of B given A might resolve the contradiction. We start by decreasing the probability of A and obtain for $\mathcal{R}_1 = \{(A)[0.75], (B)[0.6], (B \mid A)[0.9]\}$

$$\mathrm{Inc}^1_\Pi(\mathcal{R}_1) \approx 0.075 \text{ and } \mathrm{Inc}^\infty_\Pi(\mathcal{R}_1) \approx 0.025.$$

As suspected, the degree of inconsistency decreased. Next, we increase the probability of B and obtain for $\mathcal{R}_2 = \{(A)[0.75], (B)[0.65], (B \mid A)[0.9]\}$

$$\mathrm{Inc}^1_\Pi(\mathcal{R}_2) \approx 0.024 \text{ and } \mathrm{Inc}^\infty_\Pi(\mathcal{R}_2) \approx 0.008.$$

Again, the degree of inconsistency decreased significantly. Now we decrease the probability of B given A and obtain for $\mathcal{R}_3 = \{(A)[0.75], (B)[0.65], (B \mid A)[0.85]\}$

$$\mathrm{Inc}^1_\Pi(\mathcal{R}_3) = 0 \text{ and } \mathrm{Inc}^\infty_\Pi(\mathcal{R}_3) = 0.$$

Hence $\mathcal{R}_3$ yields a repair for $\mathcal{R}$.

If we had no idea, which conditionals might have caused the inconsistencies and in which way, we could try to adjust probabilities arbitrarily. For example, if we increased the probability of A in the first step instead of decreasing it, we would obtain with $\mathcal{R}_0 = \{(A)[0.85], (B)[0.6], (B \mid A)[0.9]\}$

$$\mathrm{Inc}^1_\Pi(\mathcal{R}_0) \approx 0.165 \text{ and } \mathrm{Inc}^\infty_\Pi(\mathcal{R}_0) \approx 0.057.$$

So the inconsistency values increased compared to our initial knowledge base $\mathcal{R}$ and we can see that this is not a reasonable adjustment. In the same way, we can learn that decreasing the probability of B or increasing the probability of B given A aggravates the conflict.

In contrast, the drastic measure provides no interesting information to resolve such inconsistencies. Measures based on minimal inconsistent sets are more helpful. $\mathcal{R}$ is the only minimal inconsistent set, so we could repair $\mathcal{R}$ by deleting a single conditional. Furthermore, we learn that all conditionals are in conflict with each other, so each adjustment might be reasonable. However, $\mathcal{R}$, $\mathcal{R}_0$ and $\mathcal{R}_1$ cannot be distinguished by measures based on minimal inconsistent sets, because in each case the knowledge base itself is the only minimal inconsistent subset. Therefore, they cannot provide information about reasonable adjustments, unless a conflict has been resolved by the adjustment coincidentally.

The best choice in this scenario is admittedly a minimal change measure, because it yields a best repair without further ado. A best repair (there can be several) computed by the measure from (Thimm 2009) is $\mathcal{R}_{opt} = \{(A)[0.752], (B)[0.648], (B \mid A)[0.86]\}$. As we will see later on, minimal violation measures become superior to minimal change measures for larger knowledge bases because of computational advantages.

4 Properties of Minimal Violation Measures

We now turn to some properties that have been considered interesting for inconsistency measures in the literature (Knight 2003; Hunter and Konieczny 2006; Thimm 2013).

To give an intuitive overview, Inc^p_Π is *language* and *representation invariant*. That is, the degree of inconsistency of a knowledge base determined by Inc^p_Π is independent of the number of propositional variables in the underlying language and the syntactical representation of the conditionals. Inc^p_Π is *monotone* and for $p = 1$ *super-additive*. The former means that adding new conditionals can only increase the degree of inconsistency. The latter means that if we combine two knowledge bases, the inconsistency value of the combined knowledge base is at least as large as the sum of both single inconsistency values. Furthermore, Inc^p_Π is *weakly independent*. That is, if we add consistent knowledge about propositional variables that are not contained in our current knowledge base, the inconsistency value does not increase. The term *weak* stems from the fact that stronger independence properties for inconsistent sets have been considered in the literature (Hunter and Konieczny 2006; Thimm 2013). Finally, Inc^p_Π is *continuous*. That is, small adjustments in the probabilities of the knowledge base change the corresponding inconsistency value only slightly. Some other properties have been considered in (Knight 2003; Hunter and Konieczny 2006; Thimm 2013), but in my opinion the stated ones are among the most intuitive for probabilistic knowledge bases and I leave it for future work to

answer whether minimal violation measures satisfy or violate further properties.

We need some additional notation in this section. For a conditional $c \in (\mathcal{L}_\Sigma|\mathcal{L}_\Sigma)$ let $\mathrm{At}(c)$ denote the atoms from Σ that appear in c and for a knowledge base $\mathcal{R}$ let $\mathrm{At}(\mathcal{R})$ denote the atoms appearing in $\mathcal{R}$. Note that we can consider the same knowledge base $\mathcal{R}$ with respect to different languages $(\Sigma' \mid \Sigma')$ as long as $\mathrm{At}(\mathcal{R}) \subseteq \Sigma'$. We will see that the size of Σ' does not influence the inconsistency value with respect to Inc^p_Π, but to prove this fact, we have to make a distinction between the same knowledge base in different languages. For a knowledge base $\mathcal{R}$ that is defined with respect to a language $(\mathcal{L}_\Sigma|\mathcal{L}_\Sigma)$, I call $\mathcal{R}$ *restricted to* $(\Sigma' \mid \Sigma')$ if $\Sigma' \subseteq \Sigma$ and I call $\mathcal{R}$ *lifted to* $(\Sigma' \mid \Sigma')$ if $\Sigma \subseteq \Sigma'$.

We first consider language invariance, which means that changing our language does not change the inconsistency value of a knowledge base (Knight 2003).

Lemma 4.1. *Let V be a new propositional variable not contained in Σ and let $\Sigma' = \Sigma \cup \{V\}$. Let $\mathcal{R}$ be a knowledge base over $(\mathcal{L}_\Sigma|\mathcal{L}_\Sigma)$ and let $\mathcal{R}'$ denote $\mathcal{R}$ lifted to $(\Sigma' \mid \Sigma')$. Then $\mathrm{Inc}^p_\Pi(\mathcal{R}) = \mathrm{Inc}^p_\Pi(\mathcal{R}')$.*

Proof. Let $\omega_1, \ldots, \omega_n$ be the ordered possible worlds over Σ. Let $\omega'_1, \ldots, \omega'_n, \omega'_{n+1}, \ldots, \omega'_{2n}$ denote the possible worlds over Σ', such that ω'_i, ω'_{i+n} correspond to ω_i for the variables in Σ, $\omega'_1, \ldots, \omega'_n$ falsify V, and $\omega'_{n+1}, \ldots, \omega'_{2n}$ satisfy V. Note that $A_{\mathcal{R}'} = (A_\mathcal{R}\ A_\mathcal{R})$ by construction, because $\mathcal{R}'$ corresponds to $\mathcal{R}$ and does not contain V .

Let $\mathrm{Inc}^p_\Pi(\mathcal{R}) = \delta$ and let $\vec{\pi}^*$ be minimal violating, i.e., $\|A_\mathcal{R}\vec{\pi}^*\|_p = \delta$. Then $\begin{pmatrix}\vec{\pi}^* \\ \vec{0}\end{pmatrix} \in \mathbb{R}^{2n}$ corresponds to a probability function over the interpretations of Σ' and

$$\begin{aligned}\mathrm{Inc}^p_\Pi(\mathcal{R}') &\leq \| \begin{pmatrix} A_\mathcal{R}\ A_\mathcal{R}\end{pmatrix} \begin{pmatrix}\vec{\pi}^* \\ \vec{0}\end{pmatrix} \|_p = \|A_\mathcal{R}\vec{\pi}^*\|_p \\ &= \mathrm{Inc}^p_\Pi(\mathcal{R}).\end{aligned}$$

Conversely, if $\mathrm{Inc}^p_\Pi(\mathcal{R}') = \delta'$ and $\begin{pmatrix}\vec{\pi}^*_1 \\ \vec{\pi}^*_2\end{pmatrix} \in \mathbb{R}^{2n}$ is minimal violating, then $(\vec{\pi}^*_1 + \vec{\pi}^*_2) \in \mathbb{R}^n$ corresponds to a probability function over the interpretations of Σ and

$$\begin{aligned}\mathrm{Inc}^p_\Pi(\mathcal{R}) &\leq \|A_\mathcal{R}(\vec{\pi}^*_1 + \vec{\pi}^*_2)\|_p = \|A_\mathcal{R}\vec{\pi}^*_1 + A_\mathcal{R}\vec{\pi}^*_2\|_p \\ &= \| \begin{pmatrix} A_\mathcal{R}\ A_\mathcal{R}\end{pmatrix} \begin{pmatrix}\vec{\pi}^*_1 \\ \vec{\pi}^*_2\end{pmatrix} \|_p = \mathrm{Inc}^p_\Pi(\mathcal{R}').\end{aligned}$$

Hence, $\mathrm{Inc}^p_\Pi(\mathcal{R}') \leq \mathrm{Inc}^p_\Pi(\mathcal{R}) \leq \mathrm{Inc}^p_\Pi(\mathcal{R}')$, that is, both inconsistency values have to be equal. □

Proposition 4.2 (Language invariance). *Let $\mathcal{R}$ be a knowledge base over $(\mathcal{L}_\Sigma|\mathcal{L}_\Sigma)$ and let $\mathrm{At}(\mathcal{R}) \subseteq \Sigma'$. Let $\mathcal{R}'$ denote $\mathcal{R}$ over $(\Sigma' \mid \Sigma')$. Then $\mathrm{Inc}^p_\Pi(\mathcal{R}) = \mathrm{Inc}^p_\Pi(\mathcal{R}')$.*

Proof. For $\Sigma \subseteq \Sigma'$, the claim follows from Lemma 4.1 by induction over the variables in $\Sigma' \setminus \Sigma$.

For the general case, consider $\Sigma'' = \Sigma \cap \Sigma'$ and let $\mathcal{R}'' \subset (\Sigma'' \mid \Sigma'')$ denote $\mathcal{R}$ restricted to $(\Sigma'' \mid \Sigma'')$. Then $\Sigma'' \subseteq \Sigma$ and $\Sigma'' \subseteq \Sigma'$ and therefore $\mathrm{Inc}^p_\Pi(\mathcal{R}'') = \mathrm{Inc}^p_\Pi(\mathcal{R}) = \mathrm{Inc}^p_\Pi(\mathcal{R}')$. □

A measure should also be invariant with respect to syntactical changes of the conditionals (Knight 2003). This property has also been called *irrelevance of syntax* (Thimm 2013).

Proposition 4.3 (Representation invariance). *Let $\mathcal{R}_1, \mathcal{R}_2$ be knowledge bases over $(\mathcal{L}_\Sigma|\mathcal{L}_\Sigma)$. If $\mathcal{R}_1 \equiv \mathcal{R}_2$, then $\mathrm{Inc}^p_\Pi(\mathcal{R}_1) = \mathrm{Inc}^p_\Pi(\mathcal{R}_2)$.*

Proof. As $\mathcal{R}_1 \equiv \mathcal{R}_2$, there is a bijection $B : \mathcal{R}_1 \to \mathcal{R}_2$ such that $c \equiv B(c)$ for each $c \in \mathcal{R}_1$. Consider an arbitrary conditional $c_1 \in \mathcal{R}_1$ such that $B(c_1) = c_2$. For $i = 1, 2$ let $c_i = (\mathcal{G}_i \mid \mathcal{F}_i)[\rho_i]$ and let $\vec{a}^\mathsf{T}_i$ denote the corresponding constraint vectors. By Lemma 2.1, there are two possible cases. If $\mathcal{G}_1\mathcal{F}_1 \equiv \mathcal{G}_2\mathcal{F}_2$ and $\rho_1 = \rho_2$, then $\vec{a}^\mathsf{T}_1 = \vec{a}^\mathsf{T}_2$. Otherwise, if $\mathcal{G}_1\mathcal{F}_1 \equiv \overline{\mathcal{G}_2}\mathcal{F}_2$ and $\rho_1 = 1 - \rho_2$, then also $\mathcal{G}_2\mathcal{F}_2 \equiv \overline{\mathcal{G}_1}\mathcal{F}_1$ because $\equiv$ is symmetric. Therefore, for the j-th component of the constraint vectors it holds

$$\begin{aligned}(\vec{a}^\mathsf{T}_1)_j &= 1_{\{\mathcal{G}_1\mathcal{F}_1\}}(\omega_j) \cdot (1 - \rho_1) - 1_{\{\overline{\mathcal{G}_1}\mathcal{F}_1\}}(\omega_j) \cdot \rho_1 \\ &= 1_{\{\overline{\mathcal{G}_2}\mathcal{F}_2\}}(\omega_j) \cdot \rho_2 - 1_{\{\mathcal{G}_2\mathcal{F}_2\}}(\omega_j) \cdot (1 - \rho_2) \\ &= -(1_{\{\mathcal{G}_2\mathcal{F}_2\}}(\omega_j) \cdot (1 - \rho_2) - 1_{\{\overline{\mathcal{G}_2}\mathcal{F}_2\}}(\omega_j) \cdot \rho_2) \\ &= -(\vec{a}^\mathsf{T}_2)_j.\end{aligned}$$

Hence $\vec{a}^\mathsf{T}_1 = -\vec{a}^\mathsf{T}_2$ and $|\vec{a}^\mathsf{T}_1\vec{\pi}| = |-\vec{a}^\mathsf{T}_2\vec{\pi}| = |\vec{a}^\mathsf{T}_2\vec{\pi}|$ for all $\vec{\pi} \in \mathbb{R}^n$. As $c_1 \in \mathcal{R}_1$ was arbitrary, it follows $\mathrm{Inc}^p_\Pi(\mathcal{R}_1) = \mathrm{Inc}^p_\Pi(\mathcal{R}_2)$. □

Monotonicity states that if we add additional conditionals to a knowledge base, the degree of inconsistency cannot decrease (Hunter and Konieczny 2006; Thimm 2013).

Proposition 4.4 (Monotonicity). *Let $\mathcal{R}, \mathcal{R}'$ be knowledge bases over $(\mathcal{L}_\Sigma|\mathcal{L}_\Sigma)$. If $\mathcal{R}' \subseteq \mathcal{R}$, then $\mathrm{Inc}^p_\Pi(\mathcal{R}') \leq \mathrm{Inc}^p_\Pi(\mathcal{R})$.*

Proof. Let $\{1, \ldots, m\}$ denote the indices of the conditionals in $\mathcal{R}'$ and let $\{m+1, \ldots, m+k\}$ denote the indices of the additional conditionals in $\mathcal{R} \setminus \mathcal{R}'$. Let $\vec{a}^\mathsf{T}_i$ denote the corresponding row vectors and let $\vec{\pi}$ be minimal violating for $\mathcal{R}$. Then

$$\begin{aligned}\mathrm{Inc}^p_\Pi(\mathcal{R}') &\leq \sqrt[p]{\sum_{i=1}^{m} |\vec{a}^\mathsf{T}_i\vec{\pi}|^p} \leq \sqrt[p]{\sum_{i=1}^{m+k} |\vec{a}^\mathsf{T}_i\vec{\pi}|^p} \\ &= \mathrm{Inc}^p_\Pi(\mathcal{R}).\end{aligned}$$

□

For $p = 1$, Inc^p_Π also satisfies a stronger property that has been called *super-additivity* in (Thimm 2013).

Proposition 4.5 (Super-Additivity). *Let $\mathcal{R}_1, \mathcal{R}_2$ be knowledge bases over $(\mathcal{L}_\Sigma|\mathcal{L}_\Sigma)$. If $\mathcal{R}_1 \cap \mathcal{R}_2 = \emptyset$, then $\mathrm{Inc}^1_\Pi(\mathcal{R}_1 \cup \mathcal{R}_2) \geq \mathrm{Inc}^1_\Pi(\mathcal{R}_1) + \mathrm{Inc}^1_\Pi(\mathcal{R}_2)$.*

Proof. Let $\{1, \ldots, m_1\}$ denote the indices of the conditionals in $\mathcal{R}_1$, and let $\{m_1+1, \ldots, m_1+m_2\}$ denote the indices

of the conditionals in $\mathcal{R}_2$. Let $\vec{a}_i^\mathsf{T}$ denote the corresponding row vectors. Then

$$\begin{aligned}\mathrm{Inc}^1_\Pi(\mathcal{R}_1 \cup \mathcal{R}_2) &= \min_{\vec{\pi}\in\mathbb{R}^n}\Big(\sum_{i=1}^{m_1} |\vec{a}_i^\mathsf{T}\vec{\pi}| + \sum_{i=m_1+1}^{m_1+m_2} |\vec{a}_i^\mathsf{T}\vec{\pi}|\Big)\\ &\geq \Big(\min_{\vec{\pi}\in\mathbb{R}^n}\sum_{i=1}^{m_1} |\vec{a}_i^\mathsf{T}\vec{\pi}|\Big) + \Big(\min_{\vec{\pi}\in\mathbb{R}^n}\sum_{i=m_1+1}^{m_1+m_2} |\vec{a}_i^\mathsf{T}\vec{\pi}|\Big)\\ &= \mathrm{Inc}^1_\Pi(\mathcal{R}_1) + \mathrm{Inc}^1_\Pi(\mathcal{R}_2).\end{aligned}$$

□

Remark 4.6. *For $p > 1$ super-additivity can be violated.*

If we add consistent knowledge about propositional variables that were not contained in our knowledge base before, we should expect that the knowledge base does not become more inconsistent. This intuition is captured by *weak independence* (Thimm 2013).

Proposition 4.7 (Weak Independence). *Let $\mathcal{R}_1, \mathcal{R}_2$ be knowledge bases over $(\mathcal{L}_\Sigma|\mathcal{L}_\Sigma)$. If $\mathcal{R}_2$ is consistent and $\mathrm{At}(\mathcal{R}_1) \cap \mathrm{At}(\mathcal{R}_2) = \emptyset$, then $\mathrm{Inc}^p_\Pi(\mathcal{R}_1) = \mathrm{Inc}^p_\Pi(\mathcal{R}_1 \cup \mathcal{R}_2)$.*

Proof. Let $\mathcal{P}_1$ be minimal violating for $\mathcal{R}_1$ and let $\mathcal{P}_2$ be a model of $\mathcal{R}_2$. Let $\Sigma_1 = \mathrm{At}(\mathcal{R}_1)$ and $\Sigma_2 = \Sigma \setminus \Sigma_1$. For $i = 1, 2$, let $C_i = \{c \in \mathcal{L}_\Sigma \mid c = \bigwedge_{\alpha\in\Sigma_i} \alpha^{b_\alpha}, b_\alpha \in \{0, 1\}\}$ denote the set of complete conjunctions over Σ_i, where $\alpha^0 = \overline{\alpha}$ and $\alpha^1 = \alpha$ for each atom $\alpha \in \Sigma$. Note that $\Sigma = \Sigma_1 \uplus \Sigma_2$, hence we can identify each interpretation $\omega \in \Omega$ with the (unique) complete conjunction c_1c_2 that is satisfied by ω, where $c_1 \in \Sigma_1, c_2 \in \Sigma_2$.

Now consider the function $\mathcal{P} : \Omega \to \mathbb{R}$ defined by $\mathcal{P}(c_1c_2) = (\sum_{\overline{c_2}\in\Sigma_2} \mathcal{P}_1(c_1\overline{c_2}))(\sum_{\overline{c_1}\in\Sigma_1} \mathcal{P}_2(\overline{c_1}c_2))$. As $\mathcal{P}_1$ and $\mathcal{P}_2$ are nonnegative, so is $\mathcal{P}$. Also, $\mathcal{P}(c_1c_2) \leq 1$ by normalization of $\mathcal{P}_1$ and $\mathcal{P}_2$. Furthermore,

$$\begin{aligned}\mathcal{P}(\Omega) &= \sum_{c_1\in\Sigma_1}\sum_{c_2\in\Sigma_2} \mathcal{P}(c_1c_2)\\ &= \underbrace{\sum_{c_1\in\Sigma_1}\Big(\sum_{\overline{c_2}\in\Sigma_2} \mathcal{P}_1(c_1\overline{c_2})\Big)}_{=1}\underbrace{\sum_{c_2\in\Sigma_2}\Big(\sum_{\overline{c_1}\in\Sigma_1} \mathcal{P}_2(\overline{c_1}c_2)\Big)}_{=1}\\ &= 1,\end{aligned}$$

hence $\mathcal{P} : \Omega \to [0, 1]$ is normalized and therefore a probabilistic interpretation of $(\mathcal{L}_\Sigma|\mathcal{L}_\Sigma)$.

A formula F over Σ_1 is satisfied by c_1c_2 if and only if F is satisfied by c_1. Therefore,

$$\begin{aligned}\mathcal{P}(F) &= \sum_{c_1\in\Sigma_1}\sum_{c_2\in\Sigma_2} \mathcal{P}(c_1c_2)\, 1_{\{F\}}(c_1)\\ &= \underbrace{\sum_{c_2\in\Sigma_2}\Big(\sum_{\overline{c_1}\in\Sigma_1} \mathcal{P}_2(\overline{c_1}c_2)\Big)}_{=1}\underbrace{\sum_{c_1\in\Sigma_1}\Big(\sum_{\overline{c_2}\in\Sigma_2} \mathcal{P}_1(c_1\overline{c_2})\, 1_{\{F\}}(c_1)\Big)}_{=\mathcal{P}_1(F)}\\ &= \mathcal{P}_1(F).\end{aligned}$$

Hence, $\mathcal{P}$ coincides with $\mathcal{P}_1$ for formulas over Σ_1 and analogously it follows that $\mathcal{P}$ coincides with $\mathcal{P}_2$ for formulas over Σ_2. Therefore, if we denote by $\vec{\pi}, \vec{\pi}_1, \vec{\pi}_2$ the probability vectors corresponding to $\mathcal{P}, \mathcal{P}_1, \mathcal{P}_2$, it holds $\vec{a}_c^\mathsf{T}\,\vec{\pi} = \vec{a}_c^\mathsf{T}\,\vec{\pi}_1$ for all $c \in \mathcal{R}_1$ and $\vec{a}_c^\mathsf{T}\,\vec{\pi} = \vec{a}_c^\mathsf{T}\,\vec{\pi}_2 = 0$ for all $c \in \mathcal{R}_2$. Hence, if we number the conditionals in $\mathcal{R}_1$ by $1, \ldots, m$ and the conditionals in $\mathcal{R}_2$ by $m + 1, \ldots, m + k$, we find

$$\begin{aligned}\min_{\vec{\pi}\in\mathbb{R}^n} \|A_{\mathcal{R}_1\cup\mathcal{R}_2}\vec{\pi}\|_p &\leq \sqrt[p]{\sum_{i=1}^{m+k} |\vec{a}_i^\mathsf{T}\vec{\pi}|^p}\\ &= \sqrt[p]{\sum_{i=1}^{m} |\vec{a}_i^\mathsf{T}\vec{\pi}_1|^p + 0} = \mathrm{Inc}^p_\Pi(\mathcal{R}).\end{aligned}$$

Hence, $\mathrm{Inc}^p_\Pi(\mathcal{R}_1 \cup \mathcal{R}_2) \leq \mathrm{Inc}^p_\Pi(\mathcal{R}_1)$. By monotonicity (Proposition 4.4), it also holds $\mathrm{Inc}^p_\Pi(\mathcal{R}_1) \leq \mathrm{Inc}^p_\Pi(\mathcal{R}_1 \cup \mathcal{R}_2)$ and therefore $\mathrm{Inc}^p_\Pi(\mathcal{R}_1) = \mathrm{Inc}^p_\Pi(\mathcal{R}_1 \cup \mathcal{R}_2)$. □

As a desirable property of inconsistency measures for probabilistic knowledge bases, Thimm (2009) considered *continuity*. The intuitive idea is that if we change the probabilities in a knowledge base slightly, the corresponding inconsistency value should change only slightly, too. Let $\mathcal{R}[\vec{\rho}] = \langle(\mathcal{G}_1 \,|\, \mathcal{F}_1)[\vec{\rho}_1], \ldots, (\mathcal{G}_m \,|\, \mathcal{F}_m)[\vec{\rho}_m]\rangle$ denote an ordered knowledge base with conditional probabilities $\vec{\rho} \in \mathbb{R}^m$.

Proposition 4.8 (Continuity). *If $\lim_{k\to\infty} \vec{\rho}_k = \vec{\rho}$, then $\lim_{k\to\infty} \mathrm{Inc}^p_\Pi(\mathcal{R}[\vec{\rho}_k]) = \mathrm{Inc}^p_\Pi(\mathcal{R}[\vec{\rho}])$.*

Proof. Let $\mathcal{R} = \mathcal{R}[\vec{\rho}]$ be a knowledge base and let $(\vec{\rho}_k)$ be a sequence in $\mathbb{R}^m$ such that $\lim_{k\to\infty} \vec{\rho}_k = \vec{\rho}$. Let $A_\mathcal{R}$ be the matrix with row vectors $\vec{a}_i^\mathsf{T}$ corresponding to $\mathcal{R}$. Let A_k denote the matrix with row vectors $\vec{a_{ki}}^\mathsf{T} = (1_{\{\mathcal{G}\mathcal{F}\}}(\omega_j) \cdot (1 - \vec{\rho}_{ki}) - 1_{\{\overline{\mathcal{G}}\mathcal{F}\}}(\omega_j) \cdot \vec{\rho}_{ki})_{1\leq j\leq n}$ corresponding to $\mathcal{R}[\vec{\rho}_k]$. The linearity of the limit implies that $\lim_{k\to\infty} \vec{a_{ki}}^\mathsf{T} = \vec{a_i}^\mathsf{T}$ and that $\lim_{k\to\infty} \vec{a_{ki}}^\mathsf{T}\vec{\pi} = \vec{a_i}^\mathsf{T}\vec{\pi}$ for all $\vec{\pi} \in \mathbb{R}^n$. Hence, $\lim_{k\to\infty} A_k = A_\mathcal{R}$ and $\lim_{k\to\infty} A_k\vec{\pi} = A_\mathcal{R}\vec{\pi}$. Finally, by continuity of the p-norm, it follows that $\lim_{k\to\infty} \|A_k\vec{\pi}\|_p = \|A_\mathcal{R}\vec{\pi}\|_p$. As $\vec{\pi} \in \mathbb{R}^n$ was arbitrary, it follows $\lim_{k\to\infty} \mathrm{Inc}^p_\Pi(\mathcal{R}[\vec{\rho}_k]) = \mathrm{Inc}^p_\Pi(\mathcal{R}[\vec{\rho}])$. □

5 Computing Minimal Violation Measures

In this section, we explore how Inc^p_Π can be computed and how its computational performance relates to other measures. In general, computing Inc^p_Π corresponds to a convex optimization problem. Various approved algorithms exist to solve such problems, see (Boyd and Vandenberghe 2004) for an overview. For $p = 1$ and $p = \infty$, Inc^p_Π can be computed by linear programs, as I show in the following. The key idea of introducing auxiliary variables stems from unconstrained norm optimization problems (Boyd and Vandenberghe 2004).

For $p = 1$, we introduce a new vector $\vec{y} \in \mathbb{R}^m$ containing an auxiliary variable $\vec{y}_i$ for each conditional. Basically, the auxiliary variables $\vec{y}_i$ measure the error for the i-th conditional with respect to the 1-norm.

Proposition 5.1. $\mathrm{Inc}^1_\Pi(\mathcal{R})$ *can be computed by solving the following linear program:*

$$\min_{(\vec{\pi},\vec{y})\in\mathbb{R}^{n+m}} \quad \sum_{i=1}^{m} \vec{y}_i \qquad (2)$$

subject to

$$\sum_{i=1}^{n} \vec{\pi}_i = 1$$
$$-\vec{y} \leq A_\mathcal{R}\vec{\pi} \leq \vec{y}$$
$$\vec{y} \geq 0$$
$$\vec{\pi} \geq 0.$$

Proof. Along the same line of reasoning as for Proposition 3.3, it follows that (2) has a unique solution. It remains to show that optimization problem (2) yields the same solution as optimization problem (1) for $p = 1$ and arbitrary $\mathcal{R}$ over $(\mathcal{L}_\Sigma|\mathcal{L}_\Sigma)$.

To begin with, let ϵ be an optimal solution of (1). Then there is a $\vec{\pi} \in \Pi_n$ such that $\epsilon = \|A_\mathcal{R}\vec{\pi}\|_1 = \sum_{i=1}^m |\vec{a}_i^\mathsf{T}\vec{\pi}|$. Let $\vec{y} \in \mathbb{R}^m$ be defined by $\vec{y}_i = |\vec{a}_i^\mathsf{T}\vec{\pi}|$. Then $\begin{pmatrix}\vec{\pi}\\ \vec{y}\end{pmatrix}$ is feasible for (2), hence its optimum is at most $\sum_{i=1}^m \vec{y}_i = \epsilon$.

Conversely, suppose that $\sum_{i=1}^m |\vec{y}_i|$ is optimal for (2) and that $\begin{pmatrix}\vec{\pi}\\ \vec{y}\end{pmatrix}$ is an optimal point. Then $\vec{\pi}$ is feasible for (1) and its optimum is at most $\|A_\mathcal{R}\vec{\pi}\|_1 = \sum_{i=1}^m |\vec{a}_i^\mathsf{T}\vec{\pi}| \leq \sum_{i=1}^m |\vec{y}_i|$.

Hence both optima have to be equal. □

For $p = \infty$, it suffices to introduce a single auxiliary variable $y \in \mathbb{R}$, because the maximum norm measures the maximum error with respect to all conditionals. In the following proposition, $y\,\vec{1}$ denotes multiplication of the vector $\vec{1} \in \mathbb{R}^m$ (that contains only ones) by the scalar y.

Proposition 5.2. $\mathrm{Inc}^\infty_\Pi(\mathcal{R})$ *can be computed by solving the following linear program:*

$$\min_{(\vec{\pi},y)\in\mathbb{R}^{n+1}} \quad y \qquad (3)$$

subject to

$$\sum_{i=1}^{n} \vec{\pi}_i = 1$$
$$-y\,\vec{1} \leq A_\mathcal{R}\vec{\pi} \leq y\,\vec{1}$$
$$y \geq 0$$
$$\vec{\pi} \geq 0.$$

The proof is analogous to the last one and therefore left out.

Performance Evaluation

To test the computational performance of different measures, I computed inconsistency values for three test sets each of which contained nine knowledge bases and compared the runtime results. In each test set, from one knowledge base to the next, the number of conditionals and the size of the language was increased to capture the sensitivity of different measures with respect to the problem size. From one test set to the next, the number of conflicts between variables was increased to capture the sensitivity with respect to stronger correlations between the variables. The test sets were build up inductively as described in the following.

Test Set	$\lvert\Sigma_i\rvert$	$\lvert\Omega_i\rvert$	$\lvert\mathcal{R}_i\rvert$	
A	$2i$	4^i		$3i$
B	$2i$	4^i	3 *for* $i = 1$,	$4i - 1$ *for* $i > 1$
C	$2i$	4^i	3 *for* $i = 1$,	$5i - 2$ *for* $i > 1$

Table 1: Number of propositional variables $|\Sigma_i|$, worlds $|\Omega_i|$ and conditionals $|\mathcal{R}_i|$ in test sets A, B and C. For instance, $|\mathcal{R}_1^A| = 3$, $|\mathcal{R}_9^C| = 5 \cdot 9 - 2 = 43$, $|\Omega_9^C| = 4^9 = 2^{18}$.

Test Set A: The first (inconsistent) knowledge base $\mathcal{R}_1^A$ contains three conditionals built up over two variables. Σ_i^A and $\mathcal{R}_i^A$ are obtained from Σ_{i-1}^A and $\mathcal{R}_{i-1}^A$ by adding a new copy of the variables in Σ_1^A and the conditionals in $\mathcal{R}_1^A$.

$$\Sigma_1^A = \{A_1, B_1\},$$
$$\mathcal{R}_1^A = \{(A_1)[0.8], (B_1)[0.6], (B_1 \mid A_1)[0.8]\},$$
$$\Sigma_i^A = \Sigma_{i-1}^A \cup \{A_i, B_i\}, i > 1,$$
$$\mathcal{R}_i^A = \mathcal{R}_{i-1}^A \cup \{(A_i)[0.8], (B_i)[0.6], (B_i \mid A_i)[0.8]\}, i > 1.$$

Test Set B: For $i > 1$ the knowledge bases $\mathcal{R}_i^B$ differ from $\mathcal{R}_i^A$ by a new conflicting conditional that connects B_i and A_{i-1}. In this way all variables in test set B are correlated, whereas $\{A_i, B_i\}$ and $\{A_j, B_j\}$ are independent for $i \neq j$ in test set A.

$$\Sigma_i^B = \Sigma_i^A, i \in \mathbb{N},$$
$$\mathcal{R}_1^B = \mathcal{R}_1^A,$$
$$\mathcal{R}_i^B = \mathcal{R}_i^A \cup \{(B_k \mid A_{k-1})[0.85] \mid 2 \leq k \leq i\}, i > 1.$$

Test Set C: Compared to test set B, test set C contains yet another conflicting conditional between consecutive sets.

$$\Sigma_i^C = \Sigma_i^A, i \in \mathbb{N},$$
$$\mathcal{R}_1^C = \mathcal{R}_1^A,$$
$$\mathcal{R}_i^C = \mathcal{R}_i^B \cup \{(A_i \mid B_{i-1})[0.1] \mid 2 \leq k \leq i\}, i > 1.$$

Table 1 summarizes the calculation rules for the size of the knowledge bases and the corresponding languages.

Implementations: I used LPSolve[1], which is based on the Simplex algorithm, to compute Inc^1_Π and Inc^∞_Π. To compare the performance to other measures, I applied three prototypical implementations of the drastic measure (Hunter and Konieczny 2006; Thimm 2013), the MI measure (Hunter and Konieczny 2008; Thimm 2013) that counts the number of minimal inconsistent sets and the minimal change measure from (Thimm 2009).

[1] http://lpsolve.sourceforge.net

The drastic measure was computed by Phase 1 of the Simplex algorithm, which basically searches for a feasible solution. State of the art solvers for the probabilistic satisfiability problem apply more sophisticated techniques to speed up the computation (Hansen and Perron 2008; Cozman and Ianni 2013), but these can be applied to compute Inc_Π^1 and Inc_Π^∞ as well. Therefore, Phase 1 of the Simplex algorithm seems to be a reasonable baseline in this test series.

To find all minimal inconsistent sets, increasing subsets of the knowledge base were generated in lexicographic order. Each inconsistent subset was stored. The lexicographic order guaranteed minimality and that no supersets of minimal inconsistent sets were considered as candidates. To check consistency, again Phase 1 of the Simplex algorithm was applied. There already exist very sophisticated algorithms for enumerating minimal inconsistent sets for classical logics (Konieczny and Roussel 2013), but these rely on the fact that classical knowledge bases can be transformed into a single formula in conjunctive normal form. This fact, however, does not transfer to probabilistic logics.

The minimal change measure from (Thimm 2009) was computed by an implementation in the expert system shell MECore[2] (Finthammer et al. 2009). It is based on JCobyla[3], a Java implementation of Cobyla that approximates the non-convex optimization problem by linear programs (Powell 1994). There already exists an implementation of the measure from (Thimm 2009) in the Tweety library[4], but it relies on external libraries and is difficult to set up. Therefore, it was not used. Other methods might perform better than Cobyla, but to the best of my knowledge there are no algorithms for constrained non-convex problems that can handle more than a few thousand optimization variables and the used knowledge bases induced up to 2^{18} variables.

Figure 1 visualizes the runtime results. Note that the y-axis ranges to 10 seconds for test set A and B, but to 20 seconds for test set C. Execution was canceled if algorithms required more than 5 minutes to compute an inconsistency value.

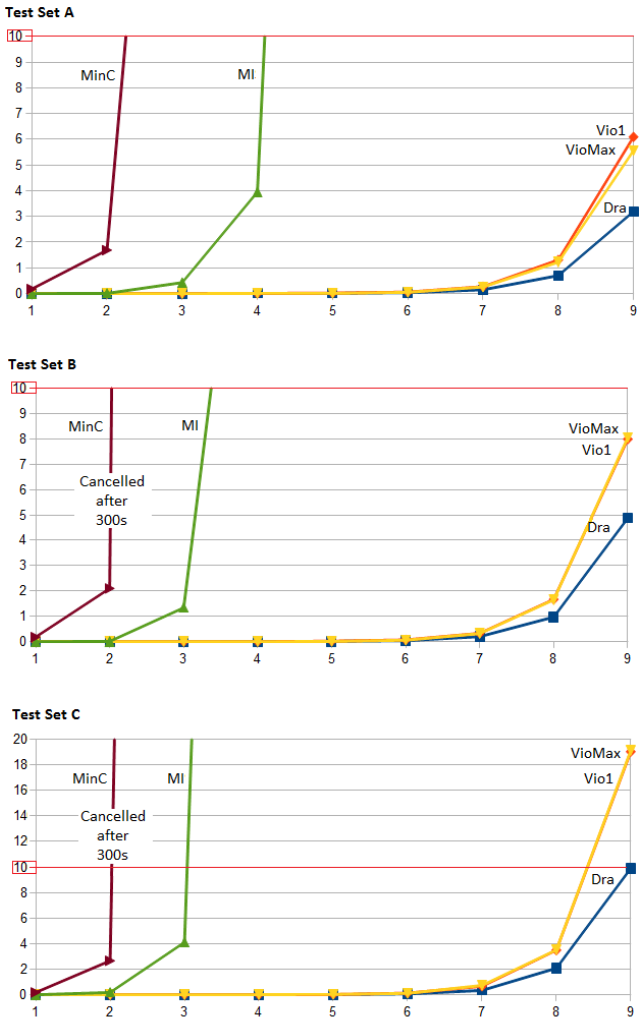

Figure 1: Runtime results in seconds (y-axis) for knowledge bases of increasing size (x-axis): Minimal change (MinC, red), minimal inconsistent sets (MI, green), Inc_Π^1 (Vio1, orange), Inc_Π^∞ (VioMax, yellow), drastic (Dra, blue) measure.

Interpretation of Performance Results: The runtime for each algorithm in each test set in Figure 1 grows exponentially from one knowledge base to the next, because the number of optimization variables corresponds to the number of worlds $|\Omega|$ that is exponential in the size of $|\Sigma|$. Note that $|\Omega|$ quadruples from one knowledge base to the next one. Inc_Π^1, Inc_Π^∞ and the drastic measure scale much better than the minimal change measure and the minimal inconsistent set measure. In the next subsection, I summarize some empirical estimates from (Boyd and Vandenberghe 2004; Matousek and Gärtner 2007) for typical optimization algorithms that support these results.

Also note that the minimal inconsistent set measure is more sensitive with respect to the size of the knowledge base. For example, when comparing test set A and B, the runtime for linear programs increases by at most 50 percent for all knowledge bases, whereas the runtime for the minimal inconsistent set measure triples from $\mathcal{R}_3^A$ to $\mathcal{R}_3^B$ and quadruples from $\mathcal{R}_4^A$ to $\mathcal{R}_4^B$. This observation corresponds to the fact that the number of possible candidates for minimal inconsistent subsets increases exponentially with the size of the knowledge base.

On Computational Complexity

Finding reasonable estimates for the performance of inconsistency measures is difficult, because it depends heavily on the applied algorithm and the structure of the knowledge base at hand. For example, one can construct examples where the Simplex algorithm requires an exponential number of iterations, even though it often performs faster than

[2]The measure was implemented by Sebastian Lewalder in his ongoing bachelor thesis.

[3]https://github.com/cureos/jcobyla

[4]http://tweety.sourceforge.net

algorithms with a polynomial runtime guarantee in practice (Matousek and Gärtner 2007). In this section, I summarize some empirical estimates for typical optimization algorithms to provide some intuition for the practical difficulty of different measures.

Empirical estimates: Practical experiments indicate that linear programs can be solved by the Simplex algorithm in about $2\overline{m}$ to $3\overline{m}$ iterations (Matousek and Gärtner 2007), where $\overline{m}$ is the number of constraints after transforming the problem to a standard form consisting of equations and non-negativity constraints. Each iteration usually causes costs in the order of $|\Omega|\,|\mathcal{R}|$, so that the overall cost can be regarded as in the order of $|\Omega|\,|\mathcal{R}|^2$.

For convex programs, Boyd and Vandenberghe (2004) estimate 10 to 100 iterations with cost $\max\{|\Omega|^3, |\Omega|^2\,|\mathcal{R}|\}$ per iteration when using interior-point methods. For the special case of $p = 2$, Inc^2_Π corresponds to a quadratic programming problem that can be solved in the order of $|\Omega|^2\,|\mathcal{R}|$ (Boyd and Vandenberghe 2004). Algorithms for non-convex programs can also be applied to convex programs, but usually are less efficient, because they rely on mechanisms to avoid (non-global) local minima. Therefore, one can expect that their computational cost is at least $|\Omega|^3$.

Practical Implications: As the number of worlds grows exponentially with the number of propositional variables, $|\Omega|$ usually dominates the size of the optimization problems. Therefore, one can expect to compute the drastic measure, Inc^1_Π and Inc^∞_Π with linear complexity, Inc^2_Π with quadratic complexity and Inc^p_Π for $p > 2$ with cubic complexity with respect to $|\Omega|$. For linear programs, several techniques can be applied to reduce the exponential influence of $|\Omega|$ (Jaumard, Hansen, and Poggi 1991; Hansen and Perron 2008; Cozman and Ianni 2013). The key idea is that only $\overline{m}$ columns of the $(\overline{m} \times \overline{n})$ constraint matrix have to be stored and in each iteration one column has to be switched. Selecting a good column from the $\overline{n} - \overline{m}$ possible candidates is the crucial problem.

Several measures rely on computing all minimal inconsistent sets (Hunter and Konieczny 2008; Thimm 2013). If $\#\mathit{MI}$ denotes the number of minimal inconsistent sets in a knowledge base, then we need to perform at least $\#\mathit{MI}$ satisfiability tests to verify their inconsistency. Based on the estimate $|\mathcal{R}|^2\,|\Omega|$ for probabilistic satisfiability tests, the cost for computing minimal consistent sets is at least $\#\mathit{MI}\,|\mathcal{R}|^2\,|\Omega|$.

As explained above, computing the non-convex problems corresponding to minimal change measures as introduced in (Thimm 2009) and (Picado-Muiño 2011) is at least as expensive as solving convex problems. Therefore, their computational cost can be expected to be greater than $|\Omega|^3$.

Table 2 summarizes the size of the optimization problems and the explained estimates for their practical computational cost. $2|\mathcal{R}|$ optimization variables for Inc^1_Π and Inc^∞_Π correspond to slack variables that have to be generated to transform the problem into a normal form for the Simplex algorithm. For the same reason the number of constraints is increased.

Note, however, that the mere number of optimization variables $\overline{n}$ and constraints $\overline{m}$ can be misleading when comparing two algorithms. For example, as Table 2 shows, the overall number of variables $\overline{n}$ is smaller for Inc^∞_Π than for Inc^1_Π. But whereas the single auxiliary variable for Inc^∞_Π appears in $2|\mathcal{R}|$ constraints, each of the $|\mathcal{R}|$ auxiliary variables for Inc^1_Π appear in only 2 constraints (c.f. Proposition 5.1 and 5.2). Therefore, the variables are looser correlated for Inc^1_Π and, indeed, Inc^∞_Π is slightly outperformed by Inc^1_Π in Figure 1 for test sets B and C.

Measure	$\overline{n}$	$\overline{m}$	Estimate
Drastic	$\lvert\Omega\rvert + \lvert\mathcal{R}\rvert$	$\lvert\mathcal{R}\rvert + 1$	$\sim \overline{n}\,\overline{m}^2$
Inc^∞_Π	$\lvert\Omega\rvert + 2\lvert\mathcal{R}\rvert + 1$	$2\lvert\mathcal{R}\rvert + 1$	$\sim \overline{n}\,\overline{m}^2$
Inc^1_Π	$\lvert\Omega\rvert + 3\lvert\mathcal{R}\rvert$	$2\lvert\mathcal{R}\rvert + 1$	$\sim \overline{n}\,\overline{m}^2$
Inc^2_Π	$\lvert\Omega\rvert$	1	$\sim \overline{n}^2\,\overline{m}$
$\mathrm{Inc}^p_\Pi, p > 2$	$\lvert\Omega\rvert$	1	$\sim \overline{n}^3$
MI	$\lvert\Omega\rvert + \lvert\mathcal{R}\rvert$	$\lvert\mathcal{R}\rvert + 1$	$> \#\mathit{MI}\,\overline{n}\,\overline{m}^2$
MinChange	$\lvert\Omega\rvert + \lvert\mathcal{R}\rvert$	$3\lvert\mathcal{R}\rvert + 1$	$> \overline{n}^3$

Table 2: Number of optimization variables $\overline{n}$, number of constraints $\overline{m}$ (without non-negativity constraints) and rough performance estimates for different measures. $\#\mathit{MI}$ denotes the number of minimal inconsistent sets. Performance estimates are based on empirical values from (Boyd and Vandenberghe 2004; Matousek and Gärtner 2007) for typical optimization algorithms.

6 Conclusion and Future Work

As shown in Section 4, minimal violation measures satisfy many desirable properties that have been considered in the literature (Knight 2003; Hunter and Konieczny 2006; Thimm 2013). In contrast to the naive drastic measure or measures based on minimal inconsistent sets (Hunter and Konieczny 2008; Thimm 2013), minimal violation measures take the numerical structure of probabilistic knowledge bases into account and in this way provide a more fine-grained insight into inconsistencies, as demonstrated in Examples 3.4 and 3.5. When applied as a guide to repair knowledge bases, they can never yield better theoretical guarantees than measures based on minimal changes, because these yield the best repair by definition (Thimm 2009; Picado-Muiño 2011). However, the lack of efficient algorithms for constrained non-convex problems prevents us from computing minimal change measures for larger knowledge bases. As explained in Section 5, minimal violation measures possess better computational properties. In particular, Inc^1_Π and Inc^∞_Π stand out among conventional measures for probabilistic logics, because they provide similar good performance guarantees like the naive drastic measure, while measuring the degree of inconsistency continuously.

One long term goal of this work is resolving inconsistencies in probabilistic knowledge bases with methods that are better guided than purely heuristic approaches and that provide better computational properties than minimal change approaches. A first algorithm based on minimal violation measures might iterate over the conditionals, check whether an adaptation yields an improvement in the inconsistency

value and select the best adaptation as illustrated in Example 3.5. To speed up repeated computations of Inc_{Π}^{1} and $\mathrm{Inc}_{\Pi}^{\infty}$, column generation techniques can be applied (Hansen and Perron 2008). In future work such an algorithm shall be implemented and evaluated in the expert system shell MECore (Finthammer et al. 2009).

It might also be interesting to ask whether the minimal violating interpretations can be used to infer reasonable information from contradictory knowledge bases. The minimal violating interpretations yield a compact and convex set just like the models of consistent knowledge bases. Therefore, computing probabilities from minimal violating interpretations of inconsistent knowledge bases can be performed like computing probabilities from the models of consistent knowledge bases. However, the question remains whether the computed probabilities yield reasonable results and whether they can be justified by some rationales.

For $p = 1$, $p = 2$ and $p = \infty$, Java-implementations of Inc_{Π}^{p} are made available in the Tweety library[5] (they can be found in the package net.sf.tweety.logics.pcl.analysis. Note that LPSolve[6] has to be installed and configured properly to use Inc_{Π}^{1} and $\mathrm{Inc}_{\Pi}^{\infty}$).

Short Papers

Axioms .2 and .4 as Interaction Axioms

Guillaume Aucher
University of Rennes 1
INRIA
Rennes, France
guillaume.aucher@irisa.fr

Abstract

In epistemic logic, some axioms dealing with the notion of knowledge are rather convoluted and it is difficult to give them an intuitive interpretation, even if some of them, like .2 and .4, are considered by some epistemic logicians to be key axioms. We show that they can be characterized in terms of understandable interaction axioms relating knowledge and belief. In order to show it, we first present a theory dealing with the characterization of axioms in terms of interaction axioms in modal logic. We then apply the main results and methods of this theory to obtain our results related to epistemic logic.

1 Introduction

The development of modern epistemic logic can be viewed as an attempt to elucidate the nature of the interaction between knowledge and belief by means of formal and logical methods. On the basis of a semantics very close to the Kripke semantics of modal logic, Hintikka and subsequent philosophers and logicians tried to formulate explicit principles governing and relating expressions of the form "a knows that φ" (subsequently formalized as $K\varphi$) and "a believes that φ" (subsequently formalized as $B\varphi$), where a is a human agent and φ is a proposition. In other words, they sought to determine 'the' logic of knowledge and belief. This quest was grounded in the observation that our intuitions of these epistemic notions comply to some systematic reasoning properties, and was driven by the attempt to better *understand* and *elucidate* them (Lenzen 1978, p. 15). For example, the interaction axioms $K\varphi \rightarrow B\varphi$ and $B\varphi \rightarrow KB\varphi$ are often considered to be intuitive principles: if agent a knows φ then (s)he also believes φ, or if agent a believes φ, then (s)he knows that (s)he believes φ.

In computer science, the logic of knowledge is usually considered to be S5, which is the logic S4 composed of the axioms $K\varphi \rightarrow \varphi$ and $K\varphi \rightarrow KK\varphi$ to which is added the axiom 5: $\neg K\varphi \rightarrow K\neg K\varphi$. This last axiom is validated in situations where the agent cannot have mistaken beliefs. For this very reason, it has been attacked by various philosophers because it cannot hold in general. Dropping this axiom 5, we obtain a rich variety of weaker logics of knowledge which have been proposed and examined by logicians (Lenzen 1979), such as S4.2, S4.3, S4.3.2 and S4.4. Even if these logics are characterized by axioms which are rather intricate, some of them have been proclaimed by some epistemic logicians as key axioms characterizing the notion of knowledge. For example, Lenzen claimed that "[t]here is strong evidence in favor of the assumption that S4.2 is the logic of knowledge" (Lenzen 1979, p. 33), where the axiom .2 is $\neg K\neg K\varphi \rightarrow K\neg K\neg\varphi$. Likewise, Kutschera argues for S4.4 as the logic of knowledge, where the axiom .4 is $(\varphi \wedge \langle K\rangle K\varphi) \rightarrow K\varphi$ (Kutschera 1976). As one can easily observe, it is difficult to provide these axioms with a natural and easily understandable reading. In fact, Lenzen derived his axiom .2 from a set of interaction axioms relating knowledge and belief.

To better grasp the intuitions underlying these intricate axioms, we show that axioms .2 and .4 can be characterized equivalently in terms of interaction axioms relating knowledge and belief. In order to do so, we first need to explain what we mean by "interaction axiom" and what we mean by "characterizing an axiom in terms of interaction axioms". This will lead us to develop a meta-theory of modal logic dealing with these notions. Then, we will apply the general results of this theory to the specific case of epistemic logic. Note that the problems that we address in this article have never been addressed in the logical literature, neither for multi-modal logics nor for combinations of modal logics (Marx and Venema 1997; Gabbay et al. 1998).

2 Towards a Theory of Interaction Axioms

In this section, we start by recalling the basics of modal logic. Then, we present our primitive meta-theory of modal logic dealing with interaction axioms.

2.1 Modal Logic

Syntax. In the rest of the article, Φ is a set of propositional letters and $\mathbb{A} \subseteq \{1, 2\}$. We define the *modal language* $\mathcal{L}_{\mathbb{A}}$ by the following BNF grammar:

$$\mathcal{L}_{\mathbb{A}} \ : \ \varphi \ ::= \ p \ \mid \ \neg\varphi \ \mid \ \varphi \wedge \varphi \ \mid \ [i]\,\varphi$$

where p ranges over Φ and i ranges over $\mathbb{A}$. The formula $\top$ is an abbreviation for $p \vee \neg p$ (for some fixed $p \in \Phi$), the

Copyright © 2014, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

formula $\bot$ is an abbreviation for $\neg\top$ and $\langle i\rangle\varphi$ an abbreviation for $\neg[i]\neg\varphi$. An occurrence of a proposition letter p is a *positive* occurrence if it is in the scope of an even number of negation signs $\neg$. It is *positive in* p if all occurrences of p in φ are positive. If $\Gamma := \{\varphi_1, \ldots, \varphi_n\} \subseteq \mathcal{L}_{\mathbb{A}}$, then $\bigwedge\Gamma$ is an abbreviation for $\varphi_1 \wedge \ldots \wedge \varphi_n$.

A *(modal) logic* L for the modal language $\mathcal{L}_{\mathbb{A}}$ is a set of formulas of $\mathcal{L}_{\mathbb{A}}$ called *theorems* which contains all propositional tautologies and which is closed under modus ponens, that is, if $\varphi \in \mathsf{L}$ and $\varphi \to \psi \in \mathsf{L}$, then $\psi \in \mathsf{L}$, and closed under uniform substitution, that is, if φ belongs to L then so do all of its substitution instances (see (Blackburn, de Rijke, and Venema 2001, Def. 1.18) for the definition of a substitution instance).

A modal logic is usually defined by a set of *inference rules* and of formulas called *axioms*. A formula is a theorem of the modal logic if it can be derived by successively applying (some of) the inference rules to (some of) the axioms. We are interested here in *normal modal logics*. These modal logics contain the axiom schema $([i](\varphi \to \psi) \wedge [i]\varphi) \to [i]\psi$, and the inference rule of necessitation: from $\varphi \in \mathsf{L}$, infer $[i]\varphi \in \mathsf{L}$, for all $i \in \mathbb{A}$. Let $A \subseteq \mathcal{L}_{\mathbb{A}}$. A modal logic for $\mathcal{L}_{\mathbb{A}}$ *generated* by the set A is the smallest normal modal logic for $\mathcal{L}_{\mathbb{A}}$ containing A. In that case, the formulas of A are called *axioms*.

If L and L' are two sets of formulas of $\mathcal{L}_{\mathbb{A}}$ (possibly logics), we denote by $\mathsf{L} + \mathsf{L}'$ the modal logic for $\mathcal{L}_{\mathbb{A}}$ generated by $\mathsf{L} \cup \mathsf{L}'$ (it is also called the *fusion* of L and L' (Marx and Venema 1997; Gabbay et al. 1998)). If x is a formula of $\mathcal{L}_{\mathbb{A}}$, then $\mathsf{L} + \mathsf{x}$ abusively denotes $\mathsf{L} + \{\mathsf{x}\}$. Note that $\mathsf{L} + \mathsf{L}'$ may be different from $\mathsf{L} \cup \mathsf{L}'$ in general, because $\mathsf{L} \cup \mathsf{L}'$ may not be closed under modus ponens or uniform substitution.

Let $\mathsf{x} \in \mathcal{L}_{\mathbb{A}}$ and let $X, X' \subseteq \mathcal{L}_{\mathbb{A}}$. We say that x is *derivable from* X *in* L when $\mathsf{x} \in \mathsf{L} + X$ and in that case we write $X \vdash_{\mathsf{L}} \mathsf{x}$. We also write $X \vdash_{\mathsf{L}} X'$ when $X \vdash_{\mathsf{L}} \mathsf{x}'$ for all $\mathsf{x}' \in X'$, and $X >_{\mathsf{L}} X'$ when it holds that $X \vdash_{\mathsf{L}} X'$ but it does not hold that $X' \vdash_{\mathsf{L}} X$.

Kripke Semantics. The Kripke semantics will be used only in the proof of Theorem 2.2. A *(bi-modal) Kripke model* $\mathcal{M}$ is a tuple $\mathcal{M} = (W, R_1, R_2, V)$ where W is a non-empty set of possible worlds, $R_1, R_2 \in 2^{W\times W}$ are binary relations over W called *accessibility relations*, and $V : \Phi \to 2^W$ is called a *valuation* and assigns to each propositional letter $p \in \Phi$ a subset of W. We often denote by $R_i(w)$ the set $R_i(w) := \{v \in W \mid wR_iv\}$ and we abusively write $w \in \mathcal{M}$ when $w \in W$.

Let $\varphi \in \mathcal{L}_{\mathbb{A}}$, let $\mathcal{M}$ be a Kripke model and let $w \in \mathcal{M}$. The *satisfaction relation* $\mathcal{M}, w \models \varphi$ is defined inductively as follows:

$$\begin{array}{lll}
\mathcal{M}, w \models p & \text{iff} & w \in V(p)\\
\mathcal{M}, w \models \varphi \wedge \varphi' & \text{iff} & \mathcal{M}, w \models \varphi \text{ and } \mathcal{M}, w \models \varphi'\\
\mathcal{M}, w \models \neg\varphi & \text{iff} & \text{not } \mathcal{M}, w \models \varphi\\
\mathcal{M}, w \models [i]\varphi & \text{iff} & \text{for all } v \in R_i(w), \mathcal{M}, v \models \varphi
\end{array}$$

If $\Gamma \subseteq \mathcal{L}_{\mathbb{A}}$, then we write $\mathcal{M}, w \models \Gamma$ when $\mathcal{M}, w \models \varphi$ for all $\varphi \in \Gamma$.

2.2 Interaction Axioms and Characterization of Axioms

In the sequel, L_1 and L_2 are two modal logics for $\mathcal{L}_1$ and $\mathcal{L}_2$ respectively, and $\mathsf{L}_{1,2}$ is a modal logic for $\mathcal{L}_{1,2}$.

Definition 2.1 (Interaction Axioms). A *set of interaction axioms* w.r.t. a pair of logics $(\mathsf{L}_1, \mathsf{L}_2)$ is a finite set of formulas $\Gamma \subseteq \mathcal{L}_{1,2}$ for which there is no $\chi \in \mathcal{L}_1 \cup \mathcal{L}_2$ such that

$$\chi \leftrightarrow \bigwedge\Gamma \in \mathsf{L}_1 + \mathsf{L}_2.$$

In the sequel, x is a formula of $\mathcal{L}_1$ and Γ is a set of interaction axioms w.r.t. $(\mathsf{L}_1, \mathsf{L}_2)$.

Definition 2.2 (Characterization of an Axiom). We say that x is *characterized* by the set of interaction axioms Γ w.r.t. $(\mathsf{L}_1, \mathsf{L}_2)$ when

$$\mathsf{L}_1 + \mathsf{x} = (\mathsf{L}_1 + \mathsf{L}_2 + \Gamma) \cap \mathcal{L}_1. \tag{1}$$

Moreover, x is *conservatively characterized* by Γ w.r.t. $(\mathsf{L}_1, \mathsf{L}_2)$ when the set of interaction axioms Γ satisfies the following condition as well:

$$\mathsf{L}_2 = (\mathsf{L}_1 + \mathsf{L}_2 + \Gamma) \cap \mathcal{L}_2. \tag{2}$$

Definition 2.2 tells us that an axiom x is characterized by a set of interaction axioms Γ if, when we add the interaction axioms to the base logics, we derive exactly the theorems for the language $\mathcal{L}_1$ obtained by only adding axiom x to L_1, and nothing else. For the case of strong characterization, by adding these interaction axioms Γ, we do not even obtain new theorems for the language $\mathcal{L}_2$ as 'side effects', the theorems for this language just remain the same as initially.

Proposition 2.1. • *If x is conservatively characterized by a set of interaction axioms w.r.t. $(\mathsf{L}_1, \mathsf{L}_2)$, then $\mathsf{x} \notin \mathsf{L}_1$.*

• *Conversely, if $\mathsf{x} \notin \mathsf{L}_1$ and Γ is a set of formulas of $\mathcal{L}_{1,2}$ such that Equation (1) holds, then Γ is a set of interaction axioms w.r.t. $(\mathsf{L}_1, \mathsf{L}_2)$.*

Proof. It follows easily from Definitions 2.1 and 2.2. □

Finally, we define a notion of minimality among the sets of interaction axioms characterizing an axiom x.

Definition 2.3 (Minimal Characterization). The axiom x is *minimally characterized* by the set of interaction axioms Γ w.r.t. $(\mathsf{L}_1, \mathsf{L}_2)$ when x is characterized by Γ w.r.t. $(\mathsf{L}_1, \mathsf{L}_2)$ and there is no set of interaction axioms Γ' such that $\Gamma >_{\mathsf{L}_1+\mathsf{L}_2} \Gamma'$ and x is still characterized by Γ' w.r.t. $(\mathsf{L}_1, \mathsf{L}_2)$.

2.3 Definability of Modalities and Characterization of Axioms

The definability of modalities in terms of other modalities is studied from a theoretical point of view in (Halpern, Samet, and Segev 2009b). This study is subsequently applied to epistemic logic in (Halpern, Samet, and Segev 2009a). Three notions of definability emerge from this work: explicit definability, implicit definability and reducibility. It has been proven that, for modal logic, explicit definability coincides with the conjunction of implicit definability and reducibility (unlike first-order logic, where the notion of explicit definability coincides with implicit definability only). In this

article, we are interested only in the notion of *explicit* definability, which is also used in (Lenzen 1979).

Definition 2.4 (Explicit Definability of a Modality). Let $\{i,j\} = \{1,2\}$. The modality $\langle i\rangle$ is *explicitly defined* in the logic $\mathsf{L}_{i,j}$ in terms of the modality $\langle j\rangle$ by a formula $\mathsf{def}_i(p) \in \mathcal{L}_j$ if, and only if,

$$\langle i\rangle p \leftrightarrow \mathsf{def}_i(p) \in \mathsf{L}_{i,j}. \qquad (\mathsf{Def}\ \langle i\rangle)$$

The following key theorem will play an important role in the last section.

Theorem 2.2. *Assume that $\langle 2\rangle$ is explicitly defined in $\mathsf{L}_1 + \mathsf{L}_2 + \Gamma$ in terms of $\langle 1\rangle$ by a formula $\mathsf{def}_2(p) \in \mathcal{L}_1$ positive in p. Then, the following are equivalent:*

- *x is characterized by Γ w.r.t. $(\mathsf{L}_1, \mathsf{L}_2)$;*
- *$\mathsf{L}_1 + \mathsf{L}_2 + \Gamma = \mathsf{L}_1 + \mathsf{x} + \{\langle 2\rangle p \leftrightarrow \mathsf{def}_2(p)\}$.*

Moreover, assume that $\langle 1\rangle$ is also explicitly defined in $\mathsf{L}_1 + \mathsf{L}_2 + \Gamma$ in terms of $\langle 2\rangle$ by a formula $\mathsf{def}_1(p) \in \mathcal{L}_2$ positive in p. Then, the following are equivalent:

- *x is conservatively characterized by Γ w.r.t. $(\mathsf{L}_1, \mathsf{L}_2)$;*
- *$\mathsf{L}_1 + \mathsf{L}_2 + \Gamma = \mathsf{L}_1 + \mathsf{x} + \{\langle 2\rangle p \leftrightarrow \mathsf{def}_2(p)\}$ and $\mathsf{L}_1 + \mathsf{L}_2 + \Gamma = \mathsf{L}_2 + \{\langle 1\rangle p \leftrightarrow \mathsf{def}_1(p)\}$.*

Finally, in both cases, the axiom x is (conservatively) characterized by Γ w.r.t. $(\mathsf{L}_1, \mathsf{L}_2)$ if, and only if, it is minimally *(conservatively) characterized by Γ w.r.t. $(\mathsf{L}_1, \mathsf{L}_2)$.*

Proof. The proof of the second part of the theorem is similar to the proof of the first part. So, we only prove the first part. Assume that x is characterized by Γ w.r.t. $(\mathsf{L}_1, \mathsf{L}_2)$. Then, $\mathsf{L}_1 + \mathsf{x} = (\mathsf{L}_1 + \mathsf{L}_2 + \Gamma) \cap \mathcal{L}_1$, and therefore $\mathsf{L}_1 + \mathsf{x} \subseteq \mathsf{L}_1 + \mathsf{L}_2 + \Gamma$. Moreover, $\langle 2\rangle p \leftrightarrow \mathsf{def}_2(p) \in \mathsf{L}_1 + \mathsf{L}_2 + \Gamma$ by assumption. Thus, $\mathsf{L}_1 + \mathsf{x} + \{\langle 2\rangle p \leftrightarrow \mathsf{def}_2(p)\} \subseteq \mathsf{L}_1 + \mathsf{L}_2 + \Gamma$. Now, we prove the converse inclusion. Assume towards a contradiction that there is $\varphi \in \mathsf{L}_1 + \mathsf{L}_2 + \Gamma$ such that $\varphi \notin \mathsf{L}_1 + \mathsf{x} + \{\langle 2\rangle p \leftrightarrow \mathsf{def}_2(p)\}$. Then, there is $\varphi' \in \mathcal{L}_1$ such that $\varphi \leftrightarrow \varphi' \in \mathsf{L}_1 + \mathsf{L}_2 + \Gamma$, because $\langle 2\rangle$ is explicitly definable in terms of $\langle 1\rangle$ in $\mathsf{L}_1 + \mathsf{L}_2 + \Gamma$. Then, $\varphi' \in (\mathsf{L}_1 + \mathsf{L}_2 + \Gamma) \cap \mathcal{L}_1$, *i.e.*, $\varphi' \in \mathsf{L}_1 + \mathsf{x}$. Then, by performing the inverse translation that we followed to obtain φ' from φ, we conclude that $\varphi \in \mathsf{L}_1 + \mathsf{x} + \{\langle 2\rangle p \leftrightarrow \mathsf{def}_2(p)\}$. This is impossible, and therefore $\mathsf{L}_1 + \mathsf{L}_2 + \Gamma = \mathsf{L}_1 + \mathsf{x} + \{\langle 2\rangle p \leftrightarrow \mathsf{def}_2(p)\}$.

Now, assume that $\mathsf{L}_1 + \mathsf{L}_2 + \Gamma = \mathsf{L}_1 + \mathsf{x} + \{\langle 2\rangle p \leftrightarrow \mathsf{def}_2(p)\}$. We are going to prove that $\mathsf{L}_1 + \mathsf{x} = (\mathsf{L}_1 + \mathsf{L}_2 + \Gamma) \cap \mathcal{L}_1$. The right to left inclusion is immediate, because $\mathsf{x} \in \mathsf{L}_1 + \mathsf{L}_2 + \Gamma$ by assumption. Now, we prove that $(\mathsf{L}_1 + \mathsf{L}_2 + \Gamma) \cap \mathcal{L}_1 \subseteq \mathsf{L}_1 + \mathsf{x}$, *i.e.*, for all Kripke models $\mathcal{M}$, for all $w \in \mathcal{M}$, if $\mathcal{M}, w \models \mathsf{L}_1 + \mathsf{x}$, then $\mathcal{M}, w \models (\mathsf{L}_1 + \mathsf{L}_2 + \Gamma) \cap \mathcal{L}_1$. In order to do so, we are going to build a Kripke model $(\mathcal{M}', w')$ such that $(\mathcal{M}, w)$ and $(\mathcal{M}', w')$ are bisimilar w.r.t. the modality $\langle 1\rangle$ and such that $\mathcal{M}', w' \models \mathsf{L}_1 + \mathsf{x} + \{\langle 2\rangle p \leftrightarrow \mathsf{def}_2(p)\}$ $(*)$, that is, $\mathcal{M}', w' \models \mathsf{L}_1 + \mathsf{L}_2 + \Gamma$ (recall the assumption). This will prove the second inclusion. If $(\mathcal{M}, w) = (W, R_1, R_2, V, w)$, then we define the (pointed) Kripke model $(\mathcal{M}', w') := (W, R_1, R_2', V, w)$, where R_2' is defined as follows. First, we define the (pointed) Kripke model $(\mathcal{M}'', w) := (W, R_1, R_2, V'', w)$ by setting V'' such that for all $q \neq p$, $V''(q) = V(q)$ and such that $V''(p) = \{v\}$. Then, for all $u, v \in W$, we set $uR_2'v$ in $\mathcal{M}'$ if, and only if, $\mathcal{M}'', u \models \mathsf{def}_2(p)$. Then, using the fact that $\mathsf{def}_2(p)$ is positive in p, one can easily show that $(*)$ holds. This proves the second inclusion.

Finally, we prove the last part of the theorem. Assume towards a contradiction that x is characterized by the set of interaction axioms Γ w.r.t. $(\mathsf{L}_1, \mathsf{L}_2)$ and that there is a set of interaction axioms Γ' such that $\Gamma >_{\mathsf{L}_1+\mathsf{L}_2} \Gamma'$ and such that x is also characterized by Γ' w.r.t. $(\mathsf{L}_1, \mathsf{L}_2)$. Because $\Gamma >_{\mathsf{L}_1+\mathsf{L}_2} \Gamma'$, we should have that $\mathsf{L}_1 + \mathsf{L}_2 + \Gamma \subset \mathsf{L}_1 + \mathsf{L}_2 + \Gamma'$. However, since x is characterized by Γ and Γ', we should also have that $\mathsf{L}_1 + \mathsf{L}_2 + \Gamma = \mathsf{L}_1 + \mathsf{L}_2 + \Gamma' = \mathsf{L}_1 + \mathsf{x} + \{\langle 2\rangle p \leftrightarrow \mathsf{def}_2(p)\}$ by the result of the first part of the theorem. This is impossible. □

3 Epistemic Logic and Interaction Axioms

We introduce the basics of epistemic logic (see (Fagin et al. 1995; Meyer and van der Hoek 1995) for more details).

3.1 Logics of Knowledge and Belief

We define the epistemic-doxastic language $\mathcal{L}_{KB}$ inductively as follows:

$$\mathcal{L}_{KB} \ : \ \varphi \ ::= \ p \ \mid \ \neg\varphi \ \mid \ \varphi \wedge \varphi \ \mid \ B\varphi \ \mid \ K\varphi$$

where p ranges over Φ. The language $\mathcal{L}_K$ is the language $\mathcal{L}_{KB}$ without the belief operator B, and the language $\mathcal{L}_B$ is the language $\mathcal{L}_{KB}$ without the knowledge operator K. The formula $B\varphi$ reads as 'the agent Believes φ' and $K\varphi$ reads as 'the agent Knows φ'. Their dual operators $\langle B\rangle\varphi$ and $\langle K\rangle\varphi$ are abbreviations of $\neg B\neg\varphi$ and $\neg K\neg\varphi$ respectively. Below, we give a list of axioms that will be used in the rest of the article.

D	$: K\varphi \to \langle K\rangle\varphi$	$\mathsf{4}$	$: K\varphi \to KK\varphi$
$\mathsf{5}$	$: \neg K\varphi \to K\neg K\varphi$	T	$: K\varphi \to \varphi$
$.\mathsf{2}$	$: \langle K\rangle K\varphi \to K\langle K\rangle\varphi$	$.\mathsf{4}$	$: (\varphi \wedge \langle K\rangle K\varphi) \to K\varphi$.

The logic $\mathsf{KD45}_B$ is the modal logic for $\mathcal{L}_B$ generated by the set of axioms $\{\mathsf{D}, \mathsf{4}, \mathsf{5}\}$. For any $\mathsf{x} \in \{.\mathsf{2}, .\mathsf{4}\}$, the logic $\mathsf{S4.x}_K$ is the modal logic for $\mathcal{L}_K$ generated by the set of axioms $\{\mathsf{T}, \mathsf{4}, \mathsf{x}\}$. We have the following relationship between these logics:

$$\mathsf{S4}_K \subset \mathsf{S4.2}_K \subset \mathsf{S4.4}_K \subset \mathsf{S5}_K.$$

3.2 Interaction Axioms for Epistemic Logic

The following interaction axioms were suggested in (Hintikka 1962):

$$K\varphi \to B\varphi \qquad (\mathrm{I}_1)$$
$$B\varphi \to KB\varphi \qquad (\mathrm{I}_2)$$

Axiom I_1 is a cornerstone of epistemic logic. Just as axiom T, it follows from the classical analysis of knowledge of Plato presented in the Theaetethus. Axiom I_2 highlights the fact that the agent has "privileged access" to his doxastic state.

$$B\varphi \to BK\varphi \qquad (\mathrm{I}_3)$$

Axiom I_3 above was suggested in (Lenzen 1978). It characterizes a notion of belief corresponding to some sort of conviction or certainty. This kind of belief is therefore different

from the notion of *weak* belief which can be represented by a probability superior to 0.5, like my belief that "it will rain tomorrow".

The last interaction axiom we will consider is in fact a definition of knowledge in terms of belief:

$$K\varphi \leftrightarrow (\varphi \wedge B\varphi) \qquad (\mathrm{I}_4)$$

This list of interaction axioms is incomplete, see (Aucher 2014) for more information about interaction axioms and axioms of epistemic logic.

4 Applying our Theory to Epistemic Logic

In (Halpern, Samet, and Segev 2009a), only the interaction axioms I_1 and I_2 suggested in (Hintikka 1962) are considered. In this section, we also add the interaction axiom I_3. Lenzen is the first to note that the belief modality can be defined in terms of knowledge if we adopt $\{I_1, I_2, I_3\}$ as interaction axioms.

Theorem 4.1. *(Lenzen 1979)*

The belief modality B is explicitly defined in the logic $\mathsf{L} = \mathsf{S4}_K + \mathsf{KD45}_B + \{I_1, I_2, I_3\}$ by the following definition:

$$B\varphi \leftrightarrow \langle K\rangle K\varphi \in \mathsf{L} \qquad (\mathsf{Def\ B})$$

Consequently, the belief modality B is also defined by (Def B) *in any logic containing* L.

This result can be contrasted with Theorem 4.8 of (Halpern, Samet, and Segev 2009a), from which it follows that the belief modality can*not* be explicitly defined in the logic $(\mathsf{S4.x})_K + (\mathsf{KD45})_B + \{I_1, I_2\}$, for any $\mathsf{x} \in \{.2, .4\}$. On the other hand, as Theorem 4.2 below shows, knowledge can be defined in terms of belief only if the logic of knowledge is S4.4, but not if the logic of knowledge is S4 or S4.2.

Theorem 4.2. *(Aucher 2014)*

- *The knowledge modality K is explicitly defined in the logic $\mathsf{L.4} := \mathsf{S4.4}_K + \mathsf{KD45}_B + \{I_1, I_2, I_3\}$ by the following definition:*

$$K\varphi \leftrightarrow \varphi \wedge B\varphi \in \mathsf{L.4} \qquad (\mathsf{Def\ K})$$

- *The knowledge modality K cannot be explicitly defined in the logic $\mathsf{S4.2}_K + \mathsf{KD45}_B + \{I_1, I_2, I_3\}$.*

Again, this result can be contrasted with Theorem 4.1 of (Halpern, Samet, and Segev 2009a), from which it follows that the knowledge modality can*not* be explicitly defined in the logic $(\mathsf{S4.4})_K + (\mathsf{KD45})_B + \{I_1, I_2\}$. We see that in both cases the increase in expressivity due to the addition of the interaction axiom I_3 plays an important role in bridging the gap between belief and knowledge.

Theorem 4.3.

- *The axiom .2 is characterized w.r.t. the pair $(\mathsf{S4}_K, \mathsf{KD45}_B)$ by the set of interaction axioms $\{I_1, I_2, I_3\}$.*
- *The axiom .4 is conservatively characterized w.r.t. the pair $(\mathsf{S4}_K, \mathsf{KD45}_B)$ by the interaction axiom I_4.*

Proof. It follows from a direct application of Theorem 2.2 to the results of (Lenzen 1979), namely the facts that $\mathsf{S4}_K + \mathsf{KD45}_B + \{I_1, I_2, I_3\} = \mathsf{S4.2}_K + \{B\varphi \leftrightarrow \langle K\rangle K\varphi\}$ and $\mathsf{S4}_K + \mathsf{KD45}_B + \{I_4\} = \mathsf{KD45}_B + \{I_4\} = \mathsf{S4.4}_K + \{B\varphi \leftrightarrow \langle K\rangle K\varphi\}$. □

5 Conclusion

Theorem 4.3 tells us that if we use S4.4 as the logic of knowledge (and KD45 as the logic of belief), then we implicitly assume that knowledge is in fact true belief (a rather strong assumption for knowledge). Although it was acknowledged by all epistemic logicians that axiom .4 characterized knowledge as true belief, this could never be justified and explained rigorously. We claim that our meta-theory of modal logic fills this conceptual gap. Likewise, if we use S4.2 as the logic of knowledge (and KD45 as the logic for belief), then Theorem 4.3 tells us that, by doing so, we are only assuming that the agent knows his beliefs and disbeliefs and that his beliefs are in fact certainties, convictions, and not simply weak beliefs.

Overall, our meta-theory of modal logic enables to carry out a rigorous and fine-grained analysis of the intuitive assumptions underlying the logics of knowledge between S4 and S5. This theory provides a meaningful logical foundation for these analysis and can serve as a means to justify and explain the intuitive arguments employed.

Stable Models of Multi-Valued Formulas: Partial versus Total Functions

Michael Bartholomew and Joohyung Lee
School of Computing, Informatics, and Decision Systems Engineering
Arizona State University, Tempe, AZ, USA
{*mjbartho,joolee*}*@asu.edu*

Abstract

Recent extensions of the stable model semantics that allow *intensional* functions—functions that can be specified by logic programs using other functions and predicates—can be divided into two groups. One group defines a stable model in terms of minimality on the values of partial functions, and the other defines it in terms of uniqueness on the values of total functions. We show that, in the context of multi-valued formulas, these two different approaches can be reduced to each other, and further, each of them can be viewed in terms of propositional formulas under the stable model semantics. Based on these results, we present a prototype implementation of different versions of functional stable model semantics by using existing answer set solvers.

Introduction

The original stable model semantics (Gelfond and Lifschitz 1988) and many extensions have been restricted to Herbrand models, where the role of functions is quite limited. Recently a few extensions of the stable model semantics were proposed to allow *intensional* functions—functions that can be specified by logic programs using other functions and predicates. Despite the different forms in which these semantics were defined, they can be essentially divided into two groups. One group defines a stable model in terms of "minimality on the values of partial functions" (Cabalar 2011; Balduccini 2013) and the other defines it in terms of "uniqueness on the values of total functions" (Lifschitz 2012; Bartholomew and Lee 2012). While it is known that they coincide on some class of formulas (Bartholomew and Lee 2013), it does not look obvious if they can be reduced to each other in full generality. Further, it is not obvious how mathematical results in answer set programming that have been established in the absence of intensional functions would carry over to these extensions.

In this note, we address such issues in the context of multi-valued formulas—a simple extension of standard propositional formulas where atoms can express functions mapping to finite domains. The convenience of using multi-valued formulas for knowledge representation is demonstrated in the context of nonmonotonic causal theories and action languages $\mathcal{C}+$ (Giunchiglia et al. 2004) and $\mathcal{BC}$ (Lee, Lifschitz, and Yang 2013). For this paper, multi-valued formulas serve as a simple but useful special case of first-order formulas to compare different extensions of the functional stable model semantics.

The total function based stable model semantics for multi-valued formulas is defined in (Bartholomew and Lee 2012). Here, following (Cabalar 2011; Balduccini 2013), we define the partial function based stable model semantics, which we call the CB-stable model semantics. This is essentially a generalization of the semantics from (Balduccini 2013). We show that multi-valued formulas under these functional stable model semantics can be viewed in terms of propositional formulas under the stable model semantics, with a slight difference to each other. This finding reveals the close relationship between the functional stable model semantics and their relationships to the propositional stable model semantics, and allows us to easily relate the mathematical results established for propositional formulas, such as the theorem on strong equivalence (Lifschitz, Pearce, and Valverde 2001) and the splitting theorem (Ferraris et al. 2009), to multi-valued formulas. In (Lee, Lifschitz, and Yang 2013), action language $\mathcal{BC}$ is defined by a translation to multi-valued formulas and by a translation to logic programs. The equivalence between the two translations follows from our finding.

Given that both versions of the functional stable model semantics can be reduced to the propositional stable model semantics, one may wonder about the relationship between the two versions of the functional stable model semantics. Interestingly, we show that the functional stable model semantics that is based on partial functions can be fully embedded into the one that is based on total functions.

These results provide a way to implement the functional stable model semantics using existing ASP solvers. We present system MVSM based on this idea. The system is essentially a preprocessor to F2LP (Lee and Palla 2009), which in turn is a preprocessor to the ASP grounder GRINGO.

Multi-Valued Formulas under the Stable Model Semantics

Review: Stable Models of Multi-Valued Formulas

A (multi-valued) signature is a finite set σ of symbols called *constants*, along with a finite set $Dom(c)$ of symbols that is disjoint from σ and contains at least two elements, assigned

Copyright © 2014, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

to each constant c. We call $Dom(c)$ the *domain* of c. A *multi-valued atom* of σ is $\bot$, or an expression of the form $c=v$ ("the value of c is v") where $c \in \sigma$ and $v \in Dom(c)$. A *(multi-valued) formula* of σ is a propositional combination of multi-valued atoms.

A *(multi-valued) interpretation* of σ is a function that maps every element of σ to an element in its domain. A multi-valued interpretation I *satisfies* an atom $c=v$ (symbolically, $I \models c=v$) if $I(c) = v$. The satisfaction relation is extended from atoms to arbitrary formulas according to the usual truth tables for the propositional connectives. We often identify an interpretation with the set of atoms of σ that are satisfied by I. We say that I is a *(multi-valued) model* of F if it satisfies F.

We understand an expression of the form $c = d$, where both c and d are constants, as an abbreviation for the formula

$$\bigvee_{v \in Dom(c) \cap Dom(d)} (c=v \wedge d=v). \tag{1}$$

Let F be a multi-valued formula of signature σ, and let I be a multi-valued interpretation of σ. The *reduct* of F relative to I (denoted $F^{\underline{I}}$) is the formula obtained from F by replacing each (maximal) subformula that is not satisfied by I with $\bot$. We call I a *multi-valued stable model* of F if I is the *only* multi-valued interpretation of σ that satisfies $F^{\underline{I}}$.

Example 1 *Take $\sigma = \{c\}$ and $Dom(c) = \{1,2,3\}$, and let F_1 be $c = 1 \vee \neg(c = 1)$ and let I_i ($i = 1,2,3$) be the interpretation that maps c to i. All three interpretations satisfy F_1, but I_1 is the only stable model of F_1: the reduct $F_1^{\underline{I_1}}$ is $c = 1 \vee \bot$, and I_1 is the only model of the reduct; the reduct of F_1 relative to other interpretations is $\bot \vee \neg\bot$, which does not have a unique model.*

If we conjoin $c = 2$ with F_1, we can check that the only stable model is $c=2$, which illustrates the nonmonotonicity of the semantics.

As shown in Example 1, formulas of the form $F \vee \neg F$ under the stable model semantics are useful for representing the concept of defaults involving functions. We abbreviate $F \vee \neg F$ as $\langle F \rangle$. For example, F_1 above can be written as $\langle c = 1 \rangle$.

Reducing Multi-Valued SM to Propositional SM

In this section we show that the multi-valued stable model semantics can be viewed as a special case of the propositional stable model semantics. Let σ be a multi-valued signature, and let σ^{prop} be the propositional signature consisting of all propositional atoms $c = v$ where $c \in \sigma$ and $v \in Dom(c)$. For example, for σ in Example 1, σ^{prop} is the set $\{c=1, c=2, c=3\}$, where each element is understood as a propositional atom. We identify a multi-valued interpretation of σ with the corresponding set of propositional atoms from σ^{prop}. It is clear that a multi-valued interpretation I of signature σ satisfies a multi-valued formula F iff I satisfies F when F is viewed as a propositional formula of signature σ^{prop}. Also, it is not difficult to show that multi-valued formulas can be turned into standard propositional formulas having the same *models*. Less obvious is whether such a translation exists while keeping same *stable models*. Theorem 1 below shows such a translation.

Given a multi-valued signature σ, by UC_σ ("Uniqueness Constraint") we denote the conjunction of

$$\bigwedge_{v \neq w \mid v,w \in Dom(c)} \neg(c = v \wedge c = w) \tag{2}$$

for all $c \in \sigma$, and by EC_σ ("Existence Constraint") we denote the conjunction of

$$\neg\neg \bigvee_{v \in Dom(c)} c = v\,, \tag{3}$$

for all $c \in \sigma$. By UEC_σ we denote the conjunction of (2) and (3) for all $c \in \sigma$. For instance, in Example 1, UEC_σ is

$$\neg(c=1 \wedge c=2) \wedge \neg(c=2 \wedge c=3) \wedge \neg(c=1 \wedge c=3) \wedge \neg\neg(c=1 \vee c=2 \vee c=3)\,.$$

Theorem 1 *Let F be a multi-valued formula of signature σ, which can be also viewed as a propositional formula of signature σ^{prop}.*

(a) If an interpretation I of σ is a multi-valued stable model of F, then I can be viewed as an interpretation of σ^{prop} that is a propositional stable model of $F \wedge UEC_\sigma$ in the sense of (Ferraris 2005).

(b) If an interpretation I of σ^{prop} is a propositional stable model of $F \wedge UEC_\sigma$ in the sense of (Ferraris 2005), then I can be viewed as an interpretation of σ that is a multi-valued stable model of F.

Note that the presence of $\neg\neg$ in (3) is essential for Theorem 1 to be valid. For instance, consider the signature containing only one constant d whose domain is $\{1,2\}$ and F to be $\top$. F has no multi-valued stable models, but $F \wedge \neg(d=1 \wedge d=2) \wedge (d=1 \vee d=2)$ has two propositional stable models: $\{d=1\}$ and $\{d=2\}$.

Multi-Valued Formulas under the CB-Stable Model Semantics

CB-Stable Models of Multi-Valued Formulas

In this section we introduce a variant of the stable model semantics in the previous section, which we call the CB-stable model semantics. Unlike the previous section, this section allows interpretations to be partially defined. That is, some constants might not be mapped to any values. By *complete* interpretations, we mean a special case of partial interpretations where all constants are defined, which can be identified with "total" interpretations in the previous section.

We consider the same syntax of a multi-valued formula as in the previous section. As with total interpretations, a partial interpretation I *satisfies* an atom $c = v$ if $I(c)$ is defined and is mapped to v. This implies that an interpretation that is undefined on c does not satisfy any atom of the form $c = w$ for any $w \in Dom(c)$. As before, it is convenient to identify a partial interpretation I with the set of atoms of σ that are satisfied by this interpretation. For instance, an interpretation of $\sigma = \{c\}$ which is undefined on c is identified with the empty set. Again, the satisfaction relation is extended from atoms to arbitrary formulas according to the usual truth tables

for the propositional connectives. We call I a *model* of F if it satisfies F.

The reduct $F^{\underline{I}}$ is defined to be the same as before. We say that a partial interpretation I is a *CB-stable model* of F if I satisfies F and no proper subset J of I satisfies $F^{\underline{I}}$.

Example 1 Continued *Under the CB-stable model semantics, $\langle c=1\rangle$ does not mean that c is mapped to 1 by default. Instead, it means that c can be mapped to 1 or undefined. As before, the reduct $F_1^{\underline{I_1}}$ relative to $I_1 = \{c=1\}$ is $c=1 \vee \bot$, and I_1 is the minimal model of the reduct.*[1] *Further, for I_0 that leaves c undefined, the reduct $F_1^{\underline{I_0}}$ is $\bot \vee \neg\bot$, and I_0 is the minimal model of the reduct.*

This difference in understanding $\langle F\rangle$ tells us that multi-valued stable models are more convenient for representing the commonsense law of inertia. For instance,

$$Loc_0 = Kitchen \rightarrow \langle Loc_1 = Kitchen\rangle$$

represents under the multi-valued stable model semantics that the location does not change by default, but under the CB-stable model semantics, the location may become unknown as well.

Reducing CB-Stable Models to Propositional SM

Similar to Theorem 1, the following theorem tells us that the CB-stable models of a multi-valued formula can be identified with the stable models of a propositional formula. The only difference is that we impose UC_σ in place of UEC_σ.

Theorem 2 *Let F be a multi-valued formula of signature σ, which can be also viewed as a propositional formula of signature σ^{prop}.*

(a) If a partial interpretation I of σ is a CB-stable model of F, then I can be viewed as an interpretation of σ^{prop} that is a propositional stable model of $F \wedge UC_\sigma$ (in the sense of (Ferraris 2005)).

(b) If an interpretation I of σ^{prop} is a propositional stable model of $F \wedge UC_\sigma$ (in the sense of (Ferraris 2005)), then I can be viewed as a partial interpretation of σ that is a CB-stable model of F.

Reducing CB Semantics to Multi-Valued SM

Reducing Multi-Valued SM to CB-Stable Models

The following corollary immediately follows from Theorems 1 and 2. It tells us that the multi-valued stable model semantics can be fully embedded into the CB-stable model semantics.

Corollary 1 *For any multi-valued formula F of signature σ and any partial interpretation I, we have that I is a multi-valued stable model of F iff I is a CB-stable model of $F \wedge EC_\sigma$.*

Unlike the way we treat $c = d$ as an abbreviation of (1), in (Balduccini 2013), it was called a *t-atom*, for which the notion of satisfaction was defined directly: *I satisfies $c = d$* if I is defined on both c and d, and maps them to the same value. This is essentially equivalent to the way we understand $c = d$ as shorthand for formula (1).[2]

Since I satisfies $c = c$ iff I is defined on c, the assertion in Corollary 1 remains valid when we replace EC_σ in the statement with $\neg\neg\Big(\bigwedge_{c\in\sigma} c = c\Big)$.

Reducing CB-Stable Models to Multi-Valued SM

Any multi-valued stable model of a formula is a CB-stable model, but not vice versa because an incomplete partial interpretation has no direct counterpart as a total interpretation. It may not look obvious how the CB-stable model semantics (based on partial functions) can be reduced to the multi-valued stable model semantics (based on total functions). Nevertheless, we show that it is possible.

Let σ be a multi-valued signature, and let σ^{none} be the signature that is the same as σ except that the domain of each constant has an additional new value NONE. Given a partial interpretation I of σ, by I^{none} we denote an interpretation of σ^{none} that agrees with I on all defined constants, and maps undefined constants to NONE. Recall that expression $\langle F\rangle$ stands for the formula $F \vee \neg F$.

Theorem 3 *Let F be a multi-valued formula of signature σ.*

(a) If an interpretation I of σ is a CB-stable model of F, then I^{none} is a stable model of $F \wedge \bigwedge_{c\in\sigma}\langle c=\text{NONE}\rangle$.

(b) If an interpretation J of σ^{none} is a stable model of $F \wedge \bigwedge_{c\in\sigma}\langle c = \text{NONE}\rangle$ then $J = I^{none}$ for some CB-stable model I of F.

For instance, in Example 1, the CB-stable models of F_1 are in a 1-1 correspondence with the stable models of $F_1 \wedge \langle c=\text{NONE}\rangle$.

System MVSM

System `mvsm`[3] is a prototype implementation of multi-valued formulas under the stable model semantics. In fact, it is a script that invokes several software, such as MVPF2LPCOMPILER, F2LP, GRINGO, CLASPD, and AS2TRANSITION. MVPF2LPCOMPILER is an implementation of the translations in Theorem 1 and Theorem 2, which translates multi-valued formulas under the stable model semantics into standard propositional formulas under the stable model semantics. As the theorems show, the translations are very similar, and the user can choose which translation to use. F2LP then transforms the propositional formula into an ASP program in the input language of GRINGO v3. AS2TRANSITION takes the output of CLASPD and outputs propositional atoms in the form of multi-valued atoms. The composition of these software is depicted in Figure 1.

Shown below is a description of the blocks world domain in the language of MVSM assuming the multi-valued stable model semantics. The syntax of declarations follows the one in the input language of the Causal Calculator v2.[4] Compared

[1] Minimality is understood in terms of set inclusion.

[2] In a sense, our treatment is more general because it allows the domains of c and d to be different.

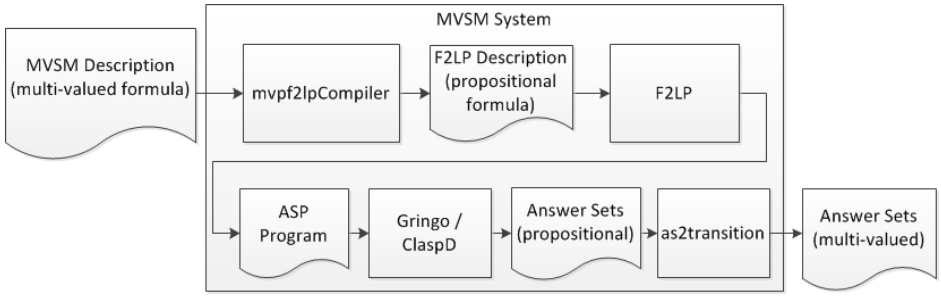

Figure 1: Architecture of MVSM

to the usual ASP encoding, explicit declaration of sorts and type checking help reduce the programmer's mistakes. The inertia and exogeneity assumptions in the last three rules have simple reading, once we understand $\langle F \rangle$ as representing defaults ($\{\ldots\}$ was used in place of $\langle \ldots \rangle$). There is no need to use strong negation.

Rough Set Semantics for Identity on the Web

Abstract

Identity relations are at the foundation of many logic-based knowledge representations. We argue that the traditional notion of equality, is unsuited for many realistic knowledge representation settings. The classical interpretation of equality is too strong when the equality statements are re-used outside their original context. On the Semantic Web, equality statements are used to interlink multiple descriptions of the same object, using `owl:sameAs` assertions. And indeed, many practical uses of `owl:sameAs` are known to violate the formal Leibniz-style semantics.

We provide a more flexible semantics to identity by assigning meaning to the subrelations of an identity relation in terms of the predicates that are used in a knowledge-base. Using those indiscernability-predicates, we define upper and lower approximations of equality in the style of rought-set theory, resulting in a quality-measure for identity relations.

1 Introduction

Identity relations are a cornerstone of logic-based knowledge representation. They allow to state and relate properties of an object using multiple names for that object, and conversely, they allow to infer that different names actually refer to the same object.

Identity relations are at the foundation of the Linked Open Data initiative and the Semantic Web (SW) in general. The SW consists of sets of assertions that are published on the Web by different authors operating in different contexts, often using different names for the same object. Identity relations allow the interlinking of these multiple descriptions of the same thing.

Identity is often understood as the sharing of all properties between two objects with different names (principle of indiscernibility). In the SW this traditional notion of identity is expressed by the `owl:sameAs` property.
According to the traditional semantics of the identity relation, identical terms can be replaced for one another in all non-modal contexts *salva veritate*. Practical uses of `owl:sameAs` are known to violate this strict condition (Halpin et al. 2010a; 2010b).

On the SW, identity assertions are extra strong because of the Open World Assumption. Stating that two objects are the same implies that from now on no new property can be stated about only one of those objects Moreover, whether or not two objects share the absence of a property cannot be concluded based on the absence of a property assertion.

Improving on the existing semantics of identity, we have the following research goals:

1. In an identity relation the pairs all look the same. We want to characterize subrelations of an identity relation in terms of the predicates that are important in a particular context.
2. Based on an existing identity relation we want to give semantically motivated suggestions for extending or limiting the identity relation.
3. We want to assess the quality of an identity relation based on the consistency with which it is applied to the data.

2 Related work

Existing research suggests six different solutions for the problem of identity on the SW.

[1] Introduce weaker versions of `owl:sameAs` (Halpin et al. 2010a; McCusker and McGuinness 2010). Candidates for replacement are the SKOS concepts `skos:related` and `skos:exactMatch`. The former is not transitive, thereby limiting the possibilities for reasoning. The latter is transitive, but can only be used in certain contexts. It is not defined in what contexts it can be used.

[2] Restrict the applicability of identity relations to specific contexts. In terms of SW technology, identities are expected to hold within a named graph or within a namespace, but not necessarily outside of it (Halpin et al. 2010a). (de Melo 2013) has successfully used the Unique Names Assumption within namespaces in order to identify many (arguably) spurious identity statements.

[3] Introduce additional vocabulary that does not weaken but extend the existing identity relation. (Halpin et al. 2010a) mention an explicit distinction that can be made between mentioning a term and using a term. Other possible extensions of `owl:sameAs` take the Fuzzyness and/or uncertainty of identity statements into account.

[4] Use domain-specific identity relations (McCusker and McGuinness 2010). Such domain-specific links are only locally valid, thereby limiting knowledge reuse.

[5] Change the modeling practice (Halpin et al. 2010a; Ding et al. 2010a). Introducing checks on editing operations

Copyright © 2014, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

violates one of the fundamental underpinnings of the SW: that anybody is allowed to say anything about anything (Antoniou et al. 2012).

(Ding et al. 2010b) who show that network analysis of the occurrence of `owl:sameAs` in datasets can provide insights into the ways in which identity is used. These latter endeavors have not yet been related to the semantics of identity.

3 Approach

First we give a short outline of our approach and then we provide a more detailed description of the individual steps.

Outline of the approach

We start by assuming that we are given an identity relation $\approx$. We will then reinterpret this relation as an indiscernibility relation relative to different sets of predicates. Pairs that have the same indiscernibility predicates are simi-discernible, i.e.: they discern resources based on the same criteria. Simi-discernibility is an equivalence relation which partitions all pairs and thus also the identity relation $\approx$. The members of the indiscernibility partition have a certain overlap with the original identity relation. The overlap between an indiscernibility subset and the identity relation is called an *identity subrelation*. Each identity subrelation is characterized in terms of predicates from the domain vocabulary. Different forms of identity can therefore be distinguished and meaningfully described. Based on whether there is a complete or a partial overlap between the simi-discernible partition members and the identity subrelations, these partition members belong either to the lower ($\underline{\approx}$) or to the higher approximation ($\overline{\approx}$) of $\approx$. Besides setting a lower and a higher bound to the identity relation, we can also calculate the quality of the identity relation and the precision of each identity subrelation.

Preliminaries

G denotes an RDF graph. It consists of a set of ground binary predicates $p(s, o)$, called "triples" in SW jargon, and often written as $\langle s, p, o\rangle$. These triples form a graph with all subjects s and objects o as nodes, and each assertion $p(s, o)$ corresponds to a directed edge labelled p between s and o.

We identify subsets of RDF terms based on their positional occurrence in triples in G: S_G, P_G, and O_G denote the subject, predicate and object terms in G respectively.

The interpretation I maps RDF terms onto resources, and triples onto truth values. The extension function Ext maps resources onto pairs of resources. $I(\langle s, p, o\rangle)$ is true iff $\langle I(s), I(o)\rangle \in Ext(I(p))$.

Reinterpreting identity as indiscernibility

We start by assuming that we are given an identity relation $\approx$, which partitions the subject terms S_G according to equation 1.

$$[x]_{\approx} = \{y \in S_G \mid x \approx y\} \tag{1}$$

Identity can be defined as the smallest equivalence relation, i.e. the most fine-grained partition of S_G. For reasoning purposes, the fact that $\approx$ is an equivalence relation is important, allowing symmetrical and transitive inferences. Identity implies indiscernibility with respect to all properties.

We can generalize the notion of indiscernibility by parameterizing the set of properties with respect to which indiscernibility is determined. According to this generalization, resources x and y are indiscernible with respect to a set of properties $PO \subseteq P_G \times O_G$ iff $\forall po \in PO(po(x) \leftrightarrow po(y))$ is the case. Every indiscernibility relation is also an equivalence relation, although not necessarily the smallest one. Moreover, every indiscernibility relation defined over the domain S_G is also an identity relation, but over a different domain.

We now reinterpret the identity relation $\approx$ as if it were an indiscernibility relation whose set of properties PO is implicit. Based on the extensional specification of the identity relation, we make the set of properties with respect to which it is indiscernible explicit. Definition 1 makes explicit the properties relative to which the terms x_i are indiscernibile.

Definition 1 (Indiscernibility properties).

$$\mathbb{IND}\text{-}\mathbb{PO}_{\approx}(\{x_1, \ldots, x_n\}) = \{\langle p, o\rangle \in P_G \times O_G \mid \bigwedge_{1 \le i \le n} \exists p_i \in [p]_{\approx}, \exists o_i \in [o]_{\approx}(\langle x_i, p_i, o_i\rangle \in G)\}$$

Notice that in definition 1 we close both the predicate terms p and the object terms o under identity. Performing these closures is important in order to identify the relevant indiscernibility properties.

In the above, we were interested in the properties that resources share with one other. But we are also interested in the predicates that are shared by a set of resources. This amounts to a simple abstraction of definition 1, equating the sets of objects (closed under identity) and only returning the set of shared RDF predicate terms (see definition 2).

Definition 2 (Indiscernibility predicates).

$$\mathbb{IND}\text{-}\mathbb{P}_{\approx}(\{x_1, \ldots, x_n\}) = \{p \in P_G \mid \exists_{p_1,\ldots,p_n \in [p]_{\approx}}([\{o \in O_G \mid \langle x_1, p_1, o\rangle\}]_{\approx} = \ldots = [\{o \in O_G \mid \langle x_n, p_n, o\rangle\}]_{\approx})\}$$

Discerning the same

In the previous section we saw that resources are *indiscernible* with respect to PO iff they cannot be told apart in a language that only contains the properties denoted by PO (the so-called indiscernibility properties):

In the same vein, and builing upon definition 2, we say that two pairs of resources are *simi-discernible* iff their indiscernibility predicates $P \subseteq P_G$ are the same.

When we look at the pairs that constitute (the extension of) an identity relation, all identity assertions look the same. But when we take the considerations of the previous section into account, we see that within a given identity relation there are pairs that assert indiscernibility based on different domain predicates. Stating this formally, simi-discernibility is an equivalence relation on pairs of resources, which induces a partition of the Cartesian product of the domain. Definition 3 makes this concrete in terms of the earlier definitions.

Definition 3 (Simi-discernibility relation).

$$\equiv_{\mathbb{IND}\text{-}\mathbb{P}_{\approx}} = \{\langle\langle x_1, x_2\rangle, \langle y_1, y_2\rangle\rangle \in (S_G^2)^2 \mid \mathbb{IND}\text{-}\mathbb{P}_{\approx}(\{x_1, x_2\}) = \mathbb{IND}\text{-}\mathbb{P}_{\approx}(\{y_1, y_2\})\}$$

Partitioning identity

The members of the partition induced by $\equiv_{\mathbb{IND}\text{-}\mathbb{P}_{\approx}}$ are sets of resource pairs that share the same sharing properties.

Notice that the partitioned pairs contain but are not limited to the identity pairs. Therefore, for sets of pairs closed under simi-discernibility we have the following three possibilities:

1. All pairs are identity pairs. This characterizes a consistent portion of the identity relation, since no simi-discernible pair is left out of this set.
2. Some pairs are identity pairs. This characterizes a portion of the identity relation which is not applied consistently with respect to the simi-discernibility relation.
3. No pairs are identity pairs. This characterizes a portion of the collection of pairs that is consistently kept out of the identity relation.

Each member of the simi-discernibility partition that is not of the third kind, i.e. every set of pairs that contains some identity pair, can be though of as an identity subrelation. The simi-discernibility partition also partitions the identity relation into *identity subrelations*. Each identity subrelation can be described in terms of its discernibility predicates, i.e. in meaningful terms drawn from the domain vocabulary.

Quality & Approximation

Not all identity subrelations have the same quality. Indeed, when we look at the subdivision into three 'categories' above, we are able to distinguish between a lower approximation of identity, as the union of subrelations from the first category (definition 4), and a higher approximation of identity, as the union of subrelations from both the first and the second category (definition 5).

Definition 4 (Lower approximation).

$$x \in \underline{\approx} \iff \{y \mid x \equiv_{\mathbb{IND}\text{-}\mathbb{P}_{\approx}} y\} \subseteq \approx$$

Definition 5 (Higher approximation).

$$x \in \overline{\approx} \iff \{y \mid x \equiv_{\mathbb{IND}\text{-}\mathbb{P}_{\approx}} y\} \cap \approx \neq \emptyset$$

Based on these approximations we can give the rough set representation $\langle \underline{\approx}, \overline{\approx} \rangle$ of identity relation $\approx$. The quality of a rough set representation is given in definition 6. The intuition behind this quality measure is that the crispness of a set should be proportional to the quality of the identity relation on which it is based. Since a consistently applied identity relation has relatively many partition sets that contain either no identity pairs (small value for $\underline{\approx}$) or only identity pairs (large value for $\overline{\approx}$), a more consistent identity relation has a higher accuracy.

Definition 6 (Quality).

$$\alpha(\approx) = \frac{|\underline{\approx}|}{|\overline{\approx}|}$$

4 Conclusion

In this paper we presented a new approach for characterizing, extending, retracting, and assessing identity relations. Our approach does this in purely qualitative terms, using schema semantics.

In section 1 we enumerated three research goals. The first goal is met, since an indiscernibility partition characterizes identity subrelations based on the predicates P (closed under identity) for which the pairs in that sets are indiscernible. In this way we can distinguish between different types of identity by treating P as a description of a (sub)set of identity pairs. We suggest that the meaning of an identity relation and its subrelations is partially defined in its use, i.e., in the indiscernibility criteria it embodies.

The second goal is met, since the notion of a rough set allows us to distinguish between pairs that must be (lower approximation) and those that may be (higher approximation) in the identity relation. If we want to add/remove pairs of the identity relation, we should not consider pairs of the former but only pairs of the latter kind.

The third goal is met, since the measure for rough set accuracy is based on the discernibility criteria of an identity set. The crispness of the set is proportional to the quality of the identity relation, based on its semantic consistency.

Abstract

In a seminal paper, Lin and Reiter introduced the progression of basic action theories in the situation calculus. In this paper, we study the progression of knowledge in multiagent settings, where after actions, an agent updates her beliefs but also updates what she believes other agents know given what has occurred. By appealing to the notion of only knowing, we are able to avoid limitations of earlier work on multiagent progression, and obtain a new general account: we show that after an action, knowledge bases are updated in a Lin and Reiter fashion at every nesting of modalities. Consequently, recent results on the first-order definability of progression carry over to a multiagent setting without too much effort.

Introduction

Long-lived agents, such as autonomous robots, have to operate purposefully after thousands of actions. As argued in (Reiter 2001), there is only one computational methodology that addresses this problem at large: the idea of *progressing* the current world state, investigated in a general way for the language of the situation calculus in (Lin and Reiter 1997). Indeed, applying repeated regression over so many actions would simply not be feasible. STRIPS technology is a simple form of progression, Lin and Reiter (LR) observe, but in an open-world setting with non-trivial action types, appealing to second-order logic is necessary (Vassos and Levesque 2008). Nonetheless, LR identified two simple cases where progression is first-order definable, and other companion results have been identified since (Liu and Lakemeyer 2009).

However, LR did not consider knowledge. The progression of epistemic theories is very easily motivated in a world where the agent can both *act* and *sense*, and the agent would deliberate on her actions based on what she knows and does not know. An equally compelling case for the progression of knowledge is in multiagent settings, such as the ones robots would inhabit. Here, it is reasonable that after actions, for computational reasons among others, an agent updates her beliefs but also updates her beliefs about what others know given that these actions have occurred.[1] Imagine, for example, a simple domain, involving agents a and b looking for gold (Figure 1). When a observes b moving to Room 2 and looking through its window, her beliefs would be as follows:

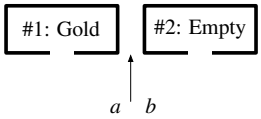

Figure 1: Agents a and b look for a room with gold.

- she still does not know where the gold is;
- a knows that b knows whether Room 2 has the gold, but cannot say what b now knows.

In general, then, progression should say precisely how a's knowledge and a's beliefs about b's knowledge would be updated after any sequence of physical and sensing actions.[2]

The progression of knowledge in the single agent case is considered in (Liu and Wen 2011), but under syntactic restrictions to the initial theory, such as limitations on quantifying-in, and that knowledge does not appear negatively. The progression of knowledge is also considered in (Lakemeyer and Levesque 2009). The results here are general. By appealing to Levesque's (1990) logic of *only knowing*, they obtain a simple specification: given an agent who only knows an action theory, the result of doing an action is that the agent only knows the LR progression of this theory.

The progression of knowledge in the multiagent case is also considered in (Liu and Wen 2011). In addition to the above limitations, formulas such as $\boldsymbol{K}_i p$, where p is objective, can be progressed, but not $\boldsymbol{K}_i \boldsymbol{K}_j \boldsymbol{K}_i p$. That is, among other things, they cannot deal with an agent's beliefs about what others believe about her. In this work, we substantially improve and extend these results. We provide a new general account of the progression of knowledge in multiagent systems that is essentially equivalent to the results in (Lakemeyer and Levesque 2009) when only a single agent is concerned. As a simple consequence of this work, earlier advances on tractable progression apply easily to our results.

[1] We use the terms "knowledge" and "belief" interchangeably, and never require that knowledge needs to be true in the real world.

[2] For simplicity, executed actions are assumed to be publicly observable, even if the information that agents receive may be private and unobservable.

Logical Foundations

The language is a second-order modal dialect with equality, and can be thought of as a situation-suppressed epistemic version of Reiter's (2001) situation calculus, as defined in (Lakemeyer and Levesque 2009). We will not go over the details here, except to note:

- the symbols of the language consist of first-order variables, second-order predicate variables, rigid functions, fluent predicate symbols, as well as these connectives and other symbols: $=, \wedge, \neg, \forall, \Box$, epistemic modalities, parentheses, period, comma;
- the language includes a countably infinite supply of *rigid terms*, which we denote R, that are taken to be isomorphic to the *domain of discourse*;
- *multiagent knowledge* and *only knowing*: the language includes modalities $\boldsymbol{K}_i$ and $\boldsymbol{O}_i$ to reason about what i knows as well as what i only knows;
- *sensing*: every action is assumed to have a binary sensing result. After an action, the agent comes to know that the action was executable (via a special symbol *Poss*), and whether the corresponding sensing outcome holds (via a special symbol SF_i). For simplicity, we keep sensing actions separate from physical ones which only affect the world but do not provide any knowledge to the agent.

A semantics is provided for well-formed formulas in this language by means of *possible worlds*. Formally, let $\mathcal{Z}$ be the set of all finite sequences of elements of R including $\langle\rangle$, the empty sequence. $\mathcal{Z}$ should be understood as the set of all finite sequences of actions. Then a *world* $w \in \mathcal{W}$ is any function from G (the set of ground atoms) and $\mathcal{Z}$ to $\{0, 1\}$.

To interpret epistemic operators, and only knowing in particular, we appeal to the notion of k-structures (Belle and Lakemeyer 2010). For ease of exposition, assume that there are only 2 agents: a (Alice) and b (Bob); a generalization to more agents is straightforward. Then,

Definition 1: A k-structure ($k \geq 1$), say e^k, for an agent is defined inductively as:

- $e^1 \subseteq \mathcal{W} \times \{\{\}\}$,
- $e^k \subseteq \mathcal{W} \times \mathbb{E}^{k-1}$, where $\mathbb{E}^m$ is the set of all m-structures.

Intuitively, a k-structure for a, denoted e^k_a, determines what a believes about the world, but also at each world, what a believes b to know, to depth $k-1$. Such an epistemic state captures the initial beliefs of an agent, and of course, as the agent acts and senses in the world, some possibilities would be discarded. To enable this, we define $w' \simeq^i_z w$ (read: "i considers w' to agree with w on the sensing results throughout action sequence z") inductively by the following:

- $w' \simeq^i_{\langle\rangle} w$ for all w';
- $w' \simeq^i_{z \cdot t} w$ iff $w' \simeq^i_z w$, $w'[Poss(t), z] = 1$ and $w'[SF_i(t), z] = w[SF_i(t), z]$.

Putting all these together, we now turn to the semantic rules for sentences of the logic. These will be defined wrt a world w, an action sequence z, a variable map μ to interpret quantification over second-order variables (see (Lakemeyer and Levesque 2009)) a structure of some depth for a, say e^k_a, and a structure of some depth for b, say e^l_b.[3] The rules for the formulas in the language are given inductively, as usual. The cases for formulas not mentioning epistemic operators is as discussed in (Lakemeyer and Levesque 2009). For epistemic operators, we use the following definition:

Definition 2: Let w be a world, e^k_i a k-structure and z any sequence of actions. Then:

- w_z is a world such that $w_z[p, z'] = w[p, z \cdot z']$ for all ground atoms p and action sequences z';
- $(e^k_i)^w_z$ is defined inductively:
  - $(e^1_i)^w_z = \{(w'_z, \{\}) \mid (w', \{\}) \in e^1_i \text{ and } w' \simeq^i_z w\}$;
  - $(e^k_i)^w_z = \left\{(w'_z, (e^{k-1}_j)^{w'}_z) \mid (w', e^{k-1}_j) \in e^k_i \text{ and } w' \simeq^i_z w\right\}$.

Here, w_z is exactly like w after z. Thus, it is intuitive to think of w_z as the *progression* of w wrt z, and analogously, $(e^k_i)^w_z$ is the progression of e^k_i wrt z given the (real) world w. Indeed, when we progress the structures in e^k_i we are insisting that only those worlds which are compatible with w are considered.[4] Then, the rules for epistemic operators are as follows:

- $e^k_a, e^l_b, w, z, \mu \models \boldsymbol{K}_a\alpha$ iff for all w', for all e^{k-1} for b, if $(w', e^{k-1}_b) \in (e^k_a)^w_z$ then $(e^k_a)^w_z, e^{k-1}_b, w', \langle\rangle, \mu \models \alpha$;
- $e^k_a, e^l_b, w, z, \mu \models \boldsymbol{O}_a\alpha$ iff for all w', for all e^{k-1} for b, $(w', e^{k-1}_b) \in (e^k_a)^w_z$ iff $(e^k_a)^w_z, e^{k-1}_b, w', \langle\rangle, \mu \models \alpha$.

The semantics for $\boldsymbol{K}_b$ and $\boldsymbol{O}_b$ is defined analogously.

Roughly speaking, then, i is said to know α after z at w iff all the structures in i's progressed epistemic state wrt (w, z) are those where α holds initially. Analogously, α is said to be only known after z at w if structures where α holds are precisely the ones in the progressed epistemic state.[5]

We say a sentence α is *satisfiable* if there is a model of "appropriate" depth where α is true (Belle and Lakemeyer 2010). We say α is *valid*, written $\models \alpha$, with the understanding that α is true wrt all models of the appropriate depth.[6]

Finally, the usual properties on introspection can be shown to hold for all action sequences. That is, both $\Box(\boldsymbol{K}_i\alpha \supset \boldsymbol{K}_i\boldsymbol{K}_i\alpha)$ and $\Box(\neg\boldsymbol{K}_i\alpha \supset \boldsymbol{K}_i\neg\boldsymbol{K}_i\alpha)$ are valid. Of course, from only knowing (Levesque 1990), we also get knowledge, that is, $\Box(\boldsymbol{O}_i\alpha \supset \boldsymbol{K}_i\alpha)$ is valid.

[3] The idea is that only formulas with some number of epistemic operators are interpreted wrt structures of a corresponding depth; see (Belle and Lakemeyer 2010) on how to make this precise.

[4] We remark that when constructing $(e^k_i)^w_z$, we use worlds w' that are compatible with w wrt i's sensing results, but then we progress the structures e^{k-1}_j that i considers possible for j at w' as if w' is the real world to obtain $(e^{k-1}_j)^{w'}_z$. The reason is that i simply does not know which world is the real one, and so at each of her possible worlds w', she would "progress" her version of j's epistemic state using w' instead of w.

[5] The difference between the rules for $\boldsymbol{K}_i\alpha$ and $\boldsymbol{O}_i\alpha$ is the "if" in the second line of the former *vs.* "iff" in the latter.

[6] In particular, it is possible to show that if a sentence is satisfiable wrt every model of the appropriate depth, it is also satisfiable wrt every model of higher depths (Belle and Lakemeyer 2010).

Basic Action Theories

We now consider the equivalent of Reiter's *action theories*, the components of which we illustrate using an example:[7]

Example 3: We develop a simple basic action theory for the gold domain in Figure 1, where the gold is to be found in either $r1$ (Room 1) or $r2$ (Room 2). We imagine a single physical action $mv(x, y)$ which gets the agent x to Room y, and a single sensing action $see(x, y)$ which allows the agent x to see through Room y's window and the action reports whether the gold is present. We also use a fluent $Gold(x)$ to say that Room x has the gold, and a fluent $At(x, y)$ to indicate that the agent x is at Room y. More precisely, the basic action theory we are imagining has the following components:

1. $\Box Poss(o) \equiv \exists x, y.\ o = see(x, y) \wedge At(x, y) \ \vee$
   $o = mv(x, y) \wedge true.$
2. $\Box[o]Gold(x) \equiv Gold(x).$
3. $\Box[o]At(x, y) \equiv o = mv(x, y) \ \vee$
   $At(x, y) \wedge \neg\exists u(o = mv(x, u)).$
4. $\Box SF_a(o) \equiv \exists x, y.\ o = see(x, y) \wedge x = a \wedge Gold(y) \ \vee$
   $o = see(x, y) \wedge x \neq a \wedge true.$
5. $\Box SF_b(o) \equiv \exists x, y.\ o = see(x, y) \wedge x = b \wedge Gold(y) \ \vee$
   $o = see(x, y) \wedge x \neq b \wedge true.$

Item 1 is a precondition axiom, items 2 and 3 are successor state axioms, and the remaining are sensing axioms. These latter axioms say this: if x is at y then its sensor would return *true* if y has the gold, and false otherwise. We assume that actions are always public in this work, and so we also need to describe what i learns when he senses j looking through the window. It is this definition that eventually leads to information asymmetry; here, we want that i does not obtain new knowledge on j's sensing. For example, SF_a will simply be *true* when $see(b, r1)$ is performed.

Finally, we want to also say that the gold is in Room 1, and so for an initial theory, we will have $\mathrm{KB}_0 = Gold(r1)$. Moreover, to say that the agents do not know where the gold is, let KB denote the conjunction of: $Gold(r1) \vee Gold(r2)$, $Gold(r1) \equiv \neg Gold(r2)$, and $\forall x, y \neg At(x, y)$. Then, lumping items 1-5 from the example as $\Box\beta$, the following sentence:

$$\mathrm{KB}_0 \wedge \boldsymbol{O}_a(\mathrm{KB} \wedge \Box\beta \wedge \boldsymbol{O}_b(\mathrm{KB} \wedge \Box\beta)) \qquad (1)$$

is a domain where Room 1 has the gold, a does not know where the gold is, and believes the same of b. In contrast, $(1) \wedge \boldsymbol{O}_b(\mathrm{KB}_0 \wedge \Box\beta)$ is a domain where, in fact, b does know where the gold is located and so, a has false beliefs about b.

Let us conclude the section with some entailments which will guide us when accounting for progression.

Proposition 4: *The following are entailed by* (1)*:*

1. $[mv(b, r2)][see(b, r2)]\neg\exists x \boldsymbol{K}_a(Gold(x))$;
2. $[mv(b, r2)][see(b, r2)]\boldsymbol{K}_a\exists x \boldsymbol{K}_b(Gold(x))$;
3. $[mv(b, r2)][see(b, r2)][mv(a, r1)][see(a, r1)]$
   $(\boldsymbol{K}_a Gold(r1) \wedge \boldsymbol{K}_a\boldsymbol{K}_b Gold(r1))$.

[7] See (Lakemeyer and Levesque 2009) for the general definition. Most significantly, since situation terms do not appear in the language, Reiter's (2001) second-order induction axiom, among other things, will not be needed, but the remaining parts of an action theory have an equivalent formulation.

Progression

In this section, we turn to the main results of this paper. The question we would like to ask is this: suppose agents are given basic action theories as their initial knowledge bases, how are we to characterize the knowledge bases after an action is performed? Only knowing will give us the answer.

What we desire for a progression theorem are transformations obeying the following properties:

1. a general characterization of the new knowledge bases regardless of the syntactic restrictions to action types;
2. progression must be allowed to iterate.

We present results supporting this desiderata for a fragment of the language referred to as *progressable sentences*:

Definition 5: A Ocnf formula is any conjunction of formulas of the form $\phi \vee \boldsymbol{O}_i\psi$, where ψ is any formula and ϕ is any fluent formula.

Definition 6: We define *progressable sentences* of depth $k \geq 1$ inductively as follows:

- *i-progressable* and *j-progressable* sentences of depth 1 are basic action theories;
- a *i-progressable* sentence of depth $k > 1$ is the conjunction of any basic action theory Σ and a Ocnf formula $\bigwedge(\phi \vee \boldsymbol{O}_j\psi)$, where each ψ is a j-progressable sentence of depth $< k$;
- a *j-progressable* sentence of depth $k > 1$ is the conjunction of any basic action theory Σ and a Ocnf formula $\bigwedge(\phi \vee \boldsymbol{O}_i\psi)$, where each ψ is a i-progressable sentence of depth $< k$.

If α is a i-progressable sentence (of any depth) then $\boldsymbol{O}_i\alpha$ is referred to a *progressable sentence.* If α is a j-progressable sentence (of any depth) then $\boldsymbol{O}_j\alpha$ is referred to as a *progressable sentence.*

Roughly, progressable sentences are those where i's beliefs about the world are precisely determined by an action theory, and i has beliefs about possible knowledge bases that j only knows.[8] Clearly, (1) would be classified as progressable, as would a sentence of the form $\boldsymbol{O}_a(\phi \wedge \Box\beta \wedge (\varphi \supset \boldsymbol{O}_b\psi \wedge \varphi' \supset \boldsymbol{O}_b\psi'))$ where, by requirement, ψ and ψ' are b-progressable, and thus, perhaps action theories themselves.

Progression for Physical Actions In the following we assume π to refer to the RHS of the precondition axioms, and γ_F to refer to the RHS of successor state axioms. Also, let $\alpha^{\vec{F}}_{\vec{P}}$ denote the formula α with every occurrence of fluent predicate symbols F_i replaced by second-order variables P_i of the same arity. The first main result is a characterization, in general terms, of what is known after a physical action.[9]

[8] Note that, then, the single agent case is essentially identical to (Lakemeyer and Levesque 2009).

[9] To avoid notational clutter, we make two simplifying assumptions: (a) we state theorems for progressable sentences of depth 2, and (b) we assume that the dynamic components $\Box\beta$ are the same at all depths. Generalizing these is straightforward but tedious.

Theorem 7: *Suppose* $\Upsilon = \boldsymbol{O}_i(\phi \wedge \Box\beta \wedge \bigwedge(\varphi_u \vee \boldsymbol{O}_j(\psi_u \wedge \Box\beta)))$*, where* $u \in \{1, \ldots, n\}$*, is a progressable theory, where* ϕ, φ_u *and* ψ_u *are fluent sentences and* $\Box\beta$ *are the dynamic components. Suppose* t *is a physical action. Then:*

$$\models \Upsilon \supset [t]\boldsymbol{O}_i(\mathcal{P}_\phi \wedge \Box\beta \wedge \bigwedge(\varphi_u \vee \boldsymbol{O}_j(\mathcal{P}_{\psi_u} \wedge \Box\beta)))$$

where for a fluent formula α*:*

$$\mathcal{P}_\alpha = \exists \vec{P}.\ [(\alpha \wedge \pi_t^o)^{\vec{F}}_{\vec{P}} \wedge \bigwedge \forall \vec{x}.\ F(\vec{x}) \equiv \gamma_{F_t^o}^{\vec{F}}].$$

This theorem says that, at all depths, if all that i knows is a basic action theory, then after an action, he knows another basic action theory where the knowledge base is the *progression* of the previous initial knowledge base. The resulting theory is still *progressable*, and so progression can iterate.

On the correctness of belief expansion, we have:

Theorem 8: *Suppose* Υ *is as above. Then*

$$\Upsilon \models [t]\boldsymbol{K}_i\alpha \ \ \textit{iff}\ \ \Upsilon' \models \boldsymbol{K}_i\alpha$$

where Υ' *is the new progressed theory from Theorem 7.*

This result says that whatever is believed by the progressed theory is equivalently believed after t from the initial knowledge base. That is, the two theories agree on the future.

Example 9: Consider the effect of $mv(b, r2)$ on the progressable theory (1). From Theorem 7, we have:

$$\models (1) \supset [mv(b, r2)]\boldsymbol{O}_a(\mathcal{P}_{\mathrm{KB}} \wedge \Box\beta \wedge \boldsymbol{O}_b(\mathcal{P}_{\mathrm{KB}} \wedge \Box\beta))$$

where $\mathcal{P}_{\mathrm{KB}}$ can be shown to be equivalent to $\{Gold(r1) \vee Gold(r2), Gold(r1) \equiv \neg Gold(r2), At(b, r2), \forall x, y.\ x \neq b \supset \neg At(x, y)\}$. Then, readers may note that the following sentences are entailed by $\boldsymbol{O}_a(\mathcal{P}_{\mathrm{KB}} \wedge \Box\beta \wedge \boldsymbol{O}_b(\mathcal{P}_{\mathrm{KB}} \wedge \Box\beta))$: $\boldsymbol{K}_a At(b, r2)$, $\boldsymbol{K}_a\boldsymbol{K}_b At(b, r2)$ and $\boldsymbol{K}_a\boldsymbol{K}_b\neg At(a, r2)$.

Finally, we remark that $\mathcal{P}_\phi$ for any initial theory ϕ is essentially the second-order account of progression given by LR; see (Lakemeyer and Levesque 2009) for discussions.

From this general definition, standard progression results on first-order definability (Liu and Lakemeyer 2009) apply in a straightforward manner. For example, we have:

Theorem 10: *Suppose* Υ *is as above, where* ϕ *and* ψ_u *are first-order formulas. If* Υ *is local-effect, then* $\mathcal{P}_\phi$ *and* $\mathcal{P}_{\psi_u}$ *from Theorem 7 are definable as first-order formulas.*

See (Liu and Lakemeyer 2009) for a definition of local-effect action theories; analogously, first-order progression for other classes of actions carry over without too much effort. See a long version of this paper for details.

Progression for Sensing Actions Letting θ_i refer to the RHS of SF_i in a basic action theory, we have the second main result of this paper:

Theorem 11: *Suppose* $\Upsilon = \boldsymbol{O}_i(\phi \wedge \Box\beta \wedge \bigwedge(\varphi_u \vee \boldsymbol{O}_j(\psi_u \wedge \Box\beta)))$*, where* $u \in \{1, \ldots, n\}$*, is a progressable theory as before. Suppose* t *is a sensing action. Then,*

$$\begin{aligned}\models \Upsilon \supset\ & (SF_i(t) \supset [t]\boldsymbol{O}_i(\phi \wedge \pi_t^o \wedge \theta_{i_t}^o \wedge \Box\beta \wedge \bigwedge(\varphi_u \vee \Psi_u))) \wedge \\ & (\neg SF_i(t) \supset [t]\boldsymbol{O}_i(\phi \wedge \pi_t^o \wedge \neg\theta_{i_t}^o \wedge \Box\beta \wedge \bigwedge(\varphi_u \vee \Psi_u)))\end{aligned}$$

where Ψ_u *is the following sentence:*

$$\begin{aligned}&\theta_{j_t}^o \supset \boldsymbol{O}_j(\psi_u \wedge \pi_t^o \wedge \theta_{j_t}^o \wedge \Box\beta) \wedge \\ &\neg\theta_{j_t}^o \supset \boldsymbol{O}_j(\psi_u \wedge \pi_t^o \wedge \neg\theta_{j_t}^o \wedge \Box\beta).\end{aligned}$$

This theorem says that after a sensing action, what i learns for herself is contingent on the outcome of $SF_i(t)$. But as far as i's beliefs about j goes, she is uncertain about the outcome of sensing for j, and so her beliefs about j would differ at one place: $\theta_{j_t}^o$ *vs.* $\neg\theta_{j_t}^o$. Let us illustrate this using an example:

Example 12: Consider the progression of the theory from Example 9 wrt the sensing action $see(b, r2)$, denoted t. Let ζ denote $\mathcal{P}_{\mathrm{KB}}$ from that example, and so for an initial theory, we have $\Upsilon = Gold(r1) \wedge \boldsymbol{O}_a(\zeta \wedge \Box\beta \wedge \boldsymbol{O}_b(\zeta \wedge \Box\beta))$. After t, from Theorem 11 we have $\Upsilon \models SF_a(t) \supset [t]\boldsymbol{O}_a(\zeta^* \wedge \Box\beta\ \wedge \theta_{b_t}^o \supset \boldsymbol{O}_b(\zeta' \wedge \Box\beta)\ \wedge \neg\theta_{b_t}^o \supset \boldsymbol{O}_b(\zeta'' \wedge \Box\beta))$ because $SF_a(t)$ is *true*, and where $\zeta^* = \zeta \wedge \pi_t^o \wedge \theta_{a_t}^o$, which is equivalent to ζ; $\zeta' = \zeta \wedge \pi_t^o \wedge \theta_{b_t}^o$, where $\theta_{b_t}^o$ is $\exists x, y.\ (t = see(x, y) \wedge x = b \wedge Gold(y) \vee (t = see(x, y) \wedge x \neq b))$, which is equivalent to $Gold(r2)$; and $\zeta'' = \zeta \wedge \pi_t^o \wedge \neg\theta_{b_t}^o$. Thus, ζ' is equivalent to $\zeta \wedge Gold(r2)$ and ζ'' is equivalent to $\zeta \wedge \neg Gold(r2)$. Thus, a now knows that b knows whether Room 2 has the gold. Formally, the progressed theory can be shown to entail $\boldsymbol{K}_a(\boldsymbol{K}_b Gold(r2) \vee \boldsymbol{K}_b\neg Gold(r2))$, $\boldsymbol{K}_a\exists x\boldsymbol{K}_b Gold(x)$, and $\neg\exists x\boldsymbol{K}_a\boldsymbol{K}_b Gold(x)$.

Example 13: As a final example on progression, consider the sentence $\mathrm{KB}_0 \wedge \boldsymbol{O}_a(\mathrm{KB} \wedge \Box\beta \wedge \boldsymbol{O}_b(\mathrm{KB} \wedge \Box\beta \wedge \boldsymbol{O}_a(\mathrm{KB} \wedge \Box\beta)))$. Its progression wrt $mv(b, r2) \cdot see(b, r2)$ simplifies to:

$$\begin{aligned}&\boldsymbol{O}_a(\zeta \wedge \Box\beta \wedge \\ &\quad (Gold(r2) \supset \boldsymbol{O}_b(\zeta \wedge Gold(r2) \wedge \Box\beta \wedge \boldsymbol{O}_a(\zeta \wedge \Box\beta))) \wedge \\ &\quad (\neg Gold(r2) \supset \boldsymbol{O}_b(\zeta \wedge \neg Gold(r2) \wedge \Box\beta \wedge \boldsymbol{O}_a(\zeta \wedge \Box\beta))))\end{aligned}$$

where ζ is from the previous example. The new knowledge base entails $\boldsymbol{K}_a\boldsymbol{K}_b\boldsymbol{K}_a At(b, r2)$ and $\boldsymbol{K}_a\boldsymbol{K}_b\neg\exists x\boldsymbol{K}_a Gold(x)$.

Conclusions

We obtained new *general* results on the progression of knowledge in multiagent systems that substantially extended previous work: we showed that given any action theory, knowledge bases at all depths can be progressed in a LR fashion after actions. For the future, we would like to consider *private* actions, and go beyond Ocnf formulas.

Interval Methods for Judgment Aggregation in Argumentation

Richard Booth[1], **Edmond Awad**[2] and **Iyad Rahwan**[2,3]

Abstract

Given a set of conflicting arguments, there can exist multiple plausible opinions about which arguments should be accepted, rejected, or deemed undecided. Recent work explored some operators for deciding how multiple such judgments should be aggregated. Here, we generalize this line of study by introducing a family of operators called *interval aggregation methods*, which contain existing operators as instances. While these methods fail to output a complete labelling in general, we show that it is possible to *transform* a given aggregation method into one that *does* always yield collectively rational labellings. This employs the *down-admissible* and *up-complete* constructions of Caminada and Pigozzi. For interval methods, collective rationality is attained at the expense of a strong *Independence* postulate, but we show that an interesting weakening of the Independence postulate is retained.

Introduction

A conflicting knowledge base can be viewed abstractly as a set of arguments (defeasible derivations), and a binary relation capturing conflicts among them, forming an *argumentation framework* (AF) (Dung 1995). Given a set of conflicting arguments, there can exist multiple plausible ways to identify (or *label*) which arguments should be accepted, rejected, or deemed undecided (Baroni, Caminada, and Giacomin 2011). The question we explore here is how to aggregate the judgments of multiple agents who have different opinions about how to evaluate a given set of arguments.

This problem of *Judgment Aggregation* (JA) has been explored extensively in classical logic (List and Puppe 2009). But it was only recently that JA has been applied to collective argument evaluation (Caminada and Pigozzi 2011; Rahwan and Tohmé 2010). Early results showed that argument-wise plurality voting cannot guarantee that the outcome of aggregation is always rational (consistent)—thus simple voting violates *Collective Rationality* (Rahwan and Tohmé 2010). On the other hand, the aggregation operators of Caminada and Pigozzi are able to guarantee collective rationality, but do so at the expense of the *Independence* property (Caminada and Pigozzi 2011).

In the present paper, we embark on a broader study of JA in argumentation. We define a general family of aggregation operators called *interval methods* and show that they contain existing operators as instances. Interval methods always satisfy a strong version of Independence, but will usually fail Collective Rationality. But despite this important barrier, we are able to fully axiomatize interval methods in terms of a set of fundamental postulates. Then, building on Caminada and Pigozzi's *down-admissible* + *up-complete* (DAUC) construction, we present an approach to transform any interval method into one satisfying *Collective Rationality* while preserving a weaker and more reasonable form of independence known as *Directionality*.

Preliminaries

We assume a countably infinite set U of argument names, from which all possible argumentation frameworks are built.

Definition 1 *An* argumentation framework *(AF for short)* $\mathcal{A} = (Args, \rightharpoonup)$ *is a pair consisting of a finite set* $Args \subseteq U$ *of arguments and an* attack *relation* $\rightharpoonup \subseteq Args \times Args$. *Sometimes we use* $Args_{\mathcal{A}}$ *and* $\rightharpoonup_{\mathcal{A}}$ *to denote the arguments and attack relation of a given AF* $\mathcal{A}$.

An AF is evaluated by assigning one of the labels `in`, `out` or `undec` to each argument in $Args_{\mathcal{A}}$, standing for *accepted*, *rejected* and *undecided* respectively (Caminada 2006). We define a unary "negation" operator on the set of labels by setting $\neg\texttt{in} = \texttt{out}$, $\neg\texttt{out} = \texttt{in}$ and $\neg\texttt{undec} = \texttt{undec}$. Given an AF $\mathcal{A}$, an $\mathcal{A}$*-labelling* is a function $L : Args \rightarrow \{\texttt{in}, \texttt{out}, \texttt{undec}\}$. For each $\texttt{x} \in \{\texttt{in}, \texttt{out}, \texttt{undec}\}$ we denote by $L^{-1}(\texttt{x})$ the inverse image of x under L, and given $A \subseteq Args_{\mathcal{A}}$ we denote by $L[A]$ the restriction of L to A.

A *rational* evaluation should somehow respect the attack relation, as captured by the notion of *complete* labelling.

Definition 2 *Let* $\mathcal{A} = (Args, \rightharpoonup)$ *be an AF and* L *be an* $\mathcal{A}$*-labelling.* L *is a* complete $\mathcal{A}$*-labelling iff, for all* $a \in Args$*:*

- *If* $L(a) = \texttt{in}$ *then* $L(b) = \texttt{out}$ *for all* $b \in Args$ *s.t.* $b \rightharpoonup a$.
- *If* $L(a) = \texttt{out}$ *then* $L(b) = \texttt{in}$ *for some* $b \in Args$ *s.t.* $b \rightharpoonup a$.
- *If* $L(a) = \texttt{undec}$ *then* $L(b) \neq \texttt{in}$ *for all* $b \in Args$ *s.t.* $b \rightharpoonup a$ *and* $L(c) = \texttt{undec}$ *for some* $c \in Args$ *s.t.* $c \rightharpoonup a$.

An admissible $\mathcal{A}$*-labelling is one that satisfies the first two conditions above. We denote the set of complete* $\mathcal{A}$*-labellings by* $Comp(\mathcal{A})$.

We assume a set of agents $Ag = \{1, \ldots, n\}$ (with $n \geqslant 2$) is fixed. An $\mathcal{A}$-*profile* is a sequence $\mathbf{L} = (L_1, \ldots, L_n)$ assigning a **complete** $\mathcal{A}$-labelling to each $i \in Ag$. Given $A \subseteq Args_{\mathcal{A}}$ we denote by $\mathbf{L}[A]$ the profile $(L_1[A], \ldots, L_n[A])$ (writing $\mathbf{L}[a]$ rather than $\mathbf{L}[\{a\}]$ for the singleton case). For each label $\mathtt{x} \in \{\mathtt{in}, \mathtt{out}, \mathtt{undec}\}$ and $a \in Args_{\mathcal{A}}$ we denote the set of agents who *voted* for label $\mathtt{x}$ for a by $V^{\mathbf{L}}_{a:\mathtt{x}}$, i.e., $V^{\mathbf{L}}_{a:\mathtt{x}} = \{i \in Ag \mid L_i(a) = \mathtt{x}\}$.

The central concept of this paper is the following.

Definition 3 *An* aggregation method *is a function F that assigns to every AF $\mathcal{A}$ and $\mathcal{A}$-profile $\mathbf{L}$ an $\mathcal{A}$-labelling $F_{\mathcal{A}}(\mathbf{L})$.*

Postulates for aggregation methods

We start with some postulates for a good aggregation method. Some are inspired by postulates in (Caminada and Pigozzi 2011; Rahwan and Tohmé 2010), which in turn were inspired by those familiar from the JA literature. We modify them to account for allowing the AF to vary. Note that free occurrences of $\mathcal{A}$ and $\mathbf{L}$ within the postulates are implicitly universally quantified. Ideally, of course, we would like the output too to be complete.

Collective Rationality $F_{\mathcal{A}}(\mathbf{L}) \in Comp(\mathcal{A})$.

Full *Collective Rationality* will turn out to be beyond the reach of the the simplest aggregation methods. However, a very weak version turns out to be relatively easy to satisfy. We call $\mathcal{A}$ a *2-loop AF* if it consists only of two arguments that mutually attack each other, i.e., $Args_{\mathcal{A}} = \{a, b\}$ and $\rightharpoonup_{\mathcal{A}} = \{(a, b), (b, a)\}$ for some distinct $a, b \in U$.

Minimal Collective Rationality For any 2-loop AF $\mathcal{A}$ we have $F_{\mathcal{A}}(\mathbf{L}) \in Comp(\mathcal{A})$.

Given an $\mathcal{A}$-profile $\mathbf{L} = (L_1, \ldots, L_n)$, we say $\mathbf{L}'$ is a *permutation* of $\mathbf{L}$ if $\mathbf{L}' = (L_{\sigma(1)}, \ldots, L_{\sigma(n)})$ for some permutation σ on Ag.

Anonymity If $\mathbf{L}'$ is a permutation of $\mathbf{L}$ then $F_{\mathcal{A}}(\mathbf{L}) = F_{\mathcal{A}}(\mathbf{L}')$.

Unanimity If there is some $\mathcal{A}$-labelling L such that $L_i = L$ for all $i \in Ag$ then $F_{\mathcal{A}}(\mathbf{L}) = L$.

The idea behind the next postulate is that AFs that are *isomorphic* should be treated the same when aggregating. Given $\mathcal{A}_1 = (Args_1, \rightharpoonup_1)$ and $\mathcal{A}_2 = (Args_2, \rightharpoonup_2)$, an isomorphism from $\mathcal{A}_1$ to $\mathcal{A}_2$ is a bijection $g : Args_1 \to Args_2$ such that, for all $a, b \in Args_1$ we have $a \rightharpoonup_1 b$ iff $g(a) \rightharpoonup_2 g(b)$. Such a g extends to a mapping between the $\mathcal{A}_1$-labellings and the $\mathcal{A}_2$-labellings. For any $\mathcal{A}_1$-labelling L we define the $\mathcal{A}_2$-labelling $g(L)$ by setting, for all $a \in \mathcal{A}_2$, $[g(L)](a) = L(g^{-1}(a))$. The function g further extends naturally to a mapping between $\mathcal{A}_1$-profiles and $\mathcal{A}_2$-profiles by setting, for any $\mathcal{A}_1$-profile $\mathbf{L} = (L_1, \ldots, L_n)$, $g(\mathbf{L}) = (g(L_1), \ldots, g(L_n))$.

Isomorphism Suppose $\mathcal{A}_1$ and $\mathcal{A}_2$ are connected by isomorphism g. Then, for any $\mathcal{A}_1$-profile $\mathbf{L}$ we have $g(F_{\mathcal{A}_1}(\mathbf{L})) = F_{\mathcal{A}_2}(g(\mathbf{L}))$.

A standard idea in aggregation is that the group evaluation concerning some item should depend only on the individuals' evaluations over that item and no others. Given we allow the AF to vary, we strengthen this property somewhat.

AF-Independence If $\mathbf{L}_1$ and $\mathbf{L}_2$ are profiles over $\mathcal{A}_1$ and $\mathcal{A}_2$ respectively and $a \in Args_{\mathcal{A}_1} \cap Args_{\mathcal{A}_2}$ then $\mathbf{L}_1[a] = \mathbf{L}_2[a]$ implies $[F_{\mathcal{A}_1}(\mathbf{L}_1)](a) = [F_{\mathcal{A}_2}(\mathbf{L}_2)](a)$.

This postulate implies the more commonly used version of Independence (just put $\mathcal{A}_1 = \mathcal{A}_2$). It roughly says that the collective label of a depends only on $\mathbf{L}[a]$ *no matter what other arguments might be present or absent in* $\mathcal{A}$.

Our first *monotonicity* postulate, in/out-*Monotonicity*, says that if some agents change their individual labels of some arguments in profile $\mathbf{L}$ so that they agree with the collective labelling $F_{\mathcal{A}}(\mathbf{L})$, assuming those collective labels are in $\{\mathtt{in}, \mathtt{out}\}$, then the collective labelling does not change.

in/out-Monotonicity Let $\mathbf{L}, \mathbf{L}'$ be $\mathcal{A}$-profiles such that for all $a \in Args_{\mathcal{A}}$ and all $i \in Ag$, $(L'_i(a) \neq L_i(a)$ implies $L'_i(a) = [F_{\mathcal{A}}(\mathbf{L})](a) \in \{\mathtt{in}, \mathtt{out}\})$. Then $F_{\mathcal{A}}(\mathbf{L}') = F_{\mathcal{A}}(\mathbf{L})$.

The intuition behind *Strong* in/out-*Monotonicity* is that if some agents in $\mathbf{L}$ move their individual labels of some arguments *closer* towards the collective label (and those collective labels belong to $\{\mathtt{in}, \mathtt{out}\}$), then the resulting collective labelling remains unchanged. To formulate it we use the notion of one label being *between* another two labels. Given $\mathtt{x}, \mathtt{y}, \mathtt{z} \in \{\mathtt{in}, \mathtt{out}, \mathtt{undec}\}$ we say that $\mathtt{y}$ is between $\mathtt{x}$ and $\mathtt{z}$ iff either $\mathtt{y} = \mathtt{x}$ or $\mathtt{y} = \mathtt{z}$ or [$\mathtt{y} = \mathtt{undec}$ and $\mathtt{x} \neq \mathtt{z}$].

Strong in/out-Monotonicity Let $\mathbf{L}$, $\mathbf{L}'$ be $\mathcal{A}$-profiles such that for all $a \in Args_{\mathcal{A}}$ such that $[F_{\mathcal{A}}(\mathbf{L})](a) \in \{\mathtt{in}, \mathtt{out}\}$ and all $i \in Ag$, $L'_i(a)$ is between $L_i(a)$ and $[F_{\mathcal{A}}(\mathbf{L})](a)$. Then $F_{\mathcal{A}}(\mathbf{L}') = F_{\mathcal{A}}(\mathbf{L})$.

The next postulate says the collective label on any argument never goes against the individual label of any agent (Caminada and Pigozzi 2011).

Compatibility For all $i \in Ag$ and $a \in Args_{\mathcal{A}}$ we have $[F_{\mathcal{A}}(\mathbf{L})](a) = \neg L_i(a)$ implies $[F_{\mathcal{A}}(\mathbf{L})](a) = \mathtt{undec}$.

Given any n-tuple (l_i) of labels the in/out-*winner in* (l_i) is the label among $\{\mathtt{in}, \mathtt{out}\}$ which appears more frequently in (l_i) (if such a label exists). E.g. the in/out-winner in $(\mathtt{in}, \mathtt{undec}, \mathtt{out}, \mathtt{undec}, \mathtt{in})$ is $\mathtt{in}$. If $\mathtt{x}$ is the in/out-winner in (l_i) then we call $\neg\mathtt{x}$ the in/out-*loser*. A weaker version of *Compatibility* can then be formulated as follows:

in/out-Plurality If $\mathtt{x}$ is the in/out-loser in $(L_i(a))_{i \in Ag}$ then $[F_{\mathcal{A}}(\mathbf{L})](a) \neq \mathtt{x}$

Proposition 1 *Let F be an aggregation method satisfying* Compatibility. *Then*
(i). *F satisfies* in/out-Plurality.
(ii). *If F satisfies* in/out-Monotonicity *then it satisfies* Strong in/out-Monotonicity.

Interval aggregation methods

Now we describe the family of *interval aggregation methods*, which will include a number of interesting special cases (and which are closely-related to the *quota rules* considered in JA by (Dietrich and List 2007)). Formally, let Int_n be the set of *intervals* of non-zero length in $\{0, 1, \ldots, n\}$ (recall n is the number of agents), i.e., $Int_n = \{(k, l) \mid k <$

$l,\ k,l \in \{0,1,\ldots,n\}\}$. Let $Y \subseteq Int_n$ be some subset of distinguished intervals in Int_n. Then we define aggregation method F^Y by setting, for each $\mathcal{A}$, $\mathcal{A}$-labelling profile $\mathbf{L}$ and $a \in Args_{\mathcal{A}}$:

$$[F^Y_{\mathcal{A}}(\mathbf{L})](a) = \begin{cases} \texttt{x} & \text{if } \texttt{x} \in \{\texttt{in}, \texttt{out}\} \text{ and} \\ & \quad (|V^{\mathbf{L}}_{a:\neg\texttt{x}}|, |V^{\mathbf{L}}_{a:\texttt{x}}|) \in Y \\ \texttt{undec} & \text{otherwise} \end{cases}$$

Definition 4 *An* interval aggregation method *is an aggregation method F such that $F = F^Y$ for some $Y \subseteq Int_n$ satisfying* **(I1)***: $(0,n) \in Y$.*

By making different choices of Y we find some special instances of interval methods.

Argument-wise plurality: Take the collective label of a to be the label among $\{\texttt{in}, \texttt{out}, \texttt{undec}\}$ that gets the most votes. If there is a tie then take undec. This corresponds to $Y_{\mathrm{AWP}} = \{(k,l) \in Int_n \mid n-(k+l) < l\}$. We use F^{AWP} to denote $F^{Y_{\mathrm{AWP}}}$.

Majority: Take the collective label of a to be x if more than half of the agents voted for it, otherwise take undec. $Y_{\mathrm{Maj}} = \{(k,l) \in Int_n \mid l > n/2\}$. We use F^{Maj} to denote $F^{Y_{\mathrm{Maj}}}$.

Sceptical initial: (Caminada and Pigozzi 2011) Take the in/out winner if it is the unanimous choice among the agents, otherwise undec. $Y_{\mathrm{Scept}} = \{(0,n)\}$. We use F^{Scept} to denote $F^{Y_{\mathrm{Scept}}}$.

Credulous initial: (Caminada and Pigozzi 2011) Take the in/out-winner x whenever no agent voted for $\neg$x, otherwise undec. $Y_{\mathrm{Cred}} = \{(0,l) \in Int_n \mid l \geqslant 1\}$. We use F^{Cred} to denote $F^{Y_{\mathrm{Cred}}}$.

in/out-*winner:* Take the in/out-winner whenever it exists. $Y_{\mathrm{iow}} = Int_n$. We use F^{iow} to denote $F^{Y_{\mathrm{iow}}}$.

We obtain the following axiomatic characterisation.

Theorem 1 *Let F be an aggregation method. Then F is an interval aggregation method iff it satisfies:* Minimal Collective Rationality*,* Anonymity*,* Unanimity*,* Isomorphism*,* AF-Independence *and* in/out-Plurality.

Thus we see that most of the postulates from the previous section are sound for the interval methods. The postulates missing from Thm. 1 are the two *Monotonicity* postulates, *Compatibility* and, most significantly, *Collective Rationality*. None of these will hold in general for interval methods, at least not without placing some extra restrictions on Y beyond only **(I1)**. Looking first at in/out-*Monotonicity* we can say the following:

Proposition 2 (i). *There exists an interval method that does not satisfy* in/out-Monotonicity.
(ii). *F^{AWP}, F^{Maj}, F^{Scept}, F^{Cred} and F^{iow} all satisfy* in/out-Monotonicity.

We obtain *Strong* in/out-*Monotonicity* for an interval method F^Y if we assume Y satisfies an extra condition saying that Y is closed under *widening* intervals:

(I2) If $(k,l) \in Y$ and $s \leqslant k,\ l \leqslant t$ then $(s,t) \in Y$.

Proposition 3 *Let F^Y be an interval method. Then F^Y satisfies* Strong in/out-Monotonicity *iff Y satisfies* **(I2)**.

Definition 5 *If $Y \subseteq Int_n$ satisfies both* **(I1)** *and* **(I2)** *then we say Y is* widening*. A* widening interval method *is an aggregation method F such that $F = F^Y$ for some widening Y.*

Putting Thm. 1 and Prop. 3 together we can see that the class of widening interval methods is characterised by the six postulates of Thm. 1 plus *Strong* in/out-*Monotonicity*.

It can be checked that each of our previous examples of interval methods, apart from Y_{AWP}, are widening and so yield interval methods that satisfy *Strong* in/out-*Monotonicity*. However if we want *Compatibility* to hold then we need to place a further restriction on Y:

(I3) If $(k,l) \in Y$ then $k = 0$.

Proposition 4 *Let F^Y be an interval method. Then F^Y satisfies* Compatibility *iff Y satisfies* **(I3)**.

Clearly, among our examples, Y_{Scept} and Y_{Cred} are the only Y that satisfy **(I3)**, which means that F^{Scept} and F^{Cred} are the only interval methods among our examples that satisfy *Compatibility*. Looking more generally, combining the previous proposition with Thm. 1 and Prop. 3 (and recalling the facts about *Compatibility* in Prop. 1) gives us the following result.

Theorem 2 *Let F be an aggregation method. Then the following are equivalent:*
(i). *$F = F^Y$ for some Y of the form $\{(0,t) \mid t \geqslant l\}$ for some $1 \leqslant l \leqslant n$.*
(ii). *F satisfies* Minimal Collective Rationality*,* Anonymity*,* Unanimity*,* Isomorphism*,* AF-Independence*,* Compatibility *and* in/out-Monotonicity

Regarding *Collective Rationality*, we know already from (Caminada and Pigozzi 2011; Rahwan and Tohmé 2010) that our examples of interval methods above fail to satisfy it. Is there any requirement we can place on Y to ensure it? Unfortunately the answer is no, as the following impossibility result (whose proof has a flavour of similar impossibility results commonly seen in JA, e.g., Thm. 1 of (List and Pettit 2002)) shows.

Theorem 3 *There is no aggregation method (for any $n > 1$) satisfying all of* Isomorphism*,* Anonymity*,* Unanimity*,* AF-Independence *and* Collective Rationality.

Thus, given the basic requirements *Isomorphism*, *Anonymity* and *Unanimity*, there is no hope to obtain *both* of *AF-Independence* and *Collective Rationality*. We now look at relaxing *AF-Independence*.

Weakening AF-Independence

One might argue that *AF-Independence* cannot be expected to hold when part of the input to the aggregation explicitly contains information (in the form of the attack relation $\rightharpoonup_{\mathcal{A}}$) regarding dependencies between arguments. Instead we might expect the following weaker version, inspired by a similar postulate for argumentation semantics from (Baroni and Giacomin 2007). The idea is that if we have a set of arguments in $\mathcal{A}$ that is *unattacked* then we can aggregate just that part without looking at the arguments outside the

set. Note $\mathcal{A} \subseteq_{\mathrm{f}} \mathcal{A}'$ indicates that $Args_{\mathcal{A}} \subseteq Args_{\mathcal{A}'}$ and $\rightharpoonup_{\mathcal{A}} = \rightharpoonup_{\mathcal{A}'} \cap (Args_{\mathcal{A}} \times Args_{\mathcal{A}})$.

Directionality Suppose $\mathcal{A} \subseteq_{\mathrm{f}} \mathcal{A}'$ and suppose $Args_{\mathcal{A}}$ is unattacked in $\mathcal{A}'$. Then for any $\mathcal{A}'$-profile $\mathbf{L}$ and $a \in Args_{\mathcal{A}}$ we have $[F_{\mathcal{A}'}(\mathbf{L})](a) = [F_{\mathcal{A}}(\mathbf{L}[Args_{\mathcal{A}}])](a)$.

Proposition 5 *Every aggregation method F that satisfies* AF-Independence *also satisfies* Directionality.

Can we construct an aggregation method that satisfies *Directionality*, *Collective Rationality* and some other desirable postulates? We show the answer is yes, using the *down-admissible* and *up-complete* constructions of (Caminada and Pigozzi 2011). We begin with the down-admissible construction, which uses the definition of the 'committedness' relation $\sqsubseteq$ according to which $L_1 \sqsubseteq L_2$ iff both $L_1^{-1}(\mathtt{in}) \subseteq L_2^{-1}(\mathtt{in})$ and $L_1^{-1}(\mathtt{out}) \subseteq L_2^{-1}(\mathtt{out})$.

Definition 6 ((Caminada and Pigozzi 2011)) *Given an $\mathcal{A}$-labelling L, the* down-admissible *labelling of L, denoted by $\downarrow L$, is the (unique) greatest element (under $\sqsubseteq$) of the set of all admissible $\mathcal{A}$-labellings M such that $M \sqsubseteq L$.*

As described in (Caminada and Pigozzi 2011), it can be arrived at by iteratively relabelling every argument that is illegally `in` or illegally `out` with `undec` until no illegal `in` or `out` labels remain. The result is a labelling that is admissible, but not necessarily complete. To ensure a complete labelling we need to additionally apply the up-complete operator.

Definition 7 ((Caminada and Pigozzi 2011)) *Given an admissible $\mathcal{A}$-labelling L, the* up-complete *labelling of L, denoted by $\uparrow L$, is the (unique) smallest element (under $\sqsubseteq$) of the set of all complete $\mathcal{A}$-labellings M such that $L \sqsubseteq M$.*

To obtain $\uparrow L$ we iteratively change every illegally `undec` argument to `in` or `out` as appropriate (Caminada and Pigozzi 2011). We denote by $\Updownarrow L$ the composite operation of performing the down-admissible followed by the up-complete procedures on an $\mathcal{A}$-labelling L.

Definition 8 *Given any aggregation method F, the* DAUC version of F *is the aggregation method $\widehat{F}$ defined by setting, for any AF $\mathcal{A}$ and $\mathcal{A}$-labelling profile $\mathbf{L}$, $\widehat{F}_{\mathcal{A}}(\mathbf{L}) = \Updownarrow(F_{\mathcal{A}}(\mathbf{L}))$.*

For the special cases of interval methods F^{Scept} and F^{Cred} this procedure was studied in detail in (Caminada and Pigozzi 2011). Their DAUC versions were called the *sceptical* and *super-credulous* aggregation methods respectively there. We lose *AF-Independence* as expected. But we can show that some postulates satisfied by the initial method F can be *inherited* by $\widehat{F}$.

Proposition 6 *Let F be any aggregation method. For each of the following postulates, if F satisfies that postulate then so does $\widehat{F}$:* Anonymity, Unanimity, Isomorphism, Directionality, Compatibility.

Corollary 1 *Let F be an interval method. Then $\widehat{F}$ satisfies* Collective Rationality, Anonymity, Unanimity, Isomorphism *and* Directionality.

Hence we have established that, for every interval method F, $\widehat{F}$ satisfies four of the six postulates that characterised the interval methods in Thm. 1, plus a weaker version (*Directionality*) of a fifth (*AF-Independence*). What about the remaining postulate from there, i.e., `in`/`out`-*Plurality*? From Props. 4 and 6 we know that if Y satisfies **(I3)** then $\widehat{F}^Y$ will satisfy *Compatibility* and hence `in`/`out`-*Plurality*. Thus **(I3)** is sufficient to obtain `in`/`out`-*Plurality*. Surprisingly, it turns out this condition is also necessary.

Proposition 7 *Let F^Y be an interval method. The $\widehat{F}^Y$ satisfies* `in`/`out`-Plurality *iff Y satisfies* **(I3)**.

One last question concerns the circumstances under which $\widehat{F}^Y$ will satisfy *(Strong)* `in`/`out`-*Monotonicity*. Since for interval methods we have that *Strong* `in`/`out`-*Monotonicity* holds iff Y is widening, one might expect that an analogous equivalence is preserved for the class of DAUC versions of the interval methods. However this remains open for now.

Strong Equivalence of Non-Monotonic Temporal Theories*

Pedro Cabalar and **Martín Diéguez**
Dept. of Computer Science
University of Corunna, Spain
{*cabalar,martin.dieguez*}*@udc.es*

Abstract

In this paper we solve the following open problem: we prove that equivalence in the logic of *Temporal Here-and-There* (THT) is not only a sufficient, but also a *necessary* condition for strong equivalence of two *Temporal Equilibrium Logic* (TEL) theories. This result has allowed constructing a tool, `ABSTEM`, that can be used to check different types of equivalence between two arbitrary temporal theories. More importantly, when the theories are not THT-equivalent, the system provides a context theory that makes them behave differently, together with a Büchi automaton showing the temporal stable models that arise from that difference.

Introduction

With the consolidation of Answer Set Programming (ASP) (Brewka, Eiter, and Truszczyński 2011) as a successful paradigm for practical knowledge representation, many examples and benchmarks formalising dynamic scenarios became available. ASP usually treats time as an integer index restricting all reasoning tasks to finite narratives. As a piece of example, consider an extremely simple ASP program where a fluent p represents that a switch is on and q represents that it is off. Moreover, suppose we have freedom to add p arbitrarily at any moment and that either p or q holds initially. A typical ASP representation could be:

$$p(0) \vee q(0) \tag{1}$$
$$p(I{+}1) \leftarrow p(I), \mathit{not}\ q(I{+}1), sit(I) \tag{2}$$
$$q(I{+}1) \leftarrow q(I), \mathit{not}\ p(I{+}1), sit(I) \tag{3}$$
$$p(I) \vee \mathit{not}\ p(I) \leftarrow sit(I) \tag{4}$$

where (1) is the initial state, (2) and (3) are the inertia rules and (4) is a choice rule for p at any situation. Predicate sit would have a finite domain $0 \ldots n$ for some constant $n \geq 0$. Planning for a goal like $p \wedge \neg q$ implies including two constraints for the last situation, $\bot \leftarrow \mathit{not}\ p(n)$ and $\bot \leftarrow q(n)$, and go increasing n until a solution is found. This strategy falls short for many temporal reasoning problems that involve dealing with infinite time such as proving the non-existence of a plan or checking the satisfaction of temporal properties of a given dynamic system. For instance, questions such as "is there a reachable state in which both p and q are false?" or "can we show that whenever p is true it will remain so forever?" can be answered by an analytical inspection of our simple program, but cannot be solved in an automated way.

To overcome these limitations, (Aguado et al. 2013) proposed a temporal extension of *Equilibrium Logic* (Pearce 1996), the best-known logical formalisation of ASP. This extension, which received the name of *Temporal Equilibrium Logic* (TEL), is defined as follows. First, it extends the monotonic basis of Equilibrium Logic, the intermediate logic of *Here-and-There* (HT) (Heyting 1930), by introducing the full syntax of the well-known *Linear-time Temporal Logic* (LTL) (Pnueli 1977). The result of this combination is called *Temporal Here-and-There* (THT). Then, a selection criterion on THT models is imposed, obtaining non-monotonicity in this way. As a result, TEL constitutes a full non-monotonic temporal logic that allows a proper definition of *temporal stable models* for any arbitrary theory in the syntax of LTL. For instance, the ASP program (1)-(4) would be represented in TEL as:

$$p \vee q \tag{5}$$
$$\Box(p \wedge \neg \bigcirc q \rightarrow \bigcirc p) \tag{6}$$
$$\Box(q \wedge \neg \bigcirc p \rightarrow \bigcirc q) \tag{7}$$
$$\Box(p \vee \neg p) \tag{8}$$

where, as usual in LTL, '$\Box$' stands for "always" and '$\bigcirc$' stands for "next." Checking whether p and q can be eventually false would correspond to look for a plan satisfying:

$$\neg\Diamond(\neg p \wedge \neg q) \rightarrow \bot \tag{9}$$

with '$\Diamond$' meaning "eventually." Similarly, to test whether p remains true after becoming true we would add:

$$\Box(p \rightarrow \Box p) \rightarrow \bot \tag{10}$$

and check that, indeed, no temporal stable model exists.

In the past years, several interesting results about TEL were obtained – see survey (Aguado et al. 2013) – but a few important questions about TEL remained unsolved. One of them has to do with the property of *strong equivalence* in TEL. In any Non-Monotonic Reasoning approach, we say that Γ_1 and Γ_2 are *strongly equivalent* when, for any arbitrary theory Γ, both $\Gamma_1 \cup \Gamma$ and $\Gamma_2 \cup \Gamma$ have the same

selected models (stable models in ASP). (Lifschitz, Pearce, and Valverde 2001) proved that checking equivalence in the logic of HT is a necessary and sufficient condition for strong equivalence in Equilibrium Logic, that is, Γ_1 and Γ_2 are strongly equivalent iff $\Gamma_1 \equiv_{HT} \Gamma_2$. A pair of strong equivalence checkers are, for instance, (Valverde 2004) and (Chen, Lin, and Li 2005). This result for propositional HT was extended to arbitrary first-order theories in (Lifschitz, Pearce, and Valverde 2007). It must be noticed that one direction of this result, the sufficient condition, is actually trivial. As HT is monotonic, $\Gamma_1 \equiv_{HT} \Gamma_2$ implies $\Gamma_1 \cup \Gamma \equiv_{HT} \Gamma_2 \cup \Gamma$ and so, their selected models will also coincide. The real significant result is the opposite direction, namely, that HT-equivalence is also a necessary condition for strong equivalence, as it shows that HT is strong enough as a monotonic basis for Equilibrium Logic. In the case of TEL, (Aguado et al. 2008) implemented a prototype checker and used it on some examples exploiting the trivial direction, i.e., that THT-equivalence is obviously a sufficient condition for strong equivalence in TEL. However, during the past six years, the question whether THT-equivalence was also necessary or not remained unanswered.

In this paper we adapt a result from (Lifschitz, Pearce, and Valverde 2007) to prove that indeed THT-equivalence is a necessary condition for TEL strong equivalence and use this proof, combined with previous theoretical results, to construct a tool, ABSTEM[1], that allows the formal study of arbitrary temporal theories in different ways. First, it implements the technique in (Cabalar and Demri 2011) to compute the temporal stable models of an arbitrary theory Γ, displaying them as a Büchi automaton. Second, given two theories Γ_1 and Γ_2, it allows checking different types of equivalence: LTL-equivalence, weak equivalence (coincidence in temporal stable models) and THT-equivalence which, as said before, corresponds to strong equivalence.

The rest of the paper is organised as follows. In the next section we recall the basic definitions of TEL. After that, we overview the automata-based techniques from (Cabalar and Demri 2011). The next section contains the main theorem. This is followed by an explanation of the implementation together with a practical example. Finally, we include some conclusions.

Temporal Equilibrium Logic

We begin defining the (monotonic) logic of THT as follows. The syntax is defined as in propositional LTL. A temporal *formula* φ can be expressed following the grammar shown below:

$$\varphi ::= \bot \mid p \mid \alpha \wedge \beta \mid \alpha \vee \beta \mid \alpha \rightarrow \beta \mid \bigcirc \alpha \mid \alpha \,\mathcal{U}\, \beta \mid \alpha \,\mathcal{R}\, \beta$$

where p is an atom of some finite signature At, and α and β are temporal formulas in their turn.

The formula $\alpha \,\mathcal{U}\, \beta$ stands for "α *until* β" whereas $\alpha \,\mathcal{R}\, \beta$ is read as "α *release* β" and is the dual of "until." Derived operators such as $\Box$ ("always") and $\Diamond$ ("at some future time") are defined as $\Box\varphi \stackrel{\text{def}}{=} \bot \,\mathcal{R}\, \varphi$ and $\Diamond\varphi \stackrel{\text{def}}{=} \top \,\mathcal{U}\, \varphi$. Other usual propositional operators are defined as follows: $\neg\varphi \stackrel{\text{def}}{=} \varphi \rightarrow \bot$, $\top \stackrel{\text{def}}{=} \neg\bot$ and $\varphi \leftrightarrow \psi \stackrel{\text{def}}{=} (\varphi \rightarrow \psi) \wedge (\psi \rightarrow \varphi)$.

Given a finite propositional signature At, an LTL-*interpretation* $\mathbf{T}$ is an infinite sequence of sets of atoms, $T_0, T_1, \ldots$ with $T_i \subseteq At$ for all $i \geq 0$. Given two LTL-interpretations $\mathbf{H}, \mathbf{T}$ we define $\mathbf{H} \leq \mathbf{T}$ as: $H_i \subseteq T_i$ for all $i \geq 0$. A THT-*interpretation* $\mathbf{M}$ for At is a pair of LTL-interpretations $\langle \mathbf{H}, \mathbf{T} \rangle$ satisfying $\mathbf{H} \leq \mathbf{T}$. A THT-interpretation is said to be *total* when $\mathbf{H} = \mathbf{T}$.

Definition 1 (Satisfaction) *We define when an interpretation $\mathbf{M} = \langle \mathbf{H}, \mathbf{T} \rangle$ satisfies a formula φ at a state $i \geq 0$, written $\mathbf{M}, i \models \varphi$, recursively as follows:*

1. $\mathbf{M}, i \models p$	*iff*	$p \in H_i$, *with p an atom.*
2. $\wedge, \vee, \bot$		*as usual*
3. $\mathbf{M}, i \models \varphi \rightarrow \psi$	*iff*	*for all* $x \in \{\mathbf{H}, \mathbf{T}\}$, $\langle x, \mathbf{T} \rangle, i \not\models \varphi$ *or* $\langle x, \mathbf{T} \rangle, i \models \psi$.
4. $\mathbf{M}, i \models \bigcirc \varphi$	*iff*	$\mathbf{M}, i{+}1 \models \varphi$
5. $\mathbf{M}, i \models \varphi \,\mathcal{U}\, \psi$	*iff*	$\exists k \geq i$ *such that* $\mathbf{M}, k \models \psi$ *and* $\forall j \in \{i, \ldots, k\text{-}1\}, \mathbf{M}, j \models \varphi$.
6. $\mathbf{M}, i \models \varphi \,\mathcal{R}\, \psi$	*iff*	$\forall k \geq i$ *such that* $\mathbf{M}, k \not\models \psi$ *then* $\exists j \in \{i, \ldots, k\text{-}1\}, \mathbf{M}, j \models \varphi$. ■

We say that $\langle \mathbf{H}, \mathbf{T} \rangle$ is a *model* of a theory Γ, written $\langle \mathbf{H}, \mathbf{T} \rangle \models \Gamma$, iff $\langle \mathbf{H}, \mathbf{T} \rangle, 0 \models \alpha$ for all formulas $\alpha \in \Gamma$. It is easy to see that restricting the study to total interpretations, THT-satisfaction collapses to LTL-satisfaction, i.e.:

Proposition 1 (from (Aguado et al. 2013)) $\langle \mathbf{T}, \mathbf{T} \rangle, i \models \varphi$ *in THT iff* $\mathbf{T}, i \models \varphi$ *in LTL.*

An interpretation $\mathbf{M}$ is a *temporal equilibrium model* of a theory Γ if it is a total model of Γ, that is, $\mathbf{M} = \langle \mathbf{T}, \mathbf{T} \rangle \models \Gamma$, and there is no $\mathbf{H} < \mathbf{T}$ such that $\langle \mathbf{H}, \mathbf{T} \rangle \models \Gamma$. An LTL-interpretation $\mathbf{T}$ is a *temporal stable model* (TS-model) of a theory Γ iff $\langle \mathbf{T}, \mathbf{T} \rangle$ is a temporal equilibrium model of Γ. By Proposition 1 it is easy to see that any TS-model of a temporal theory Γ is also an LTL-model of Γ.

As happens in LTL, the set of TS-models of a theory Γ can be captured by a Büchi automaton (Büchi 1962), a kind of ω-automaton (that is, a finite automaton that accepts words of infinite length). In this case, the alphabet of the automaton would be the set of states (classical propositional interpretations) and the acceptance condition is that a word (a sequence of states) is accepted iff it corresponds to a run of the automaton that visits some acceptance state an infinite number of times. As an example, Figure 1 shows the TS-models for the theory (5)-(8) which coincide with sequences of states of the forms $\{q\}^*\{p\}^\omega$ or $\{q\}^\omega$.

Computing Temporal Stable Models of Arbitrary Theories

Based on the techniques introduced in (Cabalar and Demri 2011), the tool ABSTEM constitutes the first implementation capable of computing TS-models for arbitrary temporal formulas, without syntactic restrictions. The method obtains the TS-models of a formula φ by performing several operations on a pair of automata derived from φ. The first automaton, denoted as A_φ, accepts the total THT-models

[1] http://kr.irlab.org/?q=abstem

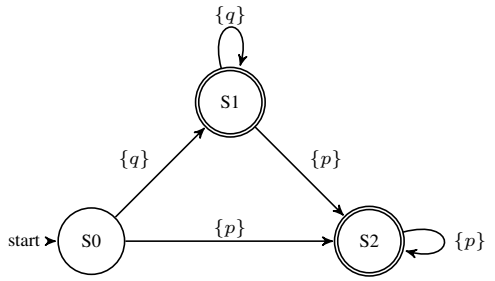

Figure 1: Temporal stable models of theory (5)-(8).

$\langle \mathbf{T}, \mathbf{T} \rangle$ of φ. By Proposition 1 this simply amounts to compute the LTL models $\mathbf{T}$ of φ using an automata construction method for LTL. The second automaton, denoted as $A_{\varphi''}$, accepts the non-total THT-models $\langle \mathbf{H}, \mathbf{T} \rangle$ of φ. The final set of TS-models is obtained from the composition $A_{\varphi} \cap \overline{h(A_{\varphi''})}$ where $h(A_{\varphi''})$ filters out the $\mathbf{H}$ component of non-total models, $\overline{h(A_{\varphi''})}$ is the complementary of $h(A_{\varphi''})$ and finally $\cap$ denotes the automata product.

The computation of $A_{\varphi''}$ is done exploiting a translation of THT into LTL first presented in (Aguado et al. 2008) and directly extrapolating the translation of HT into classical logic in (Pearce, Tompits, and Woltran 2001). It uses an extended signature $\{p' \mid p \in At\}$ so that p' represents the truth of p in $\mathbf{H}$ while p is used for $\mathbf{T}$. The translation of φ, written φ^*, is recursively defined as follows:

- $(p)^* \stackrel{\text{def}}{=} p'$, for any atom $p \in At$
- $(\alpha \rightarrow \beta)^* \stackrel{\text{def}}{=} (\alpha \rightarrow \beta) \wedge (\alpha^* \rightarrow \beta^*)$

being homomorphic for the rest of logical connectives. To impose the restriction $\mathbf{H} < \mathbf{T}$ we further include the axiom:

$$\left(\bigwedge_{p \in At} \Box(p' \rightarrow p) \right) \wedge \left(\bigvee_{p \in At} \Diamond(\neg p' \wedge p) \right) \qquad \textbf{(Ax1)}$$

Automaton $A_{\varphi''}$ is built from formula $\varphi'' \stackrel{\text{def}}{=} \varphi^* \wedge (\textbf{Ax1})$. The operation $h(A_{\varphi''})$ returns a new automaton that results from removing the atoms p' from transitions in $A_{\varphi''}$. This captures the $\mathbf{T}$-components of non-total models; in this way, its complementary automaton $\overline{h(A_{\varphi''})}$ accepts the $\mathbf{T}$ sequences that do not form a non-total model, but perhaps they are not models either. Thus, the final product $A_{\varphi} \cap \overline{h(A''_{\varphi})}$ captures those $\mathbf{T}$ such that $\langle \mathbf{T}, \mathbf{T} \rangle$ is a total model of φ and no non-total model $\langle \mathbf{H}, \mathbf{T} \rangle$ can be formed.

Temporal Strong Equivalence

For simplicity, we assume finite theories and we indistinctly represent them as the conjunction of their formulas.

Theorem 1 (Sufficient condition (Aguado et al. 2008)) *If two temporal formulas α and β are THT-equivalent then they are strongly equivalent in TEL.* ■

To prove the other direction, namely, that THT-equivalence is also a necessary condition for strong equivalence, we begin defining γ_0 as the conjunction of all formulas $\Box(p \vee \neg p)$ for all atoms $p \in At$.

Proposition 2 *Let $\langle \mathbf{H}, \mathbf{T} \rangle$ be a THT interpretation for signature At. If $\langle \mathbf{H}, \mathbf{T} \rangle \models \gamma_0$ then $\mathbf{H} = \mathbf{T}$.*

Corollary 1 *For any formula α for signature At, the LTL-models of $\alpha \wedge \gamma_0$ coincide with its TS-models.* ■

Lemma 1 *Let α and β be two LTL-equivalent formulas and let $\gamma = (\beta \rightarrow \gamma_0)$. Then, the following conditions are equivalent:*

(i) *There exists some $\mathbf{H} < \mathbf{T}$ such that $\langle \mathbf{H}, \mathbf{T} \rangle \not\models \alpha \rightarrow \beta$;*

(ii) *$\mathbf{T}$ is TS-model of $\beta \wedge \gamma$ but not TS-model of $\alpha \wedge \gamma$.* ■

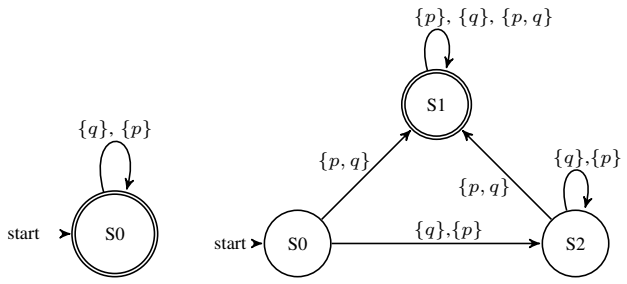
Theorem 2 (Main theorem: necessary condition) *If two temporal formulas α and β are strongly equivalent in TEL then they are THT-equivalent.* ■

Proof We will prove that if α and β are not THT-equivalent then there is some context formula γ for which $\alpha \wedge \gamma$ and $\beta \wedge \gamma$ have different TS-models. Assume first that α and β have different total models, i.e., different LTL-models. Then, the LTL-models of $\alpha \wedge \gamma_0$ and $\beta \wedge \gamma_0$ also differ (since γ_0 is an LTL tautology). But by Corollary 1, LTL-models of these theories are exactly their TS-models, and so, they also differ.

Suppose now that α and β are LTL-equivalent but not THT-equivalent. Then, there is some THT-countermodel $\langle \mathbf{H}, \mathbf{T} \rangle$ of either $(\alpha \rightarrow \beta)$ or $(\beta \rightarrow \alpha)$, and given LTL-equivalence of α and β, the countermodel is non-total, $\mathbf{H} < \mathbf{T}$. Without loss of generality, assume $\langle \mathbf{H}, \mathbf{T} \rangle \not\models \alpha \rightarrow \beta$. By Lemma 1, taking the formula $\gamma = (\beta \rightarrow \gamma_0)$, we get that $\mathbf{T}$ is TS-model of $\beta \wedge \gamma$ but not TS-model of $\alpha \wedge \gamma$. ■

Algorithm 1 StrongEquivalenceTest(α, β)

Require: Two propositional temporal formulas α, β.
Ensure: If α and β are THT-equivalent, it returns **true**. Otherwise, it returns a triple $\langle \gamma, A_1, A_2 \rangle$.



```
A1 := ltl_to_Büchi(α ∧ ¬β)
A2 := ltl_to_Büchi(β ∧ ¬α)
if A1 ≠ ∅ or A2 ≠ ∅ then
    return ⟨γ0, A1, A2⟩
end if
A=ltl_to_Büchi(¬(α → β)* ∧ (Ax1))
if A ≠ ∅ then
    A2 := h(A)
    return ⟨(β → γ0), ∅, A2⟩
end if
A=ltl_to_Büchi(¬(β → α)* ∧ (Ax1))
if A ≠ ∅ then
    A1 := h(A)
    return ⟨(α → γ0), A1, ∅⟩
end if
return true
```

Implementation and a practical example

The procedure for checking strong equivalence in `ABSTEM` is shown in Algorithm 1. It takes two arbitrary propositional temporal formulas α and β and returns either **true**, if they are strongly equivalent, or a triple with a formula γ and two

automata A_1, A_2 otherwise[2]. The meaning of this information is that A_1 captures TS-models of $\alpha \wedge \gamma$ that are not TS-models of $\beta \wedge \gamma$ and, analogously, A_2 captures TS-models of $\beta \wedge \gamma$ that are not TS-models of $\alpha \wedge \gamma$. The procedure uses an auxiliary routine ltl_to_Büchi(φ) to obtain a Büchi automaton from an LTL-formula φ.

As an example of use, let β_1 be our "switch" domain (5)-(8) plus the rule $\Box(\neg p \rightarrow q)$ trying to capture the idea that, when no information on p is available, q becomes true. This new rule is actually a new default for q that interacts with inertia rules (6),(7) destroying somehow their effect. Using ABSTEM to check the TS-models of β_1 we obtain the automaton in Figure 2(a) which corresponds to arbitrary sequences formed with states $\{p\}$ and $\{q\}$. This set of TS-models actually coincides with what one would expect from a formula of the form $\Box(p \vee q)$ since, as happens in ASP, truth minimality converts the disjunction into an exclusive or. So, we may conjecture that β_1 is equivalent to $\alpha_1 = \Box(p \vee q)$. Using ABSTEM we can check that, in fact, α_1 and β_1 have the same TS-models and, furthermore, they are also LTL-equivalent. However, α_1 and β_1 are not THT-equivalent and so, they are not strongly equivalent. The answer displayed this time by ABSTEM is negative and shows the context formula $\gamma_1 = \beta_1 \rightarrow \gamma_0$ plus a file containing the automaton in Figure 2(b). This automaton captures all the TS-models of $\beta_1 \wedge \gamma_1$ that are not TS-models of $\alpha_1 \wedge \gamma_1$.

(a) TS-models of α_1 and β_1.

(b) TS-models of $\beta_1 \wedge \gamma_1$ not of $\alpha_1 \wedge \gamma_1$.

Figure 2: Temporal stable models related to α_1 and β_1.

Conclusions

In this paper we have adapted (Lifschitz, Pearce, and Valverde 2007) to the temporal case, to prove that equivalence in the logic of Temporal Here-and-There (THT), is not only a sufficient but also a *necessary* condition for strong equivalence in Temporal Equilibrium Logic (TEL). Using this proof, we have implemented a system, ABSTEM, for analysing TEL arbitrary theories in different ways. First, ABSTEM constitutes the first tool for computing temporal equilibrium models of any arbitrary temporal theory. Second, it also allows checking three types of equivalence between two arbitrary theories: LTL, weak and strong equivalence. When equivalence is not satisfied, ABSTEM shows counterexamples in the form of a Büchi automaton. Regarding efficiency and scalability, this prototype works satisfactorily for small theories like the ones presented in the paper. It must be noted, however, that checking THT-equivalence is a PSPACE-complete problem.

Abstract

Boolean games are a framework for reasoning about the rational behaviour of agents, whose goals are formalized using propositional formulas. They offer an attractive alternative to normal-form games, because they allow for a more intuitive and more compact encoding. Unfortunately, however, there is currently no general, tailor-made method available to compute the equilibria of Boolean games. In this paper, we introduce a method for finding the pure Nash equilibria based on disjunctive answer set programming. Our method is furthermore capable of finding the core elements and the Pareto optimal equilibria, and can easily be modified to support other forms of optimality, thanks to the declarative nature of disjunctive answer set programming. Experimental results clearly demonstrate the effectiveness of the proposed method.

Introduction

Boolean games or BGs are a framework for analyzing the behaviour of competing rational agents, whose goals are formalized as propositional formulas. They offer an alternative to normal-form games (NFGs), in which the goals of agents are encoded implicitly in the form of a pay-off function. A BG is a tuple (N, V, π, Φ) with $N = \{1, \ldots, n\}$ a set of agents, V a set of propositional (action) variables, $\pi : N \rightarrow 2^V$ a control assignment function such that $\{\pi(1), \ldots, \pi(n)\}$ forms a partition of V, and Φ a set $\{\varphi_1, \ldots, \varphi_n\}$ of formulas in L_V, i.e. the logical language associated with V (Bonzon et al. 2006). The set $\pi(i)$ or π_i contains the action variables controlled by agent i. Note that each $p \in V$ is controlled by exactly one agent. Every agent i can choose to set $p \in \pi_i$ to true (undertake the action p) or to false (not undertake the action). The formula φ_i is agent i's goal. An interpretation of π_i is called a *strategy* s_i of agent i. A *strategy profile* of a BG is an n-tuple $S = (s_1, \ldots, s_n)$, with s_i a strategy of agent i for every $i \in N$. Since π partitions V and $s_i \subseteq \pi_i, \forall i \in N$, we unambiguously use the set notation $\cup_{i=1}^{n} s_i \subseteq V$ for a strategy profile $S = (s_1, \ldots, s_n)$. With s_{-i} we denote the projection of the strategy profile $(s_1, \ldots, s_n)$ on $N \setminus \{i\}$, i.e. $s_{-i} = (s_1, \ldots, s_{i-1}, s_{i+1}, \ldots, s_n)$. If s_i' is a strategy of agent i, then (s_{-i}, s_i') is a shorthand for $(s_1, \ldots, s_{i-1}, s_i', s_{i+1}, \ldots, s_n)$. In a natural way, agent i's goal induces a Boolean *utility function* u_i for agent i: for every strategy profile S, $u_i(S) = 1$ iff $S \models \varphi_i$, i.e. agent i reaches its goal in S, and $u_i(S) = 0$ otherwise. A straightforward solution concept in game theory is the notion of *pure Nash equilibrium* (PNE). A strategy profile $S = (s_1, \ldots, s_n)$ is a PNE iff, for every agent $i \in N$, s_i is a best response to s_{-i}, i.e. $u_i(S) \geq u_i(s_{-i}, s_i')$ for all strategies $s_i' \subseteq \pi_i$. An alternative solution concept of BGs is the *core*, i.e. the set of strategy profiles that are not blocked by any non-empty coalition $C \subseteq N$. A strategy profile S is blocked by a coalition $C \subseteq N$ ($C \neq \emptyset$) if there exists a strategy profile S' such that all agents outside C undertake the same actions in S and S' and if all agents in C have a strictly higher utility in S' than in S. In this paper we have restricted the discussion to PNEs, cores and Pareto optimality, since these are very common, intuitive solution concepts in the context of BGs, but our reduction to disjunctive answer set programming (ASP) can readily be generalized to alternative solution concepts (Bonzon, Lagasquie-Schiex, and Lang 2012; Dunne and Wooldridge 2012; Dunne et al. 2008).

BGs form a young and active research area (Harrenstein et al. 2001; Bonzon et al. 2006; Bonzon, Lagasquie-Schiex, and Lang 2007; Dunne et al. 2008; Bonzon, Lagasquie-Schiex, and Lang 2012; Wooldridge et al. 2013). The strength of BGs lies in their transparent and compact representation, since the propositional goals make it redundant to explicitly mention the utility for every strategy profile. Therefore, however, computing solutions such as PNEs or core elements is harder than for most other game representations. This is undoubtedly part of the reason why, to the best of our knowledge, no methods for computing the PNEs or core elements of general BGs have been proposed so far.

Currently available methods for solving BGs fall in two categories. First, given that translations from BGs to NFGs

*This research was funded by a Research Foundation-Flanders project.
Copyright © 2014, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

are available, we can readily use solvers for NFGs. However, since such translations are exponential, this circuitous method does not exploit the compactness of BGs. Moreover, its inefficiency increases rapidly with the number of action variables per agent, as shown in the Experiments section. Second, several authors have proposed methods for sub-classes of BGs. For instance, in (Bonzon, Lagasquie-Schiex, and Lang 2007), an algorithm is provided to compute PNEs, but only for BGs with an acyclic irreflexive part of their dependency graph. In (Dunne et al. 2008), a bargaining protocol for BGs allows agents to negotiate in rounds. If the logical operators in the goals are restricted to $\wedge$ and $\vee$, specific negotiation strategies yield a Pareto optimal strategy profile during the first round. Otherwise, obtaining a solution is not guaranteed. More important, none of these techniques can compute the solutions of general BGs. In (De Clercq et al. 2014), the stochastic Win-Stay Lose-probabilistic-Shift algorithm (WSLpS) is used to find solutions of BGs. In case all agents are able to reach their goal simultaneously, WSLpS converges to a Pareto optimal PNE. In the Experiments section, we show that our disjunctive ASP technique outperforms a generalized version of WSLpS for sufficiently difficult problems.

In NFGs, deciding whether a PNE exists is NP-complete when the game is represented by: (i) a set of agents, (ii) a finite set of actions per agents, (iii) a function defining for each agent which other agents may influence their utility, and (iv) the utility of each agent, explicitly given for all joint strategies of the agent and the agents influencing it (Gottlob, Greco, and Scarcello 2003). Deciding whether a BG has a PNE, on the other hand, is Σ_2^{P}-complete[1], even for 2-player zero-sum BGs (Bonzon et al. 2006). Deciding whether the core of a BG is non-empty is also Σ_2^{P}-complete (Dunne et al. 2008). In particular, the problems we tackle in this paper are at the 2nd level of the Polynomial Hierarchy.

The aim of this paper is to introduce a solver that can compute PNEs and core elements of BGs, with the option of additionally enforcing Pareto optimality or taking into account constraints (Bonzon, Lagasquie-Schiex, and Lang 2012) and costs (Dunne et al. 2008). Our solver, available online[2], is based on disjunctive ASP, a form of declarative programming (Baral 2003). In recent years, a range of Σ_2^{P} problems have been identified on which ASP solvers outperform other state-of-the-art methods (Faber, Leone, and Ricca 2005). For our BG solver, we use the state-of-the-art ASP solver DLV to compute answer sets.

Computing PNEs and Core Elements of BGs with Disjunctive ASP Programs

We first show how to compute PNEs of a BG by associating it with a disjunctive ASP program. To this end, we use the saturation technique (Eiter, Gottlob, and Mannila 1997; Baral 2003) to compare answer sets and select the desired solutions. In our case, answer sets correspond to strategy profiles. Intuitively, the idea is to create a program with 3 parts: (i) a part describing strategy profiles and checking the satisfaction of the agents' goals, (ii) a part describing alternative strategies for all agents and checking the corresponding satisfaction of the agents' goals, (iii) a part checking whether or not the agents can improve their utility by deviating from the strategy profile in the first part and selecting the PNEs by saturation.

Let $G = (N, V, \pi, \Phi)$ be a BG. We start by adding the facts $\mathit{agent}(i) \leftarrow$ for every $i \in N$ and $\mathit{action}(p) \leftarrow$ for every $p \in V$ to the first program part $\mathcal{P}_1$. Next, we add a rule to express that every $p \in V$ is either undertaken or not:

$$\mathit{act}(P) \vee \neg \mathit{act}(P) \leftarrow \mathit{action}(P) \tag{1}$$

The capital letter P is a variable, and the rule means that if there exists a constant p such that the literal $\mathit{action}(p)$ is true, then either $\mathit{act}(p)$ or $\neg\mathit{act}(p)$ should be true. For every agent $i \in N$, we add a 'rule' that checks whether its goal is satisfied or not:

$$\mathit{goal}(i) \leftarrow \varphi_i(\mathit{act}(V)) \tag{2}$$

The notation $\varphi_i(\mathit{act}(V))$ represents the formula φ_i in which every $p \in V$ is replaced by $\mathit{act}(p)$. Note that the syntax of ASP does not allow an arbitrary formula in the body, but we translate these 'rules' into valid ASP rules. First our solver transforms the goals of the agents into negation-normal form (NNF). Then 'rules' of the form $\mathit{goal} \leftarrow \varphi$, with φ a propositional formula in NNF, are recursively translated to ASP rules by introducing new atoms. For instance, a 'rule' $\mathit{goal} \leftarrow ((a \wedge b) \vee \neg c) \wedge d$ is replaced with the set of rules $\{\mathit{goal} \leftarrow z, d; z \leftarrow a, b; z \leftarrow \neg c\}$, with z a newly introduced atom. We refer to the solver's implementation[2] for more details.

The second program part is denoted as $\mathcal{P}_2$. We add the following rules to $\mathcal{P}_2$, stating that every action is either undertaken or not in the alternative strategies:

$$\mathit{act'}(P) \vee \mathit{nact'}(P) \leftarrow \mathit{action}(P) \tag{3}$$

Using saturation requires simulating the strong negation $\neg$ with a prefix '*n*'. The intuitive idea is to make all the literals of $\mathcal{P}_2$ true in the third program part, therefore using $\neg\mathit{act'}(P)$ instead of $\mathit{nact'}(P)$ would lead to contradictions. By definition, the utility of every agent who individually deviates from a PNE cannot be strictly higher than its utility in the PNE. To know if the strategy s_i is a best response to s_{-i} for agent i, it suffices that either $u_i(s_{-i}, s_i) = 1$ or $u_i(s_{-i}, s_i') = 0$, $\forall s_i' \subseteq \pi_i$. Therefore it suffices to know whether φ_i is false for i's alternative strategy in $\mathcal{P}_2$. To this end, we add the following 'rules' to $\mathcal{P}_2$ for every $i \in N$:

$$\mathit{ngoal'}(i) \leftarrow n\varphi_i(\mathit{act}(\pi_{-i}), \mathit{nact'}(\neg\pi_i), \mathit{act'}(\pi_i)) \tag{4}$$

with $n\varphi_i$ the notation for a formula, equivalent to $\neg\varphi_i$, in NNF. The notation $n\varphi_i(\mathit{act}(\pi_{-i}), \mathit{nact'}(\neg\pi_i), \mathit{act'}(\pi_i))$ is the formula $n\varphi_i$ in which every occurrence of $p \in \pi_{-i}$ is replaced by $\mathit{act}(p)$, every occurrence of $\neg p$ with $p \in \pi_i$ is replaced by $\mathit{nact'}(p)$ and every other occurrence of $p \in \pi_i$ is replaced by $\mathit{act'}(p)$. As for (2), we translate (4) into valid ASP rules. With X' we denote the set of all newly introduced atoms during the translation of (4).

[1] This is also known as $\mathrm{NP}^{\mathrm{NP}}$-complete, a complexity class at the 2nd level of the Polynomial Hierarchy.

[2] http://www.cwi.ugent.be/BooleanGamesSolver.html.

The third program part $\mathcal{P}_3$ checks whether the strategy of agent i chosen in $\mathcal{P}_1$ is a better response than its alternative strategy in $\mathcal{P}_2$, given the strategies of the other agents in $\mathcal{P}_1$. If so, we derive $\mathit{pleased}(i)$ with the following rules of $\mathcal{P}_3$:

$$\mathit{pleased}(I) \leftarrow \mathit{goal}(I); \quad \mathit{pleased}(I) \leftarrow \mathit{ngoal'}(I) \qquad (5)$$

If all agents have a better response in $\mathcal{P}_1$ than in $\mathcal{P}_2$, we derive *sat* using the following rule of $\mathcal{P}_3$, in which the body literals are compactly denoted in a set. Moreover, we exclude answer sets in which *sat* is not derived:

$$\mathit{sat} \leftarrow \{\mathit{pleased}(i) \mid i \in N\}; \qquad \leftarrow \mathit{not\ sat} \qquad (6)$$

As part of the saturation technique, we set the literals introduced in $\mathcal{P}_2$ to true if *sat* is derived, by adding the following rules to $\mathcal{P}_3$ for every $x \in X'$:

$$\begin{aligned} \mathit{act'}(P) &\leftarrow \mathit{sat}, \mathit{action}(P); \quad \mathit{ngoal'}(I) \leftarrow \mathit{sat}, \mathit{agent}(I) \\ \mathit{nact'}(P) &\leftarrow \mathit{sat}, \mathit{action}(P); \qquad x \leftarrow \mathit{sat} \end{aligned} \qquad (7)$$

Together with (5), (7) implies that all literals of the form *pleased* will also be made true if *sat* is derived. The entire program $\mathcal{P}_1 \cup \mathcal{P}_2 \cup \mathcal{P}_3$ is called the *PNE-program induced by* G. Note that the Σ_2^{P}-complexity of deciding whether there is a PNE in a BG matches the Σ_2^{P}-complexity of our grounded disjunctive ASP programs (Baral 2003). We can prove that this ASP encoding is correct, i.e. that there is a one-to-one correspondence between the answer set of the induced PNE-program and the PNEs of the BG.

Adjusting the ASP program, we obtain an analogous result for core elements. Both encodings are generalized to an extended BG framework, allowing constraints on the possible strategies of the agents (Bonzon, Lagasquie-Schiex, and Lang 2012) and costs, imposed on agents depending on their chosen strategy (Dunne et al. 2008). Similarly, we have extended our encoding to additionally enforce Pareto optimality on the solutions. Due to space constraints, we refer to the implementation of our solver for more details.

Experiments

Experimental Set-up

We evaluate the performance of our ASP based method on instances of a structured problem, which we call *project BGs*. The problem consists of n persons, who can work on several projects. Depending on the project, each person has his preferences concerning the people he might collaborate with — partners — and the people he does not want to collaborate with — anti-partners. Someone who is not a partner, is a non-partner. Partnership and anti-partnership relations are anti-reflexive, not necessarily symmetric and project dependent. The project BGs are inspired by a BG about people being invited to a party (Bonzon, Lagasquie-Schiex, and Lang 2007; Dunne et al. 2008). We include 3 parameters for project BGs: (i) the number of agents, (ii) the number of projects and (iii) the probability of an agent being another agent's partner and the probability of a non-partner being an anti-partner. In a project BG, every agent i controls an action variable p_i^m per project m, interpreted as joining the project. For every project, every agent is randomly assigned one of 13 types, determined by three parameters: (i) personal preference: (a) join the project, (b) do not join, and (c) no preference; (ii) positive partnership (only relevant if level 1 is not (b)): (a) no condition, (b) only join a project if at least one partner joins, and (c) only join a project if all partners join; and (iii) negative partnership (only relevant if level 1 is not (b)): (a) no condition, and (b) only join the project if no anti-partners join. For each agent, we (uniformly) choose the personal preference, and based on this choice we (uniformly) choose among the allowed positive and negative partnerships. The type of an agent influences its goal. For example, agent i of type (c,b,b) has two partners j and k and one anti-partner l for a project m. Then the sub-goal of agent i corresponding to project m becomes $(p_i^m \wedge (p_j^m \vee p_k^m) \wedge \neg p_l^m) \vee \neg p_i^m$. So either agent i joins the project with j or k and without l, or agent i does not join. The overall goal of an agent is formed as the conjunction of the sub-goals corresponding to all the projects. All problem instances, problem generators and solvers have been made available at http://www.cwi.ugent.be/BooleanGamesSolver.html. The measurements have been performed on a dual CPU system with two 2.4GHz Intel Xeon six core E5-4610 processors and 8GB RDIMM.

Since there are currently no solvers for general BGs, there are only few options for a baseline. We consider two baselines: an NFG solver and a heuristic approach. In this paper we use on the one hand a standard approach to compute PNEs of NFGs in ASP (De Vos and Vermeir 1999), which we call the NFG baseline. To use it on BGs, we need to translate the BGs to NFGs, compute the PNEs and translate these PNEs back to BG format. Our second baseline uses the stochastic and iterative algorithm WSLpS on BGs as suggested in (De Clercq et al. 2014), but after each iteration, we verify whether the obtained strategy profile is a PNE or core element. For some classes of BGs, it can be shown that this algorithm is guaranteed to converge to a PNE without checking the best response condition (De Clercq et al. 2014) but in general it should be regarded as a heuristic method. Since WSLpS is stochastic, we run this baseline 25 times per BG.

Results

In a first experiment, we compute 1 PNE for project BGs with a timeout of 5 minutes. The number of agents varies from 5 to 50. For each fixed number of agents, we generate 100 BGs with 1, 2 or 3 projects and a 50% probability that an agent is another agent's partner and that a non-partner agent is an anti-partner. The median computation times, within a 95% confidence interval, are plotted in Figure 1. The results show that dASP strongly outperforms the NFG baseline. It also outperforms WSLpS if the number of agents is sufficiently high. The higher the number of projects, the smaller the number of agents at which dASP starts outperforming WSLpS. Note that for a wide range of parameters, dASP still succeeds in finding a solution for all problem instances, whereas both baselines consistently time out.

Secondly, we compute core elements instead of PNEs. Since the NFG baseline is not capable of computing core elements, we limit the experiments to WSLpS and dASP. For the same range of parameters as before, we compute

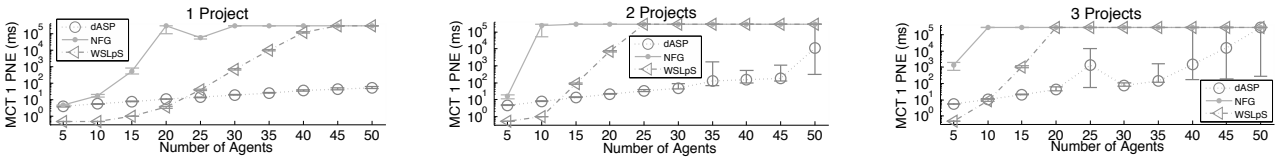

Figure 1: Median computation time (ms) of 1 PNE in project BGs.

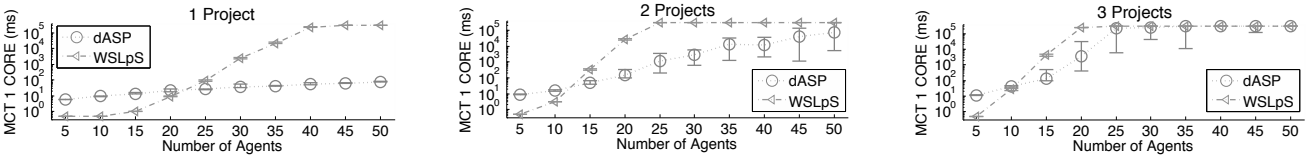

Figure 2: Median computation time (ms) of 1 core element in project BGs.

1 core element in 100 project BGs. The results are plotted in Figure 2. We observe that dASP consistently outperforms WSLpS for the more difficult problems instances.

Finally we investigate the scalability of our approach on project BGs with 2 projects, extended with costs and constraints. The constraints enforce that an agent can join at most 1 project. For both projects, an individual cost of 0, 1 or 2 is randomly assigned to joining the project. Not joining involves no costs. There are between 5 and 50 agents and we consider 100 BGs for each parameter setting. With a timeout of 10 minutes, respectively 1 PNE, 1 Pareto optimal PNE (POPNE), 1 core element or 1 Pareto optimal core element (POCORE) is computed. Note that no comparison with the baselines is made, since those are not equipped to deal with costs and constraints, nor to compute Pareto optimal solutions. The results are plotted in Figure 3. As expected, computing a PNE takes less time than computing a core element and enforcing Pareto optimality further increases the computation time of a PNE. For core elements, enforcing Pareto optimality does not demand more time. Although the computational cost is generally higher for stronger solution concepts or for BGs involving costs and constraints, our method remains suitable for medium-sized problems.

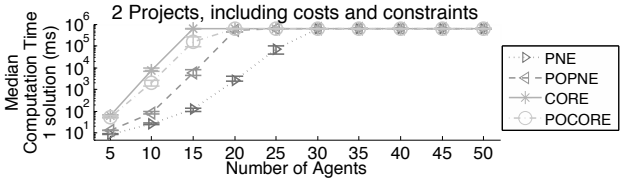

Figure 3: Computation of 1 solution in project BGs.

Conclusion

We proposed a method based on disjunctive ASP for finding the solutions of a BG. To the best of our knowledge, this is the first solver which is capable of handling general BGs (apart from methods based on an exponential translation to NFGs). Our solver can compute (Pareto optimal or arbitrary) PNEs and core elements, even in the presence of costs and constraints. Using a class of structured problems, called project BGs, we showed that our disjunctive ASP based method outperforms both a NFG based method and a heuristic method called WSLpS on sufficiently difficult problems, although for small instances WSLpS was faster on average. We also demonstrated the effectiveness of our method to find solutions under the presence of costs and constraints, and when Pareto optimality is required.

Abstract

Forgetting has been addressed in various areas in KR, including classical logic, logic programming, modal logic, and description logics. Here, we view forgetting as an abstract operator, independent of the underlying logic. We argue that forgetting amounts to a reduction in the signature of a language of a logic, and that the result of forgetting elements of a signature in a theory is the set of logical consequences over the reduced language. This definition offers several advantages. It provides a uniform approach to forgetting, applicable to any logic with a well-defined consequence relation. Obtained results are thus applicable to all subsumed formal systems, and typically are obtained much more straightforwardly. The approach also leads to insights with respect to specific logics: forgetting in first-order logic is somewhat different from the accepted approach; and the definition applied to logic programs yields a new syntax-independent notion of forgetting.

Introduction

Forgetting has been studied in the context of various logical systems, including classical propositional logic (PC), first-order logic (FOL), logic programming, modal logics, and description logics. While there is no generally-agreed upon definition, a common intuition is that in forgetting an agent becomes ignorant of, or unaware of, some part of its language.

Forgetting potentially has several pragmatic uses. For example, forgetting the part of a knowledge base (KB) that is irrelevant to a query may yield more efficient query-answering. Forgetting may provide a formal account of predicate hiding. As well, forgetting may be used in summarising a KB or reusing part of a KB or in clarifying relations between predicates.

A typical approach to addressing forgetting is to specify a host logic, give intuitions, and then provide a formal definition. Consequently, forgetting has been addressed with respect to various logics and with differing intuitions, but with no consensus as to what it means as a general concept.

In this paper, forgetting is addressed as an abstract belief change operator, independent of any specific formal system. The goal is to investigate forgetting at the *knowledge level* and thus independent of syntax. Our thesis is that forgetting amounts to a reduction in the *signature* of a language of a logic. This approach to forgetting is not new; in fact it is, implicitly or explicitly, the most common definition for the term.

This means that, for a given logic over a language with signature σ, forgetting $\sigma' \subseteq \sigma$ from a KB K is the set of consequences of K expressible over $\sigma \setminus \sigma'$. This definition is very simple but offers several advantages. Foremost, it provides a uniform approach, applicable to any logic with a well-defined consequence relation. By taking a general view, various issues are clarified, unified, and simplified. Obtained results are obviously applicable to all subsumed formal systems, and many results follow immediately. An inference-based perspective leads to simpler techniques for computing forgetting in some cases. Since forgetting results in a theory, the main computational challenge is to, if possible, determine a finite representation of forgetting, or a *uniform interpolant*. Notably, a uniform interpolant may not exist (e.g., in FOL) whereas forgetting remains well-defined.

The next section reviews related work while the third section presents notation and definitions. The fourth section presents the general approach. The next section briefly discusses applying the approach to specific logics. This is followed by a concluding section.

Background

The best-know definition of forgetting is due to George Boole, wherein forgetting an atom p from formula ϕ is given by $\phi[p/\top] \vee \phi[p/\bot]$. [Lin and Reiter, 1994] addresses forgetting in FOL. In logic programming, work has focussed on computing forgetting via program transformations. E.g.,[1] [Eiter and Wang, 2008] give an algorithm for computing forgetting in disjunctive logic programming. These approaches are syntactic, in that forgetting may produce different results for two programs that are strongly equivalent.

In modal logic, most work on forgetting *per se* has dealt with epistemic logic, although some work (e.g. [Ghilardi, 1995]) addresses uniform interpolation. [van Ditmarsch *et al.*, 2009] present an approach wherein "becoming ignorant" is modelled as an event in a dynamic epistemic logic. According to [van Ditmarsch *et al.*, 2009], there is no hard notion of what it means to forget something, whereas in the

Copyright © 2014, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

[1] The set of references is limited due to space contraints.

present approach, forgetting is uniquely defined.

In description logic, work has also focussed on uniform interpolation. E.g. [Konev *et al.*, 2009] addresses uniform interpolation in $\mathcal{EL}$. Characterizations of uniform interpolants are given via bisimulations between models. Work specifically on forgetting includes [Wang *et al.*, 2010], which addresses the problem in $\mathcal{ALC}$.

Formal Preliminaries

For an understood signature, a logic for a language is given in terms of a consequence relation $\vdash$. The relation $\vdash$ is assumed to be a Tarskian consequence relation; that is, it satisfies reflexivity, cut, and monotony. We allow sets of formulas on the right hand side of $\vdash$. $\Gamma \leftrightarrow \Psi$ abbreviates $\Gamma \vdash \Psi$ and $\Psi \vdash \Gamma$. As well, $\mathcal{C}n(\Gamma) = \{\phi \mid \Gamma \vdash \phi\}$.

The set of interpretations is denoted by Ω, where the logic and signature are understood from the context. $w \models \phi$ denotes that ϕ is true in interpretation w. $Mod(\phi)$ is the set of models of ϕ. $\Gamma \models \phi$ just if $Mod(\Gamma) \subseteq Mod(\phi)$. For the logics we consider, we have that $\Gamma \models \phi$ iff $\Gamma \vdash \phi$.

σ (σ', etc.) denotes a signature for a (given) logic. $\mathcal{L}_\sigma$ is the language defined over σ, where the language and consequence relation are clear from the context. $Sig(\Gamma)$ denotes the signature of Γ, i.e. the nonlogical symbols mentioned in formulas in Γ. We also use $Sig(w)$ to denote the signature associated with interpretation w.

The above notions may where appropriate be subscripted by a signature. E.g. for an understood logic, Ω_σ denotes the set of interpretations over, or restricted to, σ. In particular, $\mathcal{C}n_\sigma(\Gamma) = \{\phi \mid \Gamma \vdash \phi \text{ where } \phi \in \mathcal{L}_\sigma\}$

Let σ and σ' be signatures where $\sigma \subset \sigma'$. Then σ is a *reduct*[2] of σ', and σ' is an *expansion* of σ. If also $w \in \Omega_\sigma$, $w' \in \Omega_{\sigma'}$, and w and w' agree on the interpretation of symbols in σ then w is the *σ-reduct* of w', and w' is a *σ'-expansion* of w. $w'_{|\sigma}$ is the reduct of w' with respect to σ whereas $w_{\uparrow\sigma'}$ is the set of expansions of w with respect to σ'. This notation extends to sets of models and formulas in the obvious way. E.g. for $\sigma \subseteq \sigma'$, $\Gamma_{|\sigma}$ is the set of formulas in Γ with signature in σ.

The Approach

Our central definition is the following.

Definition 1 *Assume some fixed logic with language $\mathcal{L}$ and signature σ. Let $\Gamma \subseteq \mathcal{L}_\sigma$. The result of* forgetting *σ' in Γ, denoted $\mathcal{F}(\Gamma, \sigma')$, is given by:*

$$\mathcal{F}(\Gamma, \sigma') = \mathcal{C}n_\sigma(\Gamma) \cap \mathcal{L}_{\sigma \setminus \sigma'}.$$

While this definition is very simple, it specifies a unique, unambiguous operator, applicable to any "reasonable" logic. Notably, it applies to logics for which an interpolation theorem does not hold, such as classical FOL, S4, and various relevance logics and description logics. The characterization in Definition 1 is at the *knowledge level* and yields a theory. A key question then is to determine those instances of $\mathcal{F}$ that may be finitely characterized, i.e. for which a uniform interpolant exists.

$\mathcal{F}(\Gamma, \sigma')$ results in a reduced language (unless $\sigma \cap \sigma' = \emptyset$). We can re-express forgetting in the original language (as many approaches do) via:

$$\mathcal{F}_O(\Gamma, \sigma') = \mathcal{C}n_\sigma(\mathcal{F}(\Gamma, \sigma'))$$

The following results are elementary, but show that the definition of forgetting has the "right" properties.

Proposition 1 *Let Γ and Γ' be sets of sentences.*

1. $\Gamma \vdash \mathcal{F}(\Gamma, \sigma)$
2. *If* $\Gamma \leftrightarrow \Gamma'$ *then* $\mathcal{F}(\Gamma, \sigma) \leftrightarrow \mathcal{F}(\Gamma', \sigma)$
3. $\mathcal{F}(\Gamma, \sigma) = \mathcal{C}n_{\sigma'}(\mathcal{F}(\Gamma, \sigma))$ *where* $\sigma' = Sig(\Gamma) \setminus \sigma$.
4. $\mathcal{F}(\Gamma, \sigma_1 \cup \sigma_2) = \mathcal{F}(\mathcal{F}(\Gamma, \sigma_1), \sigma_2))$
5. Γ *is a* conservative extension *of* $\mathcal{F}(\Gamma, \sigma)$.

Thus, forgetting yields no new consequences; it is independent of syntax and results in a deductively-closed theory. Part 4 shows that forgetting is decomposable with respect to a signature; hence it is commutative with respect to its second argument. Last, in forgetting, no results over the reduced signature are lost.

The next results give a model-based characterisation.

Proposition 2 *Let$\sigma' \subseteq \sigma$, and let $\Gamma \subseteq \mathcal{L}_\sigma$.*

1. $Mod_{\sigma \setminus \sigma'}(\mathcal{F}(\Gamma, \sigma')) = Mod_\sigma(\Gamma)_{|(\sigma \setminus \sigma')}$
2. $Mod_\sigma(\mathcal{F}(\Gamma, \sigma')) = (Mod_\sigma(\Gamma)_{|(\sigma \setminus \sigma')})_{\uparrow\sigma}$

Thus the models of $\mathcal{F}(\Gamma, \sigma')$ are exactly the models of Γ restricted to the signature $\sigma \setminus \sigma'$. The second part expresses forgetting with respect to the original signature. The form in Proposition 2.2 has frequently appeared in the literature for characterising forgetting.

[Zhang and Zhou, 2009] give four postulates characterising their approach to forgetting in S5. An analogous result follows here.

Definition 2 *Signature σ is* irrelevant *to Γ, $IR(\Gamma, \sigma)$, iff there is Γ' such that $\Gamma \leftrightarrow \Gamma'$ and $Sig(\Gamma') \cap \sigma = \emptyset$.*

Proposition 3 $\Gamma' = \mathcal{F}_O(\Gamma, \sigma')$ *iff*

1. $\Gamma \vdash \Gamma'$
2. *If* $IR(\phi, \sigma')$ *and* $\Gamma \vdash \phi$ *then* $\Gamma' \vdash \phi$
3. *If* $IR(\phi, \sigma')$ *and* $\Gamma \nvdash \phi$ *then* $\Gamma' \nvdash \phi$
4. $IR(\Gamma', \sigma')$

Applying the Framework

We next instantiate the approach to specific logical systems, including PC, FOL, a relevance logic, and disjunctive logic programs. Given space constraints, some familiarity with these approaches is assumed.

Propositional Logic For this part, $\mathcal{L}$ is the language of PC, and $\mathcal{P}$, a signature, is a set of propositional atoms. For set of formulas Γ, Γ_{CNF} is the clause form of Γ, expressed as a set of sets of literals. $Res(S, p)$ is the set of resolvants of clauses in S with respect to p; e.g. for $S = \{\{p, q\}, \{\neg p, r\}, \{\neg p, s\}, \{t\}\}$, $Res(S, p) = \{\{q, r\}, \{q, s\}\}$. We obtain:

[2]This term is standard in model theory. It should not be confused with the term *reduct* in answer set programming.

Theorem 1 *Let $\Gamma \subseteq \mathcal{L}$ and $p \in \mathcal{P}$.*

1. $\mathcal{F}(\Gamma, p) \leftrightarrow \Gamma[p/\top] \vee \Gamma[p/\bot]$ *for finite* Γ.
2. $\mathcal{F}(\Gamma, p) \leftrightarrow \Gamma_{CNF|(\mathcal{P}\setminus\{p\})} \cup Res(\Gamma_{CNF}, p)$.

The first part shows that, restricted to PC, the result of forgetting according to Definition 1 coincides with the Boole definition. The second part gives an alternative means of computing forgetting that offers several advantages over the Boole definition. The Boole definition, while easily computable, only works for a finite set of formulas and results in a disjunction as the top-level connective in a KB (which in general may be awkward to work with). It does not readily extend to other logics including, as we will argue, FOL.

For the second means of computing forgetting, there is no need to require a finite KB, and the resulting KB is in a more useful form. However, it may result in a quadratic (in the number of clauses mentioning p) blowup of the KB. Other properties are inherited from Proposition 1 and 3. The model-theoretic characterisation of forgetting in PC is a corollary to Proposition 2.

First-Order Logic In FOL, nonlogical symbols are of two sorts: predicate and function symbols. [Lin and Reiter, 1994] define the forgetting of a predicate symbol via interpretations, using a definition analogous to Proposition 2. Forgetting a constant symbol doesn't appear to have been considered in the literature (nor for that matter, arbitrary function symbols). For forgetting a constant symbol we have the following.

Proposition 4 *Let $\Gamma \subset \mathcal{L}_\sigma$ be finite, c a constant, and $\Gamma_c = \{\phi \in \Gamma \mid c \in \sigma(\phi)\}$. For x not appearing in Γ we have:*

$$\mathcal{F}(\Gamma, c) \leftrightarrow (\Gamma \setminus \Gamma_c) \cup \{\exists x \wedge_{\mu \in \Gamma_c} \mu[c/x]\}.$$

Lin and Reiter also discuss forgetting a ground atomic formula. Our definition of forgetting is inapplicable in this case. Moreover, if Definition 1 were modified to admit ground atomic formulas, it would produce unacceptable results. E.g. consider forgetting that John is a student, $st(J)$, in Γ by taking the set of consequences $\Gamma' \subseteq \Gamma$ that don't mention $st(J)$. Then Γ' would still contain $\exists x(x = J \wedge st(x))$, since this is a consequence of Γ that does not mention $st(J)$. So not only does Γ' still entail $st(J)$, but Γ' is also not a (deductively-closed) theory.

We suggest that $st(J)$, or any well-formed formula for that matter, is not an appropriate object for forgetting: $st(J)$ is an *assertion* and the removal of this fact is in fact the removal of a *proposition*. In such a case the appropriate belief change operation is *contraction*. See the full paper for details.

Relevance Logic We next consider the relevance logic of *first degree entailment* $\mathbf{E}_{fde}$ [Anderson and Belnap Jr., 1975], a logic weaker than classical PC. $\mathbf{E}_{fde}$ provides an example where the standard Boole definition of forgetting is unsuitable. A formula of $\mathbf{E}_{fde}$ is of the form $\phi \rightarrow \psi$ where ϕ, ψ are propositional formulas formed using the standard connectives $\wedge$, $\vee$, $\neg$ but not mentioning $\rightarrow$. In $\mathbf{E}_{fde}$, the so-called "paradoxes of implication" such as $p \wedge \neg p \rightarrow \phi$ and $\phi \rightarrow p \vee \neg p$ are missing. See [Anderson and Belnap Jr., 1975] for an axiomatisation and semantic theory.

If we write $\phi \rightleftarrows \psi$ for $\phi \rightarrow \psi$ and $\psi \rightarrow \phi$, then it can be shown that $\phi \rightleftarrows \phi'$ holds where ϕ' is ϕ in CNF. Moreover, for ϕ, ψ in CNF, determining whether $\phi \rightarrow \psi$ holds can be easily determined: the entailment holds just when for each clause (disjunction) C in ψ there is a clause in ϕ whose literals are are among those in C.

With these facts, it is straightforward to define forgetting in $\mathbf{E}_{fde}$. For Γ a set of propositional formulas formed using connectives $\wedge$, $\vee$, $\neg$, define $\mathcal{C}n(\Gamma)$ by:

$$\mathcal{C}n(\Gamma) = \{\phi \mid \Gamma \rightarrow \phi\}.$$

Then Definition 1 can be applied. We obtain:

Theorem 2 *Let Γ be a set of propositional formulas formed using $\wedge$, $\vee$, $\neg$. Then*

$$\mathcal{F}(\Gamma, p) \rightleftarrows \{C \in \Gamma_{CNF} \mid \textit{ not: } p \rightarrow C\}.$$

Thus forgetting p from Γ is characterised by just those clauses in Γ, in CNF, that don't mention p. So forgetting in this case is a trivial operation once a KB is in CNF.

Logic Programming We turn next to answer set programming (ASP) [Gelfond and Lifschitz, 1988]. A (*disjunctive*) *logic program* (DLP) over a set of atoms $\mathcal{A}$ is a finite set of rules of the form

$$a_1; \ldots; a_m \leftarrow b_1, \ldots, b_n, {\sim}c_1, \ldots, {\sim}c_p$$

where $a_i, b_j, c_k \in \mathcal{A}$ and $0 \leq m, n, p$.

Operators ';' and ',' express disjunction and conjunction respectively. For atom a, ${\sim}a$ is (default) negation. A program induces 0, 1, or more *answer sets*, roughly, minimal sets of atoms that satisfy the rules. The difficulty is that a program is nonmonotonic with respect to its answer sets. E.g., the program $\{q \leftarrow {\sim}p\}$ has answer set $\{q\}$ while $\{q \leftarrow {\sim}p,\ p\}$ has answer set $\{p\}$.

More recently ASP has been put on a monotonic footing with a notion called *strong equivalence* [Lifschitz *et al.*, 2001] that provides an account of logical equivalence for programs. Subsequently, [Wong, 2008] has provided an inferential system for disjunctive rules that preserves strong equivalence. The set of inference rules may be found in the aforecited reference; the key point is that these rules allow a consequence relation $\mathcal{C}n(\cdot)$ to be defined, and consequently Definition 1 can be used.

Moreover, we can define a notion analogous to Res in Theorem 1 for computing *forget* in a DLP. That is, for a DLP P and atom a, we can define $ResLP(P, a)$ to be a set of rules such that

1. each rule in $ResLP(P, a)$ is obtained by a single application of an inference rule to rules in P; and
2. no rule in $ResLP(P, a)$ mentions a.

Then we obtain the result:

Theorem 3 *Let P be a DLP and $a \in \mathcal{A}$. Then:*

$$\mathcal{F}(P, a) \leftrightarrow P_{|(\mathcal{A}\setminus\{a\})} \cup ResLP(P, a).$$

The relation $\leftrightarrow$ is that of strong equivalence. Since we inherit the results of Proposition 1 and 3, the results of forgetting are independent of syntax, even though the expression

on the right hand side of Theorem 3 is a set of rules obtained by transforming and selecting rules in P. As in PC, forgetting an atom results in at worst a quadratic blowup in the size of the program. This then results in an interesting operator: As indicated in the Background section, there has been substantial effort in addressing forgetting in ASP. Such previous work is *syntactic*, in that the result of forgetting depends on the form of the underlying logic program, whereas the current approach is independent of how a program is expressed.

Other Logics Clearly the approach can be extended to other classes of logics. Thus, there is no obstacle in principle to providing a syntactic definition (analogous to Theorem 3) for forgetting in S5, for example by exploiting the inferential system RS5 of [Enjalbert and Fariñas del Cerro, 1989]. Further, the central definitions are applicable to description logics. The current approach then provides a definition of forgetting regardless of whether a particular system has the uniform interpolation property or not.

Conclusion

We have presented an account of forgetting as an abstract, knowledge level, belief change operator, in which forgetting constitutes a reduction in the signature of a KB. By taking a general view, various issues are clarified, unified, and simplified. To this end, the central definition is applicable to any logic with a well-defined consequence relation, and the results obtained are applicable to all subsumed logics. For a given logic and signature, we obtain a unique, syntax-independent operation of forgetting, independent also of a domain of application. Thus, to this last point, forgetting doesn't involve losing information about a domain *per se* but rather involves losing the ability to express, or represent, information about the domain.

We argue that this view leads to insights with respect to specific logics. In the literature, there is no universally-agreed on use of the term *forgetting*, and it has been used for conceptually different phenomena. Some approaches describe forgetting as "becoming ignorant" or base intuitions on forgetting knowledge. Such approaches would appear to address some form of *contraction* in an agent's knowledge.

We have considered "instantiations" of forgetting in PC, FOL, a relevance logic, and in disjunctive logic programs. Forgetting in FOL is somewhat different from the accepted approach; forgetting is readily definable in at least some relevance logics; and the definition applied to disjunctive logic programs yields a new syntax-independent definition of forgetting. Forgetting has most often been identified with uniform interpolation. Indeed there is a close relation: a uniform interpolant is a syntactic object, which may or may not exist for a given logic. Forgetting, in contrast, is well-defined for any "reasonable" logic. If a uniform interpolant exists, it corresponds to a (finite) representation of the result of forgetting. In fact, the key computational question for forgetting is whether a uniform interpolant exists and, if so, how it is determined.

Abstract

We report on an ongoing research program to develop a formal framework for automated narrative text comprehension, bringing together know-how from research in Artificial Intelligence and the Psychology of Reading and Comprehension. It uses argumentation to capture appropriate solutions to the frame, ramification, and qualification problems, and their generalizations as required for text comprehension. In this first part of the study we concentrate on the central problem of integration of the explicit information from the text narrative with the reader's implicit commonsense world knowledge, and the associated tasks of elaboration and revision.

Introduction

Text comprehension has long been identified as a key test for Artificial Intelligence (AI), with a central position in many forms of the Turing Test, and enormous benefits in human-computer interaction. The rise of computing over the Internet, where so much data is in the form of textual information, has given even greater importance to this topic. We report on a research program aiming to learn from the extensive text comprehension work in Psychology, and draw guidelines for developing frameworks for automated narrative text comprehension and, in particular, *story comprehension* (SC).

Our research program brings together know-how from research in Psychology and AI — in particular, our understanding of Reasoning about Actions and Change and Argumentation — to provide a formal representational and computational framework for SC that can be empirically evaluated and iteratively developed. This empirical evaluation, which forms an important part of the program, is based on the following methodology: *(i)* set up a corpus of stories with questions to test different aspects of story comprehension; *(ii)* harness the world knowledge used by human readers for comprehension; *(iii)* use this world knowledge in our framework and automated system, and compare its comprehension behaviour with that of the human readers.

The Psychology of Story Comprehension

Comprehending text entails the construction of a mental representation of the information contained in the text. However, no text specifies clearly and completely all the implications of text ideas or the relations between them. Therefore, comprehension depends on the ability to mentally represent the text-given information and to generate ***bridging and elaborative inferences*** that connect and elaborate text ideas resulting in a mental or ***comprehension model*** of the story. Inference generation is necessary in order to comprehend any text as a whole, i.e., as a single network of interconnected propositions instead of as a series of isolated sentences, and to appreciate the suspense and surprise that characterize narrative texts or stories, in particular (Brewer and Lichtenstein 1982; McNamara and Magliano 2009).

Although inference generation is based on the activation of background ***world knowledge***, the process is constrained by text information. Concepts encountered in the text activate related conceptual knowledge in the readers' long-term memory (Kintsch 1988). Nevertheless, at any given point in the process, only a small subset of all the possible knowledge-based inferences remain activated and become part of the mental representation: those that connect and elaborate text information in a way that contributes to the ***coherence*** of the mental model (Rapp and den Broek 2005; McNamara and Magliano 2009). Inference generation is a task-oriented process that follows the principle of ***cognitive economy*** enforced by a limited-resource cognitive system.

However, the results of this coherence-driven selection mechanism can easily exceed the limited working memory capacity of the human cognitive system. Therefore, coherence on a more global level is achieved through ***higher-level integration*** processes that operate to create macro-propositions that generalize or subsume a number of text-encountered concepts and the inferences that connected them. In the process, previously selected information that maintains few connections to other information is dropped from the mental model. This results in a more consolidated network of propositions that serves as the new anchor for processing subsequent text information (Kintsch 1998).

Comprehension also requires an iterative general ***revision mechanism*** of the readers' mental model. The feelings of suspense and surprise that stories aim to create are achieved through discontinuities or changes (in settings, motivations, actions, or consequences) that are not predictable or are wrongly predictable solely on the basis of the mental model created so far. Knowledge about the structure and the func-

Copyright © 2014, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

tion of stories leads readers to expect discontinuities and to use them as triggers to revise their mental model (Zwaan 1994). A change in time or setting in the text may serve as a clue for revising parts of the mental model while other parts remain and are integrated with subsequent text information.

The interaction of bottom-up and top-down processes for coherence carries the possibility of ***different*** but equally ***legitimate or successful comprehension*** outcomes, due to the qualitative and quantitative differences in the conceptual and mental state knowledge of different readers. Comprehension is successful if these differences are primarily in elaboration.

Scope of the Present Paper

We concentrate on the development of an appropriate Reasoning about Actions and Change and Default Reasoning framework for representing narratives and the *world knowledge* needed for the central comprehension process of *synthesizing and elaborating* the explicit text information with new inferences, and *revising* them in the presence of new narrative information. Our working hypothesis is that higher level features of comprehension, such as coherence and cognitive economy, can be tackled on top of the framework we develop. We are also assuming as solved the issue of correctly parsing the natural language of the text into some information-equivalent structured (e.g., logical) form of the story narrative, without discounting the importance of this latter problem, nor the possibility of the need to be tackled in conjunction with the problems on which we are focusing.

An excerpt from one of the stories used for the initial evaluation of our approach, is used as our running example.

Story excerpt: *[...] He aimed at the first turkey, and pulled the trigger. After a moment's thought, he opened his shotgun and saw there were no bullets in the shotgun's chamber. He loaded his shotgun, aimed at the turkey and pulled the trigger again. Undisturbed, the bird nearby continued to chirp and build its nest. Papa Joe was very confused. Would this be the first time that his shotgun had let him down?*

KRR for Story Comprehension

The close link between human commonsense reasoning, such as that used for SC, and argumentation has been recently re-enforced by new psychological evidence (Mercier and Sperber 2011) suggesting that human reasoning is in its general form inherently argumentative. In our proposed approach of KRR for SC, the reasoning to construct a comprehension model and its qualification and revision at all levels as the story unfolds, will be captured through a uniform acceptability requirement on the arguments that support the conclusions in the model. We use methods and results from Argumentation Theory in AI, e.g., (Dung 1995; Modgil and Prakken 2012), and its links to the area of Reasoning about Action and Change (RAC) with Default Reasoning on the static properties of domains (see (van Harmelen, Lifschitz, and Porter 2008) for an overview).

In particular, we use a typical RAC language of Fluents, Actions, and Times, to represent the narrative $\mathcal{N}$ of a story, and also the world knowledge $\mathcal{W}$ used for the story's comprehension. The exact time-points are mostly inconsequential, and are meant to stand for the abstract scenes in a story.

The narrative of our story excerpt is represented as a sequence of timed-observations (pj is short for "Papa Joe"):

$\text{OBS}(alive(turkey), 1)$, $\text{OBS}(aim(pj, turkey), 1)$,
$\text{OBS}(pull\_trigger(pj), 1)$, $\text{OBS}(\neg gun\_loaded, 4)$,
$\text{OBS}(load\_gun, 5)$, $\text{OBS}(pull\_trigger(pj), 6)$,
$\text{OBS}(chirp(bird), 10)$, $\text{OBS}(nearby(bird), 10)$.

World knowledge is represented as a collection of unit-arguments, in the form of simple associations between concepts in the language. This stems from a key observation in Psychology that typically all world knowledge, and irrespective of type, is inherently default. It is not in the form of an elaborate formal theory of detailed definitions of concepts, but rather is better regarded as a collection of relatively loose semantic associations between concepts, reflecting typical rather than absolute information. Thus, knowledge need not be fully qualified at the representation level, since it can be qualified via the reasoning process by the relative strength of other (conflicting) pieces of knowledge. This addresses the ***endogenous qualification problem***, while the implicit priority of information in the narrative over any unit-argument also addresses the ***exogenous qualification problem***.

The world knowledge needed to make sense of our story excerpt is given below, with the priorities $p1 \succ c1$, $p2 \succ c1$:

$c1:\ \texttt{cau}(fired\_at(pj, X), \{aim(pj, X), pull\_trigger(pj)\})$
$c2:\ \texttt{cau}(\neg alive(X), \{fired\_at(pj, X), alive(X)\})$
$c3:\ \texttt{cau}(noise, \{fired\_at(pj, X)\})$
$c4:\ \texttt{cau}(\neg chirp(bird), \{noise, nearby(bird)\})$
$c5:\ \texttt{cau}(gun\_loaded, \{load\_gun\})$
$p1:\ \texttt{pro}(\neg fired\_at(pj, X), \{\neg gun\_loaded\})$
$p2:\ \texttt{pro}(\neg fired\_at(pj, X), \{\neg noise\})$ (story-specific)

Each unit-argument is of the general form $\texttt{arg}(H, B)$, with a literal (a fluent / action or its negation) H for its head, and a set of literals B for its body. Unit-arguments are able to capture information pertaining to how properties are caused to come about ($\texttt{cau}(H, B)$), how they relate to each other ($\texttt{pro}(H, B)$), and how they persist ($\texttt{per}(H, \{H\})$); unit-arguments of the latter type are implicitly assumed to be present for each literal H. Conflicts between unit-arguments are resolved based on the priority relation $\succ$ that holds between them. In general, the priority relation $\succ$ includes *(i)* $\texttt{cau}(H, B_1) \succ \texttt{per}(\neg H, B_2)$; *(ii)* $\texttt{per}(H, B_1) \succ \texttt{pro}(\neg H, B_2)$; and *(iii)* any given story-specific priorities.

The priority amongst these basic units of knowledge gives a form of non-monotonic reasoning (NMR) for deriving new properties that hold in the story. In particular, priorities in *(i)* address the ***frame problem***, ensuring that properties cease to persist when there is causal evidence to the contrary. When we need to reason with defeasible property information, such as default rules about the normal state of the world in which a story takes place, we are also faced with a ***generalized frame problem***, where "a state of the world persists irrespective of the existence of general state laws". Hence, if we are told that the world is in fact in some exceptional state that violates a general (default) property, this will continue to be the case in the future, until we learn of (or derive) some causal information that returns the world into its normal state. The solution to this generalized frame problem is

captured succinctly by inclusion of the priorities in *(ii)*.

Story-specific priorities account for the proper qualification of information in the context of a specific story. In our example story, for instance, we are told (outside the excerpt) that the gun had always made a loud noise when it fired. This is captured by including the story-specific priority $p2 \succ c1$.

In accordance to psychological evidence, the use of unit-arguments as loose associations allows for the *"fast thinking"* and easy elaboration with new inferences critical in narrative comprehension. On the other hand, easy elaboration and the extreme form of qualification that it needs are mitigated by the requirement that elaborative inferences need to be *grounded* on the narrative and *sceptical* in nature.

Argumentation Semantics

Given a narrative $\mathcal{N}$ and a world knowledge $\mathcal{W}$, we formulate an argumentation framework $\langle \mathcal{A}, \mathcal{T}, \mathcal{D} \rangle$ by defining the set of arguments $\mathcal{A}$, the attacking relation $\mathcal{T} \subseteq \mathcal{A} \times \mathcal{A}$, and the defending relation $\mathcal{D} \subseteq \mathcal{A} \times \mathcal{A}$, as in the sequel.

Arguments in $\mathcal{A}$ are collections of tuples, each comprising a unit-argument, the time-point at which it is applied, and the inference that follows from its application. The introduction of time-points is necessitated as each given unit-argument can be possibly applied multiple times, with each application qualified by other conflicting knowledge in different ways.

The inference that follows is of the form (X, T), where X is a fluent / action literal, and T the time-point at which it is inferred to hold. We allow a unit-argument $\texttt{arg}(H, B)$ to be used in the usual forward direction to draw (H, T) as inference (with T the time-point at which the unit-argument's head is applied), given that the premises B hold (at the appropriate time-point). In addition, we allow a unit-argument to be used in a backward direction (capturing, in this manner, reasoning by reductio ad absurdum) to draw $(\neg X, T)$ as inference (with T the time-point at which the unit-argument's body is applied), given that $X \in B$ and that the premises $B \setminus \{X\}$ and $\neg H$ hold (at the appropriate time-points).

Despite the use of defeasible world knowledge, the framework includes ***reasoning by contradiction***. The psychological debate on whether humans reason by contradiction, e.g., contraposition (Rips 1994; Johnson-Laird and Yang 2008) notwithstanding, it is still natural for a formal argumentation framework to capture such indirect reasoning; e.g., (Kakas and Mancarella 2013; Kakas, Toni, and Mancarella 2013). A main consequence is that it gives a form of ***backward persistence***, e.g., from an observation to support (but not necessarily conclude, due to a possible qualification) that the observed property holds also at previous time-points. Note also that the separation of the inference type (e.g., forward and backward) is known to be significant in preference-based argumentation (Modgil and Prakken 2012), and necessitates a careful treatment of the definition of attacks and defences.

To reflect the suggestion by Psychology that inferences drawn by readers are strongly tied to the story, we require that the activation conditions of argument tuples must be eventually traced back to the explicit information in the narrative of the story representation. Thus, each argument is restricted so that the premises of each tuple it contains are supported either directly by the narrative itself, or by inferences of other tuples in the argument in a non-cyclic manner.

The second key suggestion by Psychology that inferences are sceptical is reflected by allowing attacks to be generated "easily", and insisting that defences are "harder" to generate. Therefore, in case of "equally strong" arguments (leading to a non-deterministic split), there is an attack, but no defense.

Roughly, an argument A_1 attacks an argument A_2, and thus $(A_1, A_2) \in \mathcal{T}$, if they draw conflicting conclusions. The use of contrapositive reasoning for backward inference also means that it is possible to have arguments that support conclusions that are not contrary to each other, but whose unit-arguments have conflicting heads. For instance, in our running example we can use the causal unit-argument $c1$ in A_1 to forward derive $fired\_at(pj, X)$ and the property unit-argument $p1$ in A_2 to backward derive gun_loaded from $fired\_at(pj, X)$; despite that the derived conclusions of A_1 and A_2 are not in conflict, the unit-arguments used have conflicting heads. Although not all such *indirect* conflicts are important, a certain subset does need to be accounted for.

Assuming that $(A_1, A_2) \in \mathcal{T}$, an argument A_2 defends an argument A_1, and thus $(A_2, A_1) \in \mathcal{D}$, if the former undercuts the latter, but the latter does not undercut the former. Undercutting means that a unit-argument in A_2 has a higher priority than a unit-argument in A_1, capturing, in effect, a weakness in the chain of reasoning that A_1 used to attack A_2; cf. (Modgil and Prakken 2012). Again, care needs to be taken in dealing with indirect conflicts, as a result of the *defeasible nature* of the world knowledge and the allowance of reasoning by contradiction on such defeasible information.

Finally, an argument Δ is acceptable if it does not have a conflict with the narrative or itself, and for every argument A that attacks Δ, Δ defends A. An acceptable argument corresponds to a comprehension model of the story $\mathcal{N}$ under the world knowledge $\mathcal{W}$. A comprehension model can be tested, as is often done in Psychology, through a series of multiple-choice questions with answers of the form "X holds at T". Such an answer is accepted if (X, T) is entailed by the comprehension model, it is rejected if $(\neg X, T)$ is entailed by the comprehension model, and it is possible otherwise.

Evaluation through Empirical Studies

We have implemented the KRR framework as a Prolog system able to read a story narrative as a sequence of segments, compute a comprehension model, answer questions, and repeat the process, revising its conclusions as more parts of the story narrative become available. The process runs in time polynomial in the size of the world knowledge and the size of the story narrative, and is sound w.r.t. the framework.

In the first part of the evaluation of our approach we carried a *psychological study* to ascertain the world knowledge that is activated to successfully comprehend stories such as our example story on the basis of data obtained from human readers. We developed a set of inferential questions to follow the reading of pre-specified story segments. These assessed the extent to which readers connected, explained, and elaborated key story elements. Readers were instructed to answer each question and to justify their answers using a "think-aloud" method of answering questions while reading, in order to reveal the world knowledge that they had used.

The qualitative data from the readers was pooled together and analysed as to the frequencies of the types of responses in conjunction with the information given in justifications and think-aloud protocols. Considering those readers that demonstrated successful comprehension according to psychological criteria, our system was able to identify the most popular answers to questions, and also to recognize questions for which no single answer was (sceptically) accepted, following the variability demonstrated by human readers.

Related Work and Conclusions

Automated story understanding has been an ongoing endeavor of AI for more than forty years (Mueller 2002; 2013). Logic-related approaches have largely proceeded under the assumption that standard logical reasoning techniques can subsequently be applied; e.g., satisfiability (Mueller 2003) or planning (Niehaus and Young 2009). To our knowledge there has been very little work relating story comprehension with computational argumentation, an exception being (Bex and Verheij 2010), in which a case is made for combining narrative and argumentation techniques in the context of legal reasoning. Argumentation for reasoning about actions and change, on which our formal framework builds, has been studied in (Vo and Foo 2005; Michael and Kakas 2009).

To complete a fully automated approach to SC we continue drawing lessons from Psychology to address further the computational aspects of cognitive economy and coherence, by applying "computational heuristics" on top of the semantic framework we have developed. We are also investigating the systematic extraction or acquisition of commonsense world knowledge using lexical databases (Miller 1995; Baker, Fillmore, and Lowe 1998; Palmer, Gildea, and Kingsbury 2005), knowledge base archives (Lenat 1995), or automated extraction of commonsense knowledge from text (Michael and Valiant 2008; Michael 2009; 2011; 2013).

We envisage that the strong inter-disciplinary nature of our work can provide a concrete and important test-bed for evaluating the development of frameworks in AI while at the same time offering valuable feedback for Psychology.

Abstract

Several researchers have developed properties that ensure compatibility of a concept similarity or dissimilarity measure with the formal semantics of Description Logics. While these authors have highlighted the relevance of the triangle inequality, none of their proposed dissimilarity measures satisfy it. In this work we present a theoretical framework for dissimilarity measures with this property. Our approach is based on concept relaxations, operators that perform stepwise generalizations on concepts. We prove that from any relaxation we can derive a dissimilarity measure that satisfies a number or properties that are important when comparing concepts.

1 Introduction

By nature description logics are well equipped for representing precise knowledge in a formal manner. As ontologies and description logics (DL) reach out to a broader audience some limitations become evident. In practice, it often occurs that two concepts have similar meanings, but no precise logical relationship can be established. Similarity measures, or dually dissimilarity measures, are attempts to quantify the differences between concepts. They are crucial in areas such as information retrieval in ontologies, ontology alignment, inductive logic programming and for some tasks in non-monotonic reasoning such as model-based revision or aggregation.

In a DL setting similarity can be defined between individuals, concepts, or even ontologies. In this work we focus exclusively on concept similarity. A large number of concept similarity measures has been developed, most of which are tailored to the specific needs of a particular field, such as biomedicine (Pesquita et al. 2009), or geospatial reasoning (Janowicz and Wilkes 2009). These approaches can be classified according to various criteria, such as the ones given in (Borgida, Walsh, and Hirsh 2005). Initially, the quality of similarity measures has only been measured in terms of empirical evaluations. Increasingly, researchers are starting to look at theoretical properties that ensure compatibility of a similarity measure with the formal semantics of description logics. Works such as (d'Amato, Staab, and Fanizzi 2008) and (Lehmann and Turhan 2012) list amongst others the properties of a metric, in particular the triangle inequality, as well as soundness with respect to equivalence and subsumption.

The triangle inequality has been somewhat controversial and in some applications such as (Janowicz and Wilkes 2009) it is not needed. In other applications such as metric-based conceptual clustering and distance-based optimization methods it is crucial (Fayyad et al. 1996). Unfortunately, even the measures presented in (Lehmann and Turhan 2012) and (d'Amato, Staab, and Fanizzi 2008) with their otherwise good theoretical properties do not satisfy the triangle inequality. Our results aim to provide knowledge engineers from these fields with an adequate measure.

In this work, we give a general framework that can be used to construct concept dissimilarity measures with good theoretical properties, including the triangle inequality. The framework is based on concept relaxations, operators that can be used to successively make concepts more general. A directed distance between two concepts C and D can then be defined as the number of times D needs to be relaxed before it subsumes C. We show that the maximum of the two directed distances yields a good dissimilarity measure. Finally, we demonstrate ways to instantiate the framework.

2 Preliminaries

2.1 Description Logics

Description logics are a family of knowledge representation formalisms (Baader 2003). Every description logic $\mathcal{L}$ provides a set of *concepts* $\mathsf{C}(\mathcal{L})$. Concept descriptions are recursively obtained from a set of *concept names* $\mathcal{N}_C$ and a set of *role names* $\mathcal{N}_R$ using concept constructors such as conjunction $\sqcap$, existential restrictions $\exists$ or the top concept $\top$, among others. The description logic that only allows for these three constructors is called $\mathcal{EL}$. In $\mathcal{EL}$, concepts can be visualized as *$\mathcal{EL}$-Description Trees* where node labels represent concept names and edges represent roles. For example the tree in Figure 1 represents the concept

$$\mathsf{Person} \sqcap \exists \mathsf{c}.\mathsf{Male} \sqcap \exists \mathsf{c}.\exists \mathsf{c}.\mathsf{Female}. \qquad (1)$$

Using a model based semantics one can define a generality relation on concepts. If D is more general than C, in other words D subsumes C, we write $C \sqsubseteq D$. We say that C and D are *equivalent* (denoted by $C \equiv D$) if both $C \sqsubseteq D$ and $D \sqsubseteq C$ hold.

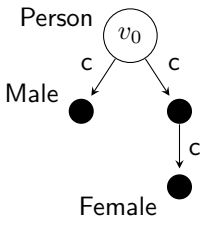

Figure 1: $\mathcal{EL}$-Description Tree for (1)

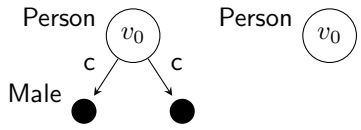

Figure 2: Consecutive applications of ρ_{depth} to (1)

In description logics, axioms are typically stored in ontologies, which can be divided into TBoxes and ABoxes. We define our framework in the absence of background ontologies.

2.2 Similarity and Dissimilarity on Concepts

When similarity measures were first investigated within the DL community, researchers mainly focused on adaptations of existing measures from other fields (cf. (Borgida, Walsh, and Hirsh 2005) for a survey). The quality of these measures was mainly examined in an empirical way, showing that they perform well in a given setting, but providing little transferable insight. It was only in (d'Amato, Staab, and Fanizzi 2008) that qualitative criteria were developed, based on the ones given by (Bock and Diday 2000). The following definition is slightly adapted to dissimilarity between concepts.

Definition 1 (Dissimilarity (Bock and Diday 2000)). *Let $\mathcal{L}$ be a DL language. A function $d\colon \mathsf{C}(\mathcal{L}) \times \mathsf{C}(\mathcal{L}) \to \mathbb{R}$ is called a* dissimilarity measure *if it satisfies the following properties for all $C, D \in \mathsf{C}(\mathcal{L})$.*

- positiveness: $d(C, D) \geq 0$
- reflexivity: $d(C, C) = 0$, *and*
- symmetry: $d(C, D) = d(D, C)$.

These properties can be expected to hold for any dissimilarity measure. In a description logics context it should also be compatible with the semantics of the logic. To ensure this, (d'Amato, Staab, and Fanizzi 2008) and more recently (Lehmann and Turhan 2012) have introduced an extended set of properties. These properties are originally stated for similarity measures, here we present their equivalents for dissimilarity measures.

Definition 2. *A dissimilarity measure $d\colon \mathsf{C}(\mathcal{L}) \times \mathsf{C}(\mathcal{L}) \to \mathbb{R}$ is called*

- equivalence closed *if $d(C, D) = 0 \implies C \equiv D$,*
- equivalence sound *if $D \equiv E \implies d(C, D) = d(C, E)$,*
- subsumption preserving *if $C \sqsubseteq D \sqsubseteq E \implies d(C, D) \leq d(C, E)$*
- reverse subsumption preserving *if $C \sqsubseteq D \sqsubseteq E \implies d(D, E) \leq d(C, E)$*
- structurally dependent *if for all sequences $(C_n)_n$ of atoms with $C_i \not\sqsubseteq C_j$ for all $i, j \in \mathbb{N}$, $i \neq j$ the concepts*

$$D_n = \prod_{i \leq n} C_i \sqcap D, E_n = \prod_{i \leq n} C_i \sqcap E$$

satisfy $\lim_{n\to\infty} d(D_n, E_n) = 0$ for all $C, D, E \in \mathsf{C}(\mathcal{L})$.

- *We say that d fulfills the* triangle inequality *if $d(C, E) \leq d(C, D) + d(D, E)$ for all $C, D, E \in \mathsf{C}(\mathcal{L})$.*

A dissimilarity d is a *metric* if it satisfies the triangle inequality and is additionally strict, i.e. $d(x, y) = 0$ implies $x = y$.

A desirable feature of a good dissimilarity measure is that concepts with more common features should be less dissimilar than concepts with few common features. Structural dependence is a formalization of this idea. Another attempt has been introduced in (d'Amato, Staab, and Fanizzi 2008), where it is formalized in terms of common subsumers.

Definition 3 ((Strict) Monotonicity). *A dissimilarity measure $d\colon \mathsf{C}(\mathcal{L}) \times \mathsf{C}(\mathcal{L}) \to \mathbb{R}$ is called* (strictly) monotone *if for all $C, D, E \in \mathsf{C}(\mathcal{L})$ that satisfy*

- *every common subsumer of C and E also subsumes D,*
- *there is a common subsumer of C and D that does not subsume E,*

it holds that $d(C, D) \leq d(C, E)$, respectively $d(C, D) < d(C, E)$.

3 General Framework

We provide a general framework for defining dissimilarity measures. All dissimilarity measures obtained within this framework have all properties from Section 2.2, except monotonicity and structural dependence. The framework is based on *concept relaxation operators*, operators that allow a stepwise generalization of concepts.

Definition 4 (Relaxation). *A* (concept) relaxation *is an operator $\rho\colon \mathsf{C}(\mathcal{L}) \to \mathsf{C}(\mathcal{L})$ that satisfies the following three properties for all $C, D \in \mathcal{L}$.*

1. *ρ is* non-decreasing*, i.e. $C \sqsubseteq D$ implies $\rho(C) \sqsubseteq \rho(D)$,*
2. *ρ is* extensive*, i.e. $C \sqsubseteq \rho(C)$, and*
3. *ρ is* exhaustive*, i.e. $\exists k \in \mathbb{N}_0\colon \top \sqsubseteq \rho^k(C)$, where ρ^k denotes ρ applied k times, and ρ^0 is the identity.*

Examples for relaxation operators that can be used to instantiate the framework are presented in Section 4.

A dissimilarity measure that is equivalence sound and closed should have the value $d(C, D) = 0$ if and only if $C \equiv D$, i.e. iff $C \sqsubseteq D$ and $D \sqsubseteq C$. Like (Lehmann and Turhan 2012) and (Suntisrivaraporn 2013) we first introduce directed measures d^d_ρ that capture how "far" D is from being a subsumer of C, and vice versa. If both $C \sqsubseteq D$ and $D \sqsubseteq C$ hold, then both directed measures will be 0. The directed measure $d^d_\rho(C, D)$ counts how often we need to successively relax D to reach a subsumer of C. If we think of concepts in terms of sets of individuals, then the intuition behind successive relaxations can be visualized as in Figure 3.

Definition 5 (Directed measure). *Let ρ be a relaxation on $\mathsf{C}(\mathcal{L})$. For $C, D \in \mathsf{C}(\mathcal{L})$ the* directed measure *$d^d_\rho(C, D)$ is defined as*

$$d^d_\rho(C, D) = \min\{k \in \mathbb{N}_0 \mid C \sqsubseteq \rho^k(D)\},$$

where ρ^k denotes ρ applied k times, and ρ^0 is the identity.

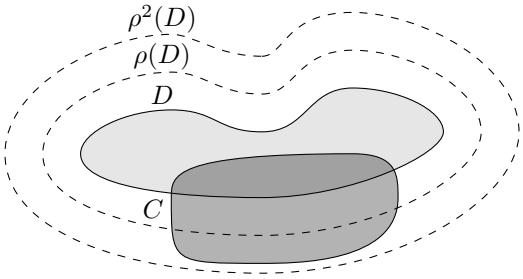

Figure 3: D needs to be relaxed twice before it subsumes C, i.e. $d^d_\rho(C, D) = 2$

The directed measure is always finite because ρ is exhaustive. We can then define the *relaxation dissimilarity* based on a relaxation operator simply as the maximum of the two directed measures.

Definition 6 (Relaxation Dissimilarity). *Let $\rho\colon \mathcal{L} \to \mathcal{L}$ be a relaxation on $\mathsf{C}(\mathcal{L})$. For two concepts C and D the* relaxation dissimilarity $d_\rho(C, D)$ *is defined as*

$$d_\rho(C, D) = \max\{d^d_\rho(C, D), d^d_\rho(D, C)\}.$$

Theorem 1. *For every relaxation ρ the operator d_ρ is a dissimilarity measure, that is equivalence sound, equivalence closed, subsumption preserving and reverse subsumption preserving, and satisfies the triangle inequality.*

Proof. Positiveness, reflexivity and symmetry follow trivially from Definitions 5 and 6, and therefore d_ρ is a dissimilarity measure.

We have the following chain of equivalences: $C \equiv D$, iff $C \sqsubseteq D$ and $D \sqsubseteq C$, iff $C \sqsubseteq \rho^0(D)$ and $D \sqsubseteq \rho^0(C)$, iff $d^d_\rho(C, D) = d^d_\rho(D, C) = 0$, iff $d_\rho(C, D) = 0$. Thus d_ρ is both equivalence sound and equivalence closed.

To prove the triangle inequality, let C, D, E be concept descriptions and let $d_\rho(C, D) = d_1$, $d_\rho(D, E) = d_2$. Then in particular, $d^d_\rho(C, D) \leq d_1$ and thus $C \sqsubseteq \rho^{d_1}(D)$ by extensivity. Similarly, we obtain $D \sqsubseteq \rho^{d_2}(E)$. Since relaxations are non-decreasing we obtain from the latter

$$\rho^{d_1}(D) \sqsubseteq \rho^{d_1+d_2}(E)$$

and therefore $C \sqsubseteq \rho^{d_1+d_2}(E)$, i.e. $d^d_\rho(C, E) \leq d_1 + d_2$. Analogously, it can be shown that $d^d_\rho(E, C) \leq d_1 + d_2$ and thus $d_\rho(C, E) \leq d_1 + d_2 = d_\rho(C, D) + d_\rho(D, E)$.

To show subsumption preservation let $C \sqsubseteq D \sqsubseteq E$ with $d_\rho(C, E) = d$. Then in particular, $E \sqsubseteq \rho^d(C)$ and thus also $D \sqsubseteq \rho^d(C)$. On the other hand, $C \sqsubseteq \rho^0(D) \sqsubseteq \rho^d(D)$ by extensivity, which yields $d_\rho(C, D) \leq k = d_\rho(C, E)$, which proves subsumption preservation. □

A comparison of these properties with those of some existing measures is provided in Table 1.

4 Instantiations

Theorem 1 shows that our framework produces dissimilarity measures with good theoretical properties. The framework can be instantiated with any relaxation operator. The behaviour of the resulting measures can vary greatly depending on the relaxation. This is demonstrated by the following examples. A trivial relaxation in any description logic is the operator $\rho_\top$ that maps every concept to $\top$. It results in a very coarse dissimilarity measure $\rho_\top$ that is 0 iff the concepts are equivalent and 1 otherwise.

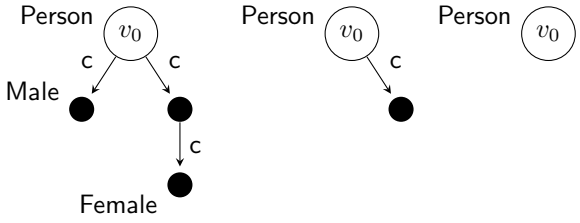

Figure 4: Consecutive application of ρ_{leaves} to (1)

Relaxations from tree operations For the lightweight logic $\mathcal{EL}$ (Baader, Küsters, and Molitor 1999) have proven a close connection between $\mathcal{EL}$ concepts and description trees. Due to this connection any operator that maps description trees to strict subtrees gives rise to a relaxation. One possibility is the operator ρ_{depth} that reduces the role depth of each concept by 1, simply by pruning the description tree (cf. Figure 2). The corresponding dissimilarity ρ_{depth} measures the first depth-level where the concepts differ in the description tree. It gives higher weight to features at a smaller depth. For example, if we compare the concepts $\mathsf{F} := \mathsf{Male} \sqcap \exists\mathsf{hasChild}.\top$ and $\mathsf{HoJ} := \mathsf{Male} \sqcap \exists\mathsf{marriedTo}.(\mathsf{Female} \sqcap \mathsf{Judge})$ to the concept $\exists\mathsf{hasChild}.\top$ the value will be 2 in both cases, since the change occurs at the lowest level, in the concept name Male. This is counterintuitive, since F and $\exists\mathsf{hasChild}.\top$ share more common features than HoJ and $\exists\mathsf{hasChild}.\top$. A slightly better behaviour can be achieved by the relaxation ρ_{leaves} that removes all leaves from a description tree (Figure 4).

Relaxations from distances between models As logics become more expressive, it becomes harder to directly define a relaxation on the concepts. Since the models remain simple labeled graphs, even for complex descriptions, one solution is to identify concepts with the set of their models. Similar to related work from Section 5 one might start with a simple distance between models, e.g. an edit distance, and generalize it to a Hausdorff distance between sets of models. However, since the model space is infinite the Hausdorff distance can often not be computed directly.

A workaround is to use the distance on the model space to define dilations, as used in mathematical morphology (Serra 1982), on sets of models. For some distances, such as a simple tree edit distance, the dilated sets themselves correspond to DL concepts. The operator that maps a concept to the concept corresponding to its dilated set of models can be shown to be a relaxation. All these instantiations will be further studied in our future work.

(d'Amato, Staab, and Fanizzi 2008)	✓	✓	–	✓	✓	–	–
relaxation dissimilarity	✓	–	✓	✓	✓	–	✓

5 Existing Metrics for Other Logics

Outside of description logics several works have proposed metrics between logical objects. Works such as (Nienhuys-Cheng 1998; Ramon and Bruynooghe 1998) exploit the fact that is relatively easy to define a metric on ground expressions in first order logic. They extend these ground distances to sets of atoms, or Herbrand interpretations using constructions such as Hausdorff distances or Manhattan distances.

In some cases it is straightforward to define a distance between two terms if one is a generalization of the other. To obtain a distance between two arbitrary terms one can simply use the sum of the distances to their least general common generalization. In a general form (Birkhoff 1993) has presented this idea as the classical distance in graded lattices. It is used to define a distance between first order literals by (Hutchinson 1997), who then generalizes it to a distance between clauses using the Hausdorff metric. This idea can also be extended to cases where there is no unique minimally general generalization (De Raedt and Ramon 2009).

6 Discussion

In this work, we have presented a framework for dissimilarity measures whith good theoretical properties (cf. Table 1). Our measures satisfy at the same time the properties of a metric, in particular the triangle inequality, and they are compatible with the semantics of description logics, in particular they are equivalence sound. Some hints for instantiations of the proposed framework have been provided, and will be the focus of future work.

The similarity measures that we have presented here are defined for concepts without TBoxes. If the background ontology is an acyclic TBox, they can trivially be adapted by comparing only unfolded concepts. In principle, it is possible to generalize relaxations with respect to general TBoxes, but it is left for future work how to instantiate them.

Acknowledgments. This work was initiated during the stay of Felix Distel at Telecom ParisTech in summer 2012, supported by a grant from this institution. Felix Distel has also been supported by the Collaborative Research Center 912 'Highly Adaptive Energy-Efficient Computing'. The authors would like to thank Anni-Yasmin Turhan for fruitful discussions.

Abstract

The Region Connection Calculus (RCC) is a well-known calculus for representing part-whole and topological relations. It plays an important role in qualitative spatial reasoning, geographical information science, and ontology. The computational complexity of reasoning with RCC has been investigated in depth in the literature. Most of these works focus on the consistency of RCC constraint networks. In this paper, we consider the important problem of redundant RCC constraints. For a set Γ of RCC constraints, we say a constraint (xRy) in Γ is *redundant* if it can be entailed by the rest of Γ. A *prime subnetwork* of Γ is a subset of Γ which contains no redundant constraints but has the same solution set as Γ. It is natural to ask how to compute a prime subnetwork, and when it is unique. In this paper, we show that this problem is in general intractable, but becomes tractable if Γ is over a tractable subclass of RCC. If $\mathcal{S}$ is a tractable subclass in which weak composition distributes over non-empty intersections, then we can show that Γ has a unique prime network, which is obtained by removing all redundant constraints from Γ. As a byproduct, we identify a sufficient condition for a path-consistent network being minimal.

1 Introduction

Qualitative spatial reasoning (QSR) is a common subfield of artificial intelligence and geographical information science, and has applications in GIS, cognitive robotics, high-level understanding of video data etc. The Region Connection Calculus (RCC) (Randell, Cui, and Cohn 1992) is perhaps the most well-known calculus for representing qualitative spatial information. Based on a binary connectedness relation, it defines a class of binary topological relations between regions in a connected topological space (e.g., the real plane). The RCC is an expressive formalism for representing topological information, and the computational complexity of reasoning with RCC has been investigated in depth in the literature. Most of these works focus on the consistency or satisfiablility of RCC constraint networks.

In this paper, we consider the important problem of redundant RCC constraints. Given a set Γ of RCC constraints, we say a constraint (xRy) in Γ is *redundant* if it can be entailed by the rest of Γ, i.e., removing (xRy) from Γ will not change the solution set of Γ. It is natural to ask when a network is redundant and how to get an irredundant subset without changing the solution set. We call a subset of Γ a *prime subnetwork* of Γ if it contains no redundant constraints but has the same solution set as Γ.

We show that it is in general co-NP hard to determine if a constraint is redundant in a network of RCC constraints, but Γ is over a tractable subclass, then a prime subnetwork can be found in $O(n^5)$ time. If in addition weak composition distributes over non-empty intersections of relations in $\mathcal{S}$, then Γ has a unique prime subnetwork, which is obtained by removing all redundant constraints from Γ.

As in the case of propositional logic formulas (Liberatore 2005), redundancy of RCC constraints "often leads to unnecessary computation, wasted storage, and may obscure the structure of the problem" (Belov et al. 2012). Finding a prime subnetwork can be useful in at least the following aspects: a) computing and storing the relationships between spatial objects and hence saving space for storage and communication; b) facilitating comparison between different constraint networks; c) handling the inconsistency by modifying critical constraints; d) unveiling the essential graphical structure of a network; and e) adjusting geometrical objects to meet topological constraints (Wallgrün 2012).

Motivational Example: Placename Footprints

To motivate our discussion, we focus briefly on one specific application to illustrate just one of our five uses of prime subnetworks: saving space for storage. Figure 1 gives a small example of a set of spatial regions formed by the geographic "footprints" associated with placenames in the Southampton area of the UK. The footprints are derived from crowd-sourced data, formed from the convex hull of the sets of coordinate locations at which individuals used the placenames on social media. Using such data sets in natural language placename searches frequently requires queries over the topological relationships between footprints (e.g., "is Clarence Pier in Southampton?"). Computing such relationships on-the-fly requires computationally intensive and slow geometric operations; by contrast Web-search queries demand rapid responses.

One potential solution is to cache the topological rela-

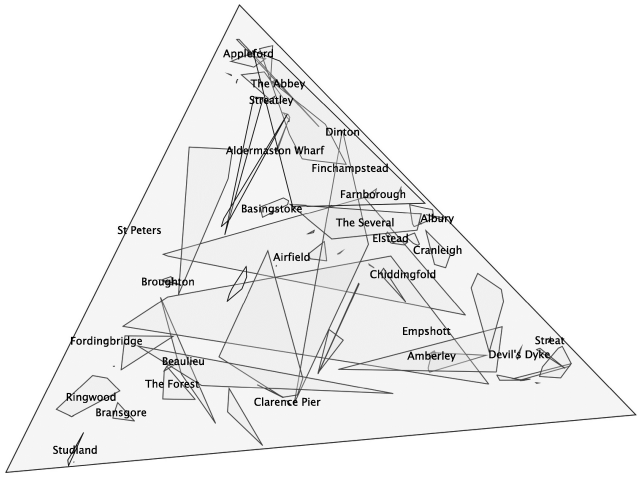

Figure 1: Examples of crowd-sourced geographic placename "footprints" around Southampton, UK

tions between all footprints of interest. However, even the small example in Figure 1, the 84 footprints then require $84 * 83/2 = 3486$ stored relations. The moderate-sized footprint data set from which Figure 1 contains a total of 3474 footprints leads to a constraint network with $6,032,601$ relations. It is easy to see that as crowd-sourced data sources continue to grow, the volumes of such data is set to explode. In the case of footprints, many of the relationships can be inferred, and computing the prime subnetwork can reduce the number of stored relationships to be approximately linear in the number of footprints. In the case of the Southampton constraint network, 1324 redundant relations lead to a prime subnetwork with only 2150 relations needing to be stored. For the full data set, $5,713,563$ redundant relations lead to a prime subnetwork of just $319,038$ relations (in contrast to the full constraint network of more than 6 million relations).

In Section 2 we recall the RCC constraint language and then define the key notions of redundant constraint and prime subnetwork in Section 3. We present our major results in Section 4 and conclude the paper in Section 5.

2 RCC Constraint Language

The RCC was introduced in (Randell, Cui, and Cohn 1992). Let U be the set of nonempty regular closed sets of $\mathbb{R}^2$. We call each element in U a region. For two regions a, b, we say a is a *part* of b, written $a\mathbf{P}b$, if $a \subseteq b$; say a is *connected* to b, written $a\,\mathbf{C}\,b$, if $a \cap b \neq \varnothing$. Using $\mathbf{C}$ and $\mathbf{P}$, we define

$$
\begin{aligned}
x\,\mathbf{PP}\,y &\equiv x\,\mathbf{P}\,y \wedge \neg(y\,\mathbf{P}\,x)\\
x\mathbf{O}y &\equiv (\exists z)(z\,\mathbf{P}\,x \wedge z\,\mathbf{P}\,y)\\
x\,\mathbf{DR}\,y &\equiv \neg(x\mathbf{O}y)\\
x\,\mathbf{PO}\,y &\equiv x\mathbf{O}y \wedge \neg(x\,\mathbf{P}\,y) \wedge \neg(y\,\mathbf{P}\,x)\\
x\,\mathbf{EQ}\,y &\equiv x\,\mathbf{P}\,y \wedge y\,\mathbf{P}\,x\\
x\,\mathbf{DC}\,y &\equiv \neg(x\mathbf{C}y)\\
x\,\mathbf{EC}\,y &\equiv x\,\mathbf{C}\,y \wedge \neg(x\mathbf{O}y)\\
x\,\mathbf{TPP}\,y &\equiv x\,\mathbf{PP}\,y \wedge (\exists z)(z\,\mathbf{EC}\,x \wedge z\,\mathbf{EC}\,y)\\
x\,\mathbf{NTPP}\,y &\equiv x\,\mathbf{PP}\,y \wedge \neg(x\,\mathbf{TPP}\,y)
\end{aligned}
$$

Write $\mathbf{PP}^{-1}$, $\mathbf{TPP}^{-1}$ and $\mathbf{NTPP}^{-1}$ for the converses of $\mathbf{PP}$, $\mathbf{TPP}$ and $\mathbf{NTPP}$, respectively. Then

(1) $\mathcal{B}_5 = \{\mathbf{DR}, \mathbf{PO}, \mathbf{EQ}, \mathbf{PP}, \mathbf{PP}^{-1}\}$

(2) $\mathcal{B}_8 = \{\mathbf{DC}, \mathbf{EC}, \mathbf{PO}, \mathbf{EQ}, \mathbf{TPP}, \mathbf{NTPP}, \mathbf{TPP}^{-1}, \mathbf{NTPP}^{-1}\}$

are two jointly exhaustive and pairwise disjoint (JEPD) sets of relations, i.e., for any two regions $a, b \in U$, a, b is related by exactly one relation in $\mathcal{B}_l$ ($l = 5, 8$). We call the Boolean algebra generated by relations in $\mathcal{B}_l$ the RCCl algebra, which consists all relations that are unions of the basic relations in $\mathcal{B}_l$. For convenience, we denote a non-basic RCCl relation R as the subset of $\mathcal{B}_l$ it contains. For example, we write $\{\mathbf{DR}, \mathbf{PO}, \mathbf{PP}\}$ for the relation $\mathbf{DR} \cup \mathbf{PO} \cup \mathbf{PP}$, and write $\star_5$ and $\star_8$ for the universal relation.

The composition of two basic RCC5/8 relations is not necessarily a relation in RCC5/8. For two RCC5/8 relations R and S, we call the smallest relation in RCC5/8 that contains $R \circ S$ the *weak composition* of R and S, written $R \circ_w S$ (Düntsch, Wang, and McCloskey 2001; Li and Ying 2003).

RCC5/8 Constraint Network

An RCC5/8 constraint has the form (xRy), where x, y are variables taking values from U, the set of regions, R is an RCC5/8 relation (not necessarily basic). Given a set Γ of RCC5/8 constraints over variables $V = \{v_1, v_2, ..., v_n\}$, we say Γ is *consistent* or *satisfiable* if there is an assignment $\sigma : V \to U$ such that $(\sigma(v_i), \sigma(v_j))$ satisfies the constraint in Γ that relates v_i to v_j.

Without loss of generality, we assume Γ has the form $\{x_i R_{ij} x_j\}_{i,j=1}^n$, where, for any $1 \leq i, j \leq n$, there is a unique constraint R_{ij}, and $R_{ji} = R_{ij}^{\sim}$ and $R_{ii} = \mathbf{EQ}$. In this sense, we call Γ a *constraint network*. Let $\Gamma = \{x_i R_{ij} x_j\}_{i,j=1}^n$ and $\Gamma' = \{x_i R'_{ij} x_j\}_{i,j=1}^n$ be two RCC5/8 constraint networks. We say Γ and Γ' are *equivalent* if they have the same set of solutions; and say Γ *refines* Γ' if $R_{ij} \subseteq R'_{ij}$ for all (i, j). We say an RCC5/8 network Γ is a *basic* network if each constraint is either the universe relation or a basic relation; and say a basic network *complete* if there are no universal relations.

Suppose $\mathcal{S}$ is a subset of RCC5/8. We say an RCC5/8 network $\Gamma = \{v_i R_{ij} v_j\}$ is over $\mathcal{S}$ if $R_{ij} \in \mathcal{S}$ for every pair of variables v_i, v_j. The consistency problem over $\mathcal{S}$, written as $\mathsf{CSP}(\mathcal{S})$, is the decision problem of the consistency of an arbitrary constraint network over $\mathcal{S}$. It is well known that the consistency problem over RCC5/8, i.e., $\mathsf{CSP}(RCC5/8)$, is NP-complete and RCC8 has three maximal tractable subclasses that contain all basic relations (Renz 1999) and RCC5 has only one (Jonsson and Drakengren 1997).

We say a network $\Gamma = \{v_i R_{ij} v_j\}$ *path-consistent* if for every $1 \leq i, j, k \leq n$, we have

$$R_{ij} \subseteq R_{ik} \circ_w R_{kj}. \tag{3}$$

A cubic algorithm, henceforth called the *path-consistency algorithm* or PCA, has been devised to enforce path-consistency. For any RCC5/8 network Γ, the PCA either detects inconsistency of Γ or returns a path-consistent network,

written Γ_p, which is equivalent to Γ and known as the *algebraic closure* or *a-closure* of Γ (Ligozat and Renz 2004). It is easy to see that in this case Γ_p also refines Γ, i.e., we have $S_{ij} \subseteq R_{ij}$ for each constraint $(x_i S_{ij} x_j)$ in Γ_p.

Proposition 1. *Let $\mathcal{S}$ be a tractable subclass of RCC5/8 which contains all basic relations. An RCC5/8 network Γ over $\mathcal{S}$ is consistent if applying PCA to Γ does not result inconsistency.*

In particular, we have

Proposition 2. *A basic RCC5/8 network Γ is consistent if it is path-consistent.*

Distributive Subalgebra

Write $\widehat{\mathcal{B}}_5$ for the closure of $\mathcal{B}_5$ under converse, intersection, and weak composition in RCC5. Then $\widehat{\mathcal{B}}_5$ contains the basic relations as well as

$$\{\mathbf{PO}, \mathbf{PP}\}, \{\mathbf{PO}, \mathbf{PP}^{-1}\}, \{\mathbf{PO}, \mathbf{PP}, \mathbf{PP}^{-1}, \mathbf{EQ}\},$$
$$\{\mathbf{DR}, \mathbf{PO}, \mathbf{PP}\}, \{\mathbf{DR}, \mathbf{PO}, \mathbf{PP}^{-1}\}, \{\mathbf{DR}, \mathbf{PO}\}, \star_5,$$

where $\star_5 = \{\mathbf{DR}, \mathbf{PO}, \mathbf{PP}, \mathbf{PP}^{-1}, \mathbf{EQ}\}$. It is interesting to note that in $\widehat{\mathcal{B}}_5$ the weak composition operation is *distributive* over nonempty intersections in the following sense.

Lemma 3. *Let R, S, T be three relations in $\widehat{\mathcal{B}}_5$. Suppose $S \cap T$ is nonempty. Then we have*

$$R \circ_w (S \cap T) = R \circ_w S \cap R \circ_w T \tag{4}$$
$$(S \cap T) \circ_w R = S \circ_w R \cap T \circ_w R. \tag{5}$$

In what follows, we call such a subclass a distributive subalgebra. Formally, we have

Definition 4. Let $\mathcal{S}$ be a subclass of RCC5/8. We say $\mathcal{S}$ is a *distributive subalgebra* if

- $\mathcal{S}$ contains all basic relations, and is closed under converse, weak composition, and intersection;
- weak composition distributes over nonempty intersections of relations in $\mathcal{S}$.

3 Redundant Constraint and Prime Subnetwork

We give a formal definition of redundant constraints.

Definition 5. Suppose Γ is an RCC5/8 network over variables $V = \{v_1, ..., v_n\}$. We say Γ *entails* a constraint $(v_i R v_j)$, written $\Gamma \models (v_i R v_j)$, if for every solution $\{a_1, ..., a_n\}$ of Γ we have $(a_i, a_j) \in R$. A constraint $(v_i R v_j)$ in Γ is *redundant* if $\Gamma \setminus \{(v_i R v_j)\}$ entails $(v_i R v_j)$. We say Γ is *reducible* if it has a redundant constraint, and *irreducible* otherwise. We say a subset Γ' of Γ is a *prime* subnetwork of Γ if Γ' is irreducible and equivalent to Γ.

Each universal constraint $(v_i \star v_j)$ in Γ is, by definition, a redundant constraint in Γ.

Given an RCC5/8 network Γ, a very interesting question is, *how to find a prime subnetwork of* Γ? This problem is clearly at least as hard as determining if Γ is reducible. Similar to the case of propositional logic formulars (Liberatore 2005), we have the following result for RCC5/8.

Proposition 6. *Let Γ be an RCC5/8 network and suppose (xRy) is a constraint in Γ. It is co-NP-complete to decide if (xRy) is redundant in Γ.*

A naive method to obtain a prime subnetwork is to remove redundant constraints one by one from Γ until we get an irreducible network. Suppose we have an oracle which can tell if a constraint is redundant. Then in an additional $O(n^2)$ time we can find an irreducible network that is equivalent to Γ by removing several constraints from Γ.

Despite that it is in general intractable to determine if a constraint is redundant, we have a polynomial time procedure if the constraints are all taken from a tractable subclass.

Proposition 7. *Let $\mathcal{S}$ be a tractable subclass of RCC5/8 that contains all basic relations. Suppose Γ is a network over $\mathcal{S}$. Then in $O(n^3)$ time we can determine whether a constraint is redundant in Γ and in $O(n^5)$ time find all redundant constraints of Γ. In addition, a prime subnetwork for Γ can be found in $O(n^5)$ time.*

Definition 8. The *core* of an RCC5/8 network Γ, written Γ_c, is defined to be the set of non-redundant constraints in Γ.

It is easy to see that the core of Γ is contained in every prime subnetwork of Γ. *Are prime subnetworks unique*? In general this is not the case.

In the following we assume without loss of generality that Γ has the following property:

$$(\forall i, j)[(i \neq j) \rightarrow (\Gamma \not\models (v_i \, \mathbf{EQ} \, v_j))]. \tag{6}$$

In the next section we show that, if Γ is a constraint network over a distributive subalgebra of RCC5/8, then Γ_c is the unique prime network of Γ. This is quite surprising, as, in general, knowing that (xRy) and (uSv) are both redundant in Γ does not imply that (uSv) is redundant in $\Gamma \setminus \{(xRy)\}$.

4 Networks over a Distributive Subalgebra

In this section, we assume $\mathcal{S}$ is a distributive subalgebra of RCC5/8. Let Γ be a consistent network over $\mathcal{S}$ which satisfies (6). We show that Γ_c is equivalent to Γ and hence the unique prime network of Γ.

Definition 9 (cf. (Chandra and Pujari 2005; Liu and Li 2012)). Suppose $\Theta = \{v_i T_{ij} v_j\}_{1 \leq i,j \leq n}$ is an RCC5/8 network. We say Θ is *minimal* if for every pair of variables v_i, v_j $(i \neq j)$ and every basic relation α in T_{ij}, there exists a solution $\{a_1, a_2, \cdots, a_n\}$ of Θ such that (a_i, a_j) is an instance of α.

Each consistent RCC5/8 constraint network has a unique minimal network, but it is in general NP-hard to compute it.

Notation: We write Γ_m for the minimal network of Γ, Γ_p for the a-closure of Γ, and Γ_c for the core of Γ.

To prove that Γ_c is equivalent to Γ, we need two important results. The first result, stated in Theorem 10, shows that Γ_m is exactly Γ_p. The second result, stated in Proposition 11, shows that a particular constraint (xRy) is redundant in Γ iff its corresponding constraint in Γ_p is redundant. Our main result, stated in Theorem 12, then follows immediately.

Theorem 10. *Let $\mathcal{S}$ be a distributive subalgebra of RCC5/8. Suppose Γ is a consistent network over $\mathcal{S}$ and Γ_p its a-closure. Then Γ_p is Γ_m, the minimal network of Γ.*

Proposition 11. *Let $\mathcal{S}$ be a distributive subalgebra of RCC5/8. Suppose Γ is a consistent network over $\mathcal{S}$ which satisfies* (6)*. Assume that (xRy) and (xSy) are the constraints from x to y in Γ and Γ_p respectively. Then (xRy) is redundant in Γ iff (xSy) is redundant in Γ_p.*

Recall that Theorem 10 asserts that Γ_p is minimal. As a consequence, we have our main result.

Theorem 12. *Let $\mathcal{S}$ be a distributive subalgebra of RCC5/8. Suppose Γ is a consistent network over $\mathcal{S}$ which satisfies* (6) *and Γ_c the core of Γ. Then Γ_c is equivalent to Γ and hence the unique prime network of Γ.*

Recall that Proposition 7 shows that the core of an RCC5/8 network over a tractable subclass can be found in $O(n^5)$ time. In the next subsection we show this can be improved if the network is over a distributive subalgebra.

A Cubic Algorithm for Computing the Core of Γ

We first consider the special case when Γ is path-consistent.

Lemma 13. *Let $\mathcal{S}$ be a distributive subalgebra of RCC5/8. Suppose Γ is a path-consistent network over $\mathcal{S}$. Then a constraint $(v_iR_{ij}v_j)$ is redundant in Γ iff $R_{ij} = \bigcap\{R_{ik} \circ_w R_{kj} : k \neq i, j\}$, i.e., R_{ij} is the intersection of the weak compositions of all paths from v_i to v_j which have length 2.*

Suppose Γ is a consistent network over a distributive subalgebra of RCC5/8 and satisfies (6). Proposition 11 and Lemma 13 suggest a simple way for computing Γ_c, the unique prime network of Γ. By Proposition 11, a constraint $(v_iR_{ij}v_j)$ in Γ is redundant iff the corresponding constraint $(v_iS_{ij}v_j)$ in Γ_p is redundant. Furthermore, Lemma 13 shows that $(v_iS_{ij}v_j)$ is redundant in Γ_p iff S_{ij} is the intersection of all $S_{ik} \circ_w S_{kj}$ ($k \neq i, j$). We hereby have the following cubic algorithm for finding all redundant constraints in Γ. For each constraint $(v_iS_{ij}v_j)$, to verify if $S_{ij} = \bigcap\{S_{ik} \circ_w S_{kj} : k \neq i, j\}$, we introduce a relation P_{ij} which consists of all basic relations α that are not in $S_{ik} \circ_w S_{kj}$ for some $k \neq i, j$ and then check if $P_{ij} \cup S_{ij}$ is the universal relation.

Algorithm 1: Algorithm for finding redundant constraints in constraint networks over a distributive subalgebra $\mathcal{S}$ of RCC5/8, where $\star_l$ is the universal relation in RCCl.

Input: a consistent constraint network $\Gamma = \{v_iR_{ij}v_j : 1 \leq i, j \leq n\}$ over $\mathcal{S}$.
Output: $Redun$: the set of redundant constraints of Γ.

```
Redun ← ∅;
Γ_p = the a-closure of Γ;
for each constraint (v_i S_ij v_j) ∈ Γ_p do
    P_ij ← ∅;
    for each variable v_k ∈ V \ {v_i, v_j} do
        temp_ij = S_ik ∘_w S_kj;
        for each basic RCC5/8 relation α do
            if α ∉ temp_ij then
                P_ij ← P_ij ∪ {α};
            end
        end
    end
    if P_ij ∪ S_ij = ⋆_l then
        Redun ← Redun ∪ {(v_i R_ij v_j)};
    end
end
```

5 Conclusion

In this paper, we have systematically investigated the computational complexity of redundancy checking for RCC5/8 constraints. Although it is in general co-NP-complete, we have shown that a prime network can be found in $O(n^5)$ for any consistent network over a tractable subclass of RCC5/8. If the constraints are taken from a distributive subalgebra, we proved that the core of the constraint network is the unique prime network and can be found in cubic time.

Some of these results (e.g., all results before Theorem 10) can be applied to many other qualitative calculi e.g. Interval Algebra (Allen 1983) immediately, but Proposition 11 and Theorem 12 do use the particular algebraic properties of RCC5/8. Future work will consider how to extend our results to these qualitative calculi.

Abstract

Belief revision is an operation that aims at modifying old beliefs so that they become consistent with new ones. The issue of belief revision has been studied in various formalisms, in particular, in qualitative algebras (QAs) in which the result is a disjunction of belief bases that is not necessarily representable in a QA. This motivates the study of belief revision in formalisms extending QAs, namely, their propositional closures: in such a closure, the result of belief revision belongs to the formalism. Moreover, this makes it possible to define a contraction operator thanks to the Harper identity. Belief revision in the propositional closure of QAs is studied, an algorithm for a family of revision operators is designed, and an open-source implementation is made freely available on the web.

Keywords: qualitative algebras, belief revision, belief contraction, propositional closure

Introduction

Belief revision is an operation of belief change that consists in modifying minimally old beliefs so that they become consistent with new beliefs (Alchourrón, Gärdenfors, and Makinson 1985). One way to study this issue following a knowledge representation angle is to consider a formalism and to study some belief revision operators defined on it: how they are defined and how they can be implemented.

In particular, it is rather simple to define a revision operator on a qualitative algebra (QA, such as the Allen algebra) by reusing the work of (Condotta et al. 2010) about the related issue of belief merging. The result of such a belief revision is a set of belief bases to be interpreted disjunctively, and which is not necessarily representable as a single belief base: QAs are not closed under disjunction.

This gives a first motivation for the study of belief revision in the propositional closure of a QA: the revision operator in such a closure gives a result that is necessarily representable in the formalism. Another motivation lies in the possibility of defining a contraction operator in this formalism, thanks to the Harper identity.

The first section of the paper contains some preliminaries about various notions used throughout the paper. The next section briefly describes some properties of such a formalism. Finally, an algorithm and an implementation of this algorithm for a revision operator in the propositional closure of a QA are presented with an example.

The research report (Dufour-Lussier et al. 2014) is a long version of this paper including more detailed preliminaries, the proofs and some additional examples.

Preliminaries

Qualitative algebras

Qualitative algebras (QAs) are formalisms that are widely used for representation depending on time and/or on space (Stock 1997). Formulas built upon QAs are closed under conjunction, though the symbol $\wedge$ is not systematically used. Some of the usual notations and conventions of QAs are changed to better fit the scope of this paper. In particular, the representation of knowledge by graphs (namely, qualitative constraint networks) is not well-suited here, because of the propositional closure introduced afterwards.

First, the Allen algebra is introduced: it is one of the most famous QAs and it will be used in our examples throughout the paper. Then, a general definition of QAs is given.

The Allen algebra is used for representing relations between time intervals (Allen 1983). A formula of the Allen Algebra can be seen as a conjunction of constraints, where a constraint is an expression of the form $x\ r\ y$ stating that the interval x is related to the interval y by the relation r. 13 base relations are introduced (cf. figure 1); a relation r is either one of these base relations or the union of base relations $r_1, \ldots, r_m$ denoted by $r_1 \mid \ldots \mid r_m$.

For example, if one wants to express that the maths course is immediately before the physics course which is before the English course (either with a time lapse, or immediately before it), one can write the formula:

$$\texttt{maths}\ \mathsf{m}\ \texttt{physics} \quad \wedge \quad \texttt{physics}\ \mathsf{b} \mid \mathsf{m}\ \texttt{english}$$

$\mathcal{L}_{\text{Allen}}$ is the set of the formulas of the Allen algebra.

Qualitative algebras in general are defined below, first by their syntax and then by their semantics.

bi, mi, oi, si, di and fi represent respectively the inverse relations of the relations represented by b, m, o, s, d and f.

Figure 1: The base relations of $\mathcal{L}_{\text{Allen}}$.

Syntax. A finite set of symbols $\mathfrak{B}$ is given (with $|\mathfrak{B}| \geq 2$). A *base relation* is an element of $\mathfrak{B}$. A *relation* is an expression of the form $r_1 \mid \ldots \mid r_m$ ($m \geq 0$), such that a base relation occurs at most once in a relation and the order is irrelevant (e.g. $r_1 \mid r_2$ and $r_2 \mid r_1$ are equivalent expressions). The set of relations is denoted by $\mathfrak{R}$.

A finite set of symbols $\mathcal{V}$, disjoint from $\mathfrak{B}$, is given. A *(qualitative) variable* is an element of $\mathcal{V}$.

A *constraint* is an expression of the form $x\ r\ y$ where $x, y \in \mathcal{V}$ and $r \in \mathfrak{R}$.

A *formula* φ is a conjunction of n constraints ($n \geq 1$): $x_1\ r_1\ y_1\ \wedge\ \ldots\ \wedge\ x_n\ r_n\ y_n$. A constraint of φ is one of the constraints of this conjunction. Let $\mathcal{L}_{\text{QA}}$ be the set of the formulas of the considered QA. The atoms of $\mathcal{L}_{\text{QA}}$ are the constraints.

A formula $\varphi \in \mathcal{L}_{\text{QA}}$ is under normal form if for every $x, y \in \mathcal{V}$ with $x \neq y$, there is exactly one $r \in \mathfrak{R}$ such that $x\ r\ y$ is a constraint of φ. Then, this relation r is denoted by $r_\varphi(x, y)$.

A *scenario* σ is a formula under normal form such that, for every variables x and y, $x \neq y$, $r_\sigma(x, y) \in \mathfrak{B}$. Therefore, there are $|\mathfrak{B}|^{|\mathcal{V}|\times(|\mathcal{V}|-1)}$ scenarios.

Semantics. The semantics of a QA can be defined classically, thanks to a domain, a variable being mapped into a subset of this domain and a relation being mapped on a relation between such subsets. For Allen algebra, the domain is the set $\mathbb{Q}$ of rational numbers and, given an interpretation $\mathcal{I}$, a variable x is mapped to an interval $\mathcal{I}(x) = [a, b]$ of $\mathbb{Q}$ ($a < b$). The semantics of each of the basic relations is defined. For example, $\mathcal{I}$ satisfies $x_1\ \mathsf{m}\ x_2$ if $b_1 = a_2$ where $\mathcal{I}(x_i) = [a_i, b_i]$. $\mathcal{I}$ satisfies $x_1\ (r_1 \mid \ldots \mid r_m)\ x_2$ if it satisfies one of the constraints $x_1\ r_k\ x_2$ for $k \in \{1, \ldots, m\}$. A formula is consistent (or satisfiable) if there exists an interpretation satisfying each of its constraints. Finally, for $\varphi_1, \varphi_2 \in \mathcal{L}_{\text{QA}}$, $\varphi_1 \models \varphi_2$ if, for every interpretation $\mathcal{I}$ satisfying φ_1, it satisfies also φ_2. The research report give more details on this first definition of the semantics.

The semantics can be characterized a posteriori thanks to consistent scenarios.

Let Ω be the set of consistent scenarios on the variables of $\mathcal{V}$. It can be proven that $|\Omega| \leq |\mathfrak{B}|^{|\mathcal{V}|\times(|\mathcal{V}|-1)/2}$: if $x\ r\ y$ is a constraint of a consistent scenario σ then $y\ r^-\ x$ is also a constraint of σ.

Let $\mathcal{M} : \mathcal{L} \to 2^\Omega$ be defined by

$$\mathcal{M}(\varphi) = \{\sigma \in \Omega \mid \sigma \models \varphi\}$$

for $\varphi \in \mathcal{L}$, where $\models$ is the entailment relation defined below, thanks to the semantics based on a domain.

Ω and $\mathcal{M}$ make it possible to define a semantics on $\mathcal{L}$ which coincides with the semantics based on a domain (hence the same entailment relation $\models$): $\varphi_1 \models \varphi_2$ iff $\mathcal{M}(\varphi_1) \subseteq \mathcal{M}(\varphi_2)$. However, this second semantics is more practical to use for defining revision operators on QAs.

Belief change

Belief revision is an operation of belief change. Intuitively, given the set of beliefs ψ an agent has about a static world, it consists in considering the change of their beliefs when faced with a new set of beliefs μ, assuming that μ is considered to be unquestionable by the agent. The resulting set of beliefs is noted $\psi \dot{+} \mu$, and depends on the choice of a belief revision operator $\dot{+}$. In (Alchourrón, Gärdenfors, and Makinson 1985), the principle of minimal change has been stated and could be formulated as follows: ψ is minimally changed into ψ' such that the conjunction of ψ' and μ is consistent, and the result of the revision is this conjunction. Hence, there is more than one possible $\dot{+}$ operator, since the definition of $\dot{+}$ depends on how belief change is "measured". More precisely, the minimal change principle has been formalized by a set of postulates, known as the AGM postulates (after the names of the authors of (Alchourrón, Gärdenfors, and Makinson 1985)).

In (Katsuno and Mendelzon 1991b), revision has been studied in the framework of propositional logic (with a finite set of variables). The AGM postulates are translated into this formalism and a family of revision operators is defined based on distance functions d on Ω, where Ω is the set of interpretations: the revision of ψ by μ according to $\dot{+}^d$ ($\psi\ \dot{+}^d\ \mu$) is such that

$$\mathcal{M}(\psi\ \dot{+}^d\ \mu) = \{\omega \in \mathcal{M}(\mu) \mid d(\mathcal{M}(\psi), \omega) = d^*\}$$
$$\text{with } d^* = d(\mathcal{M}(\psi), \mathcal{M}(\mu)) \quad (1)$$

Intuitively, d^* measures, using d, the minimal modification of ψ into ψ' needed to make $\psi' \wedge \mu$ consistent.

This approach can be extended to other formalisms for which a model-theoretic semantics can be defined and such that a distance function can be specified on the set of interpretations Ω. However, in some of these formalisms, a representability issue can be raised: it may occur that a subset Σ of Ω is not representable, i.e. there is no formula φ such that $\mathcal{M}(\varphi) = \Sigma$. This representability issue is addressed below, for the case of QAs.

Belief contraction is the operation of belief change that associates to a set of beliefs ψ and a set of beliefs μ, a set of beliefs $\psi \dot{-} \mu$ such that $\psi \dot{-} \mu \not\models \mu$. In propositionally closed formalisms, the Harper identity makes it possible to define a contraction operator $\dot{-}$ thanks to a revision operator $\dot{+}$ with

$$\psi \dot{-} \mu = \psi \vee (\psi \dot{+} \neg\mu) \quad (2)$$

Belief merging is another operation of belief change. Given some sets of beliefs $\psi_1, \ldots, \psi_n$, their merging is a set of beliefs Ψ that contains "as much as possible" of the beliefs in the ψ_i's. Intuitively, Ψ is the conjunction of $\psi'_1, \ldots, \psi'_n$ such that each ψ_i has been minimally modified into ψ'_i in order to make this conjunction consistent. Some postulates of belief merging have been proposed and discussed (Konieczny and Pérez 2002), in a similar way as the AGM postulates.

Belief revision in qualitative algebras

In (Condotta et al. 2010) a belief merging operator is defined that can be easily adapted for defining a revision operator. It is based on a distance between scenarios. Let δ be a distance function on $\mathfrak{B}$. Let $\sigma, \tau \in \Omega$, be two scenarios based on the same set of variables $\mathcal{V}$. Then, d is defined by

$$d(\sigma, \tau) = \sum_{x,y \in \mathcal{V}, x \neq y} \delta(r_\sigma(x,y), r_\tau(x,y))$$

One of the possibilities for δ is the use of a neighborhood graph, i.e. a connected, undirected graph whose vertices are the base relations: $\delta(r,s)$ is the length of the shortest path between r and s. Then, the scenarios of the revision of ψ by μ according to $\dot{+}^d$ are the scenarios of μ that are the closest ones to scenarios of ψ according to d. The set of optimal scenarios is not necessarily representable in $(\mathcal{L}_{\text{QA}}, \models)$. One solution to address this issue is to consider that the result of revision is a set of scenarios.

Algorithms for implementing this kind of belief revision in QAs are presented in (Dufour-Lussier et al. 2012) and (Hué and Westphal 2012).

Propositional closure of a qualitative algebra

The propositional closure of a QA $(\mathcal{L}_{\text{QA}}, \models)$ is a formalism $(\widehat{\mathcal{L}}_{\text{QA}}, \models)$ defined as follows. $\widehat{\mathcal{L}}_{\text{QA}}$ is the smallest superset of $\mathcal{L}_{\text{QA}}$ that is closed for $\neg$ and $\wedge$. Then, $\widehat{\mathcal{L}}_{\text{QA}}$ is closed for $\vee$: $\varphi_1 \vee \varphi_2$ is an abbreviation for $\neg(\neg\varphi_1 \wedge \neg\varphi_2)$. The entailment relation is based on the consistent scenarios: $\varphi_1 \models \varphi_2$ if $\mathcal{M}(\varphi_1) \subseteq \mathcal{M}(\varphi_2)$, $\mathcal{M}$ being extended on $\widehat{\mathcal{L}}_{\text{QA}}$ by $\mathcal{M}(\varphi_1 \wedge \varphi_2) = \mathcal{M}(\varphi_1) \cap \mathcal{M}(\varphi_2)$ and $\mathcal{M}(\neg\varphi) = \Omega \setminus \mathcal{M}(\varphi)$.

Proposition 1 (representability). *Every set of scenarios $\Sigma \subseteq \Omega$ is representable in $\widehat{\mathcal{L}}_{QA}$. More precisely, with $\varphi = \bigvee_{\sigma \in \Sigma} \sigma$, $\mathcal{M}(\varphi) = \Sigma$.*

Every formula of $\widehat{\mathcal{L}}_{\text{QA}}$ can be written in DNF (disjunctive normal form, i.e. disjunction of conjunctions constraints), since it is a propositionally closed formalism, but the following proposition goes beyond that.

Proposition 2 (DNF-w/oN form). *Every $\varphi \in \widehat{\mathcal{L}}_{QA}$ is equivalent to a formula in DNF using no negation symbol.*

Belief revision in $(\widehat{\mathcal{L}}_{\text{QA}}, \models)$

Given a distance function d on Ω, a revision operator on $(\widehat{\mathcal{L}}_{\text{QA}}, \models)$ can be defined according to equation (1). Indeed, proposition 1 implies that $\{\omega \in \mathcal{M}(\mu) \mid d(\mathcal{M}(\psi), \omega) = d^*\}$ is representable.

An algorithm for computing $\dot{+}^d$ in $\widehat{\mathcal{L}}_{\text{QA}}$

The principle of the algorithm is based on the following proposition.

Proposition 3 (revision of disjunctions). *Let ψ and μ be two formulas of $\widehat{\mathcal{L}}_{QA}$ and $\{\psi_i\}_i$ and $\{\mu_j\}_j$ be two finite families of $\widehat{\mathcal{L}}_{QA}$ such that $\psi = \bigvee_i \psi_i$ and $\mu = \bigvee_j \mu_j$.*

Let $d^*_{ij} = d(\mathcal{M}(\psi_i), \mathcal{M}(\mu_j))$ for any i and j. Then:

$$\psi \dot{+}^d \mu \equiv \bigvee_{i,j,d^*_{ij}=d^*} \psi_i \dot{+}^d \mu_j$$
$$\text{with } d^* = d(\mathcal{M}(\psi), \mathcal{M}(\mu))$$
$$\text{Moreover, } \quad d^* = \min_{ij} d^*_{ij} \tag{3}$$

The algorithm for $\dot{+}^d$ in $\widehat{\mathcal{L}}_{\text{QA}}$ consists roughly in putting ψ and μ in DNF-w/oN form then applying proposition 3 on them, using the $\dot{+}^d$ algorithm on $\mathcal{L}_{\text{QA}}$ for computing the $\psi_i \dot{+}^d \mu_j$'s. More details are given in the research report.

Implementation: the REVISOR/PCQA engine

REVISOR is a collection of several revision engines that are open-source and freely available.[1]

In particular, REVISOR/QA implements $\dot{+}^d$ in three QAs: the Allen algebra, INDU—an extension of the Allen algebra taking into account relations between intervals according to their lengths (Pujari, Kumari, and Sattar 1999)—and RCC8—a QA for representing topological relations between regions of space (Randell, Cui, and Cohn 1992). Moreover, it is easy to use a different qualitative algebra, by giving in the code some tables (composition table, inverse relation table, and table for the values $\delta(r,s)$ for $r, s \in \mathfrak{B}$). The engine is written in Perl, but can be used through a Java library. The worst-case complexity of this implementation is of the order of $O\left(|\mathfrak{B}|^{\frac{|\mathcal{V}|\cdot(|\mathcal{V}|-1)}{2}}\right)$.

REVISOR/PCQA implements $\dot{+}^d$ on the propositional closures of the QAs $\mathcal{L}_{\text{Allen}}$, INDU and RCC8: it actually uses REVISOR/QA and is one of the engines of REVISOR. The worst-case complexity of this implementation is of the order of $O\left(|\mathcal{V}|^4 |\mathfrak{B}|^{\frac{|\mathcal{V}|\cdot(|\mathcal{V}|-1)}{2}}\right)$, according to a coarse analysis.

The following example has been executed using REVISOR/PCQA, and is included with the source code. The `README` file associated with REVISOR/QA on the REVISOR website explains how it can be executed.

This example uses a belief contraction operator. According to (2), a contraction operator $\dot{-}^d$ can be defined that is based on $\dot{+}^d$. Now let us consider the set of beliefs ψ of an agent called Maurice about the dates of birth and death of famous mathematicians. Maurice thought that Boole was born after de Morgan and died before him and that de Morgan and Weierstraß were born the same year (say, at the same time) but the former died before the latter:

$\psi =$ `Boole d De Morgan` $\wedge$ `De Morgan s Weierstraß`

[1] http://revisor.loria.fr

where, Boole is the interval of time between the birth and the death of Boole, and so on. Now, Germaine, a friend of Maurice, tells him that she is not sure whether Boole was born strictly after Weierstraß. Since Maurice trusts Germaine (and her doubts), he wants to make the contraction of its original beliefs ψ by μ with

$$\mu = \texttt{Boole bi} \mid \texttt{mi} \mid \texttt{oi} \mid \texttt{f} \mid \texttt{d Weierstraß}$$

The result, computed by REVISOR/PCQA in less than one second, is $\psi \dot{-}^d \mu$, equivalent to the following formula:

$$\begin{array}{l} (\texttt{Boole d De Morgan} \wedge \texttt{De Morgan s Weierstraß}) \\ \vee (\texttt{Boole s Weierstraß} \wedge \texttt{De Morgan di Weierstraß}) \\ \vee (\texttt{Boole s De Morgan} \wedge \texttt{De Morgan s Weierstraß}) \\ \vee \begin{pmatrix} \texttt{Boole d De Morgan} \wedge \texttt{Boole s Weierstraß} \\ \wedge \texttt{De Morgan o Weierstraß} \end{pmatrix} \end{array}$$

Actually, the last term of this disjunction corresponds to the reality, provided that the intervals of time correspond to a year granularity: George Boole (1815-1864), Augustus De Morgan (1806-1871), Karl Weierstraß (1815-1897).

In (Dufour-Lussier et al. 2014), other examples of use of REVISOR/PCQA, including an analysis of the computing time, are presented. In particular, it is shown that it may be the case that a family of revision problems, albeit formalizable in both $\mathcal{L}_{\text{Allen}}$ and in $\widehat{\mathcal{L}}_{\text{Allen}}$, are solved in much less time in the more expressive formalism $\widehat{\mathcal{L}}_{\text{Allen}}$.

Conclusion

This paper has presented an algorithm for distance-based belief revision in the propositional closure $\widehat{\mathcal{L}}_{\text{QA}}$ of a qualitative algebra $\mathcal{L}_{\text{QA}}$, using the revision operation on $\mathcal{L}_{\text{QA}}$. This work is motivated by the fact that it gives a revision operation whose result is representable in the formalism, by the fact that some practical examples are easily represented in $\widehat{\mathcal{L}}_{\text{QA}}$ whereas they are quite difficult to represent in $\mathcal{L}_{\text{QA}}$, and by the fact that it makes it possible to define a contraction operator thanks to the Harper identity (which requires disjunction and negation). The preprocessing of the algorithm consists in putting the formulas into a disjunctive normal form without negation. Then, proposition 3, which reduces a revision of disjunctions to a disjunction of the least costly revisions, is applied. REVISOR/PCQA is an implementation of this revision operator for the Allen algebra, INDU and RCC8.

A first direction of research following this work is the improvement of the computation time of the REVISOR/PCQA system. One way to do it is to parallelize it. A sequential optimization would consist in finding a heuristic for ranking the pairs (i, j), with the aim of starting from the best candidates, in order to obtain a low upper bound of d^* sooner (hence a pruning of a part of the search trees developed for the computation of $\dot{+}^d$ in $(\mathcal{L}_{\text{QA}}, \models)$).

Another direction of research is to study how other belief change operations can be implemented in this formalism, in particular belief merging (Konieczny and Pérez 2002) and knowledge update (Katsuno and Mendelzon 1991a).

How to Argue for Anything: Enforcing Arbitrary Sets of Labellings Using AFs

Sjur K. Dyrkolbotn
Durham Law School, Durham University, UK
s.k.dyrkolbotn@durham.ac.uk

Abstract

We contribute to the investigation of possible outcomes of argumentation under semantics formulated using argumentation frameworks (AFs). In particular, we study this question for the labelling-based formulation of such semantics, generalizing previous work which has focused on extensions. In this paper, we restrict attention to the preferred and semi-stable semantics, showing that as long as we have a sufficient number of fresh arguments available, we can in fact argue for anything. That is, for any set of finite labellings there is an AF that enforces exactly this set as the outcome of argumentation.

1 Introduction

Formal argumentation in the style of (Dung 1995) is becoming an increasingly important formalism in artificial intelligence.[1] Dung observed that by representing argumentation scenarios by directed graphs, referred to as argumentation frameworks (AFs) in this context, various denotational semantics for non-monotonic reasoning could be formulated using graph-theoretic terms. Such semantics work by prescribing to an AF a set of *extensions*, sets of arguments that are regarded as successful when held together. In (Caminada 2006) it was shown that extensions could be defined in terms of three-valued labellings to the argument set, with every argument obtaining the status of being either accepted, defeated or undetermined. Hence an AF can be viewed as a theory in three-valued logic, and it has since been observed that Łukasiewicz logic is particularly well-suited for reasoning about argumentation (Dyrkolbotn and Walicki 2013; Dyrkolbotn 2013).

In recent work, the question of the *signature* of an argumentation semantics has been studied, asking about the structure of the different possible sets of extensions that can arise from an AF under a given semantics (Dunne et al. 2013). This work is interesting in that it promises to provide a bird's-eye view on the behavior of argumentation semantics, allowing us to develop a better understanding of their expressive power and meta-logical properties.

[1] We point to (Rahwan and Simari 2009) for a recent volume devoted to the use of abstract argumentation theory in AI.

However, developing this theory with respect to sets of extensions is unsatisfactory since the behavior of argumentation semantics is fundamentally three-valued. In particular, it seems to us that the question should also be studied when outcomes of argumentation are represented more realistically as sets of labellings. In this paper we make a contribution in this regard, by characterizing the possible outcomes of finite argumentation under the preferred and semi-stable semantics.[2] In particular, we show that *every* set of labellings can be enforced, as long as we have a sufficient number of additional arguments available. The proof is constructive and also demonstrates that the time needed to enforce a given set of labellings is linear in the number of possible labellings that are not in the outcome.

The structure of the paper is as follows. In Section 2 we present necessary background on AFs and semantics formulated using labellings. Then in Section 3 we prove the main result by constructing canonical AFs that can be used to enforce sets of labellings. In Section 4 we offer a conclusion.

2 Background

We give a terse background on AFs and the labelling-based approach to argumentation semantics, for more details we point to (Rahwan and Simari 2009, Chapter 2). First let us fix a countably infinite set Π of arguments. Then we can define an AF simply as a set of directed edges $E \subseteq \Pi \times \Pi$. If $(p, q) \in E$ we think of it as encoding the fact that p represents an argument that attacks the argument represented by q. We use the notation $E^+(x) = \{y \in \Pi \mid (x, y) \in E\}, E^-(x) = \{y \in \Pi \mid (y, x) \in E\}$, and extend it to sets such that $E^*(A) = \bigcup_{x \in A} E^*(x)$ for $* \in \{+, -\}$. We also define $\Pi(E) = \{x \mid E^+(x) \cup E^-(x) \neq \emptyset\}$, the set of arguments from Π which appear in some attack from E. We will often present AFs by simply depicting the attacks they contain, as in Figure 1.

Given an AF E, an argumentation semantics is used to identify sets of arguments that can be held successfully together. Typically, this involves various formalizations of the

[2] We remark that (Dunne et al. 2013) also notes the possibility of studying signatures with respect to labellings rather than extensions. They have little to say about it, however, apart from listing it as an important direction for future work.

Figure 1: An AF E such that $\Pi(E) = \{p, q, q', p'\}$

intuition that the set should be internally consistent and able to defend itself against attacks from other arguments. Different semantics differ about the details, but they have the same signature: they are defined as an operator $\mathcal{S}$ which takes an AF E and returns a set of sets of $\mathcal{S}(E) \subseteq 2^{\Pi}$, the set of acceptable sets, called extensions. Moreover, to the best of our knowledge, all semantics share the property that arguments in an extension should be internally consistent, free of internal conflict. Formally, for all such semantics $\mathcal{S}$, all AFs E and all $A \in \mathcal{S}(E)$, we have $E^-(A) \subseteq \Pi \setminus A$, such that no two arguments in A attack each other.

For a given argument, it is accepted or it is not, but a boolean perspective fails to do justice to the nature of the structure $(E, \mathcal{S})$ in two important ways. First, it is not clear whether we should say that p is accepted on E under $\mathcal{S}$ when there *exists* some $A \in \mathcal{S}(E)$ such that $p \in A$, or whether we should require $p \in A$ for *all* such A. Both notions of acceptance have been used, and the former is typically dubbed *credulous* while the latter is referred to as *skeptical*.[3]

The second sense in which acceptance is not a binary notion has to do with the structure of E. In particular, given any $A \in \mathcal{S}(E)$ the status of p with respect to A can be any of the following:

$$\begin{array}{ll} 1 : p \in A & 2 : p \in E^+(A) \\ 3 : p \in \Pi \setminus (A \cup E^+(A)) & \end{array} \quad (1)$$

Notice that by conflict-freeness of A, it follows that if $p \in E^+(A)$ then $p \notin A$. Hence when the focus is on the status of individual arguments, we might as well view $\mathcal{S}(E)$ as a set of partitions of Π into three disjoint sets or, equivalently, as a collection of *labellings* (Caminada 2006), functions $\mathsf{c} : \Pi \to \{1, \frac{1}{2}, 0\}$ such that for all $x \in \Pi$:

$$\mathsf{c}(x) = 0 \iff \exists y \in E^-(x) : \mathsf{c}(y) = 1 \quad (2)$$

For any AF E we let $\mathsf{cf}(E)$ be the set of all labellings for E, and we define $\mathsf{c}^1 = \{x \in \Pi \mid \mathsf{c}(x) = 1\}, \mathsf{c}^0 = \{x \mid \mathsf{c}(x) = 0\}$ and $\mathsf{c}^{\frac{1}{2}} = \{x \in \Pi \mid \mathsf{c}(x) = \frac{1}{2}\}$. This, in particular, defines a semantics for argumentation such that for all E, we regard $A \subseteq \Pi$ as acceptable if there is some $\mathsf{c} \in \mathsf{cf}(E)$ such that $\mathsf{c}^1 = A$.[4] In applications of argumentation theory, this is usually considered too permissive, and a range of various restrictions has been considered, each giving rise to a new semantics, the most well-known of which are defined in Figure 2.

Admissible:	$a(E) = \{\mathsf{c} \in \mathsf{cf}(E) \mid E^-(\mathsf{c}^1) \subseteq \mathsf{c}^0\}$
Complete:	$c(E) = \{\mathsf{c} \in \mathsf{cf}(E) \mid \mathsf{c}^1 = \{x \in \Pi \mid E^-(x) \subseteq \mathsf{c}^0\}\}$
Grounded:	$g(E) = \{\bigcap c(E)\}$
Preferred:	$p(E) = \{\mathsf{c}_1 \in a(E) \mid \forall \mathsf{c}_2 \in a(E) : \mathsf{c}_1^1 \not\subset \mathsf{c}_2^1\}$
Semi-stable:	$ss(E) = \{\mathsf{c}_1 \in a(E) \mid \forall \mathsf{c}_2 \in a(E) : \mathsf{c}_1^{\frac{1}{2}} \not\supset \mathsf{c}_2^{\frac{1}{2}}\}$
Stable:	$s(E) = \{\mathsf{c} \in a(E) \mid \mathsf{c}^{\frac{1}{2}} = \emptyset\}$

Figure 2: Various semantics, defined for any $E \subseteq \Pi \times \Pi$

To illustrate the definition, consider the AF in Figure 1. We notice, in particular, that the set of admissible and complete extensions is $a(E) = c(E) = \{\emptyset, \{q\}, \{q'\}\}$, that the grounded extension is empty, that the preferred and semi-stable extensions are $p(E) = ss(E) = \{\{q\}, \{q'\}\}$ and that E does not have any stable extensions (the labellings corresponding to these sets can be easily recovered using Equation (1)).

We can now illustrate why the approach from (Dunne et al. 2013), which focuses on extensions rather than labellings, fails to do full justice to the question of characterizing the possible outcomes of argumentation. For instance, consider enforcing the outcome where one argument, call it w, is accepted, while all other arguments from Π are defeated. That is, there should be only one acceptable labelling and it should assign 1 to w and 0 to all other arguments. Looking at extensions alone there is no way to distinguish this from the case when w is accepted and all other arguments are undecided: in both cases it will hold that $\{w\}$ is the only extension. If we go on by attempting to enforce the outcome that *all* arguments in Π are rejected we come across a *validity* of argumentation that (Dunne et al. 2013) is unable to capture. It is easy to see, in particular, that while many AFs exist for which the empty set is the only admissible extension, it is impossible to construct an AF such that every argument is defeated, since then no arguments labelled 1 would be around to defeat them.

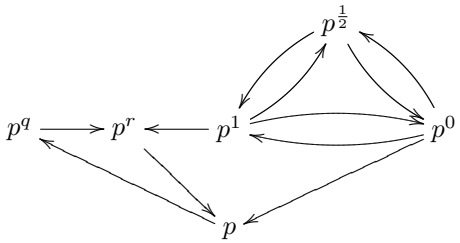
Due to validities of this type, it seems difficult in general to characterize the set of all infinite labellings that can be enforced without the addition of new arguments. In the following we therefore restrict attention to finite AFs, a restriction which is also made in (Dunne et al. 2013). The upshot is that we can always assume availability of additional arguments to help ensure that a given outcome for $V \subset \Pi$ is obtained.[5]

[3] It is natural to view skeptical and credulous acceptance as dual *modalities*, suggesting the study of the set of validities characterizing their interactions. This, in particular, is a different approach to modal reasoning about AFs than that explored in (Grossi 2010b; 2010a), where modalities are used to talk about AFs, to allow semantics to be defined in terms of modal formulas addressing the graph structure. It is closer to what is called an "object level" approach in (Caminada and Gabbay 2009), where arguments are regarded as atoms in a propositional language.

[4] Hence it is not hard to see that values assigned by labellings correspond to the three points of Equation 1 whenever we restrict attention to conflict-free sets of accepted arguments. Notice, in particular, that $p \in \mathsf{c}^0 \iff p \in E^+(\mathsf{c}^1)$ and $p \in \mathsf{c}^{\frac{1}{2}} \iff p \in \Pi \setminus (\mathsf{c}^1 \cup \mathsf{c}^0)$

[5] We remark that in the context of logic-based approaches to argumentation, such as those explored in (Dyrkolbotn and Walicki 2013; Dyrkolbotn 2013), this restriction is suitable as long as we do not consider languages with *infinitary* connectives. Moreover, we note that while the finiteness restriction is not in itself crucial and may be dropped, the presence of a sufficient amount of additional arguments is indeed needed for the results presented in the next section.

3 Enforcing an Arbitrary Set of Labellings



We now proceed to show how canonical AFs can be used to enforce arbitrary sets of labellings to finite $V \subset \Pi$ under preferred and semi-stable semantics. The same AFs will be canonical for both, so our result is relevant also to the investigation of translations between semantics (Dvorák and Woltran 2011; Dvorák and Spanring 2012). In particular, our constructions provide an alternative to the approach of modifying AFs so that their behavior under one semantics can be captured by another. For *any* argumentation semantics which prescribes labellings, we can capture it using preferred and semi-stable semantics, by using the canonical AF.

To construct it formally, assume we are given a finite $V \subseteq \Pi$ and a set of three-valued assignments $F \subseteq \left\{1, \frac{1}{2}, 0\right\}^V$. Then we will construct E_F and show that it enforces F on V in the following sense, for $\mathcal{S} \in \{p, ss\}$:

$$\{\mathsf{c}|_V \mid \mathsf{c} \in \mathcal{S}(E_F)\} = F \tag{3}$$

We rely on two basic constructions to show that there exists E_F which satisfies this equation, for all V, F. First we introduce, for all $p \in \Pi$, the AF Ł_p, which we refer to as a *circuit* for p. It is defined as depicted below.

(4)

The reader may easily verify that Ł_p satisfies the following property, for both preferred and semi-stable $\mathcal{S}$:

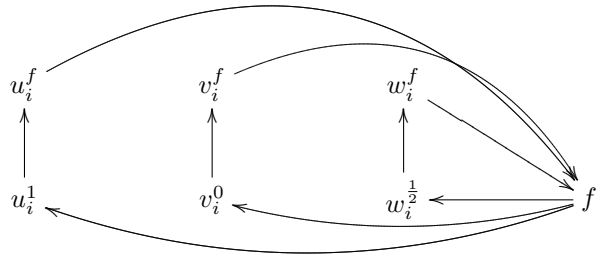
$$\{\mathsf{c}|_p \mid \mathsf{c} \in \mathcal{S}(\text{Ł}_p)\} = \{\{p \mapsto 0\}, \{p \mapsto 1\}, \{p \mapsto \frac{1}{2}\}\} \tag{5}$$

That is, in the AF Ł_p, the semantic status of p is completely open: for any of the three values p could have, the preferred and semi-stable semantics admit labellings for Ł_p that give p this value. This implies that for any finite set $V = \{p_1, \ldots, p_n\}$ there is an AF which characterizes the set $X = \left\{1, \frac{1}{2}, 0\right\}^V$, containing *all* functions from V to $\left\{1, \frac{1}{2}, 0\right\}$. In particular, we can take E_X to be the following AF (assuming, of course, that all arguments p_i^x used to construct a circuit for p_i are fresh, i.e. do not occur in V).

$$E_X = \bigcup_{1 \leq i \leq n} \text{Ł}_{p_i} \tag{6}$$

To show the general claim, for arbitrary $F \subseteq X$, we will start from E_X and then inductively define E_F in terms of $E_{F'}$ such that $F = F' \setminus \{f\}$. We will show, in particular, how to obtain E_F from $E_{F'}$ by ensuring that f becomes *forbidden* while all other assignments from F' are still permitted. To explain how to do this, let us first observe the following crucial property, allowing us to characterize any of the three values that p_i can have by an argument that is accepted if, and only if, p_i has this value. In particular, the reader can easily verify that the following holds, for preferred and semi-stable $\mathcal{S}$ and all $\mathsf{c} \in \mathcal{S}(\text{Ł}_{p_i})$:

$$\begin{cases} \mathsf{c}(p_i) = 1 \iff \mathsf{c}(p_i^1) = 1 \\ \mathsf{c}(p_i) = 0 \iff \mathsf{c}(p_i^0) = 1 \\ \mathsf{c}(p_i) = \frac{1}{2} \iff \mathsf{c}(p_i^{\frac{1}{2}}) = 1 \end{cases} \tag{7}$$



Notice also that $\mathsf{c}(p_i^y) \in \{1, 0\}$ for all y, i and $\mathsf{c} \in \mathcal{S}(\text{Ł}_{p_i})$. That is, the arguments witnessing to the value of p_i are always assigned one of the boolean values. This will be important to keep in mind below. Now, assume as induction hypothesis that we have been able to define $E_{F'}$ for $F' = F \cup \{f\}$ based on E_X such that Equation (3) holds for F', and such that Equation (7) holds for all $\mathsf{c} \in \mathcal{S}(E_{F'})$. To define E_F we first partition V according to the values assigned by f:

$$V = V_1 \cup V_0 \cup V_{\frac{1}{2}}$$

where $V_1 = \{x \mid f(x) = 1\} = \{u_1, \ldots, u_k\}, V_0 = \{x \mid f(x) = 0\} = \{v_1, \ldots, v_l\}, V_{\frac{1}{2}} = \{x \mid f(x) = \frac{1}{2}\} = \{w_1, \ldots, w_m\}$ (notice that this implies that all V_i's are disjoint). Next we let $\{f, x^f \mid x \in V\}$ be a collection of $|V|+1$ fresh arguments, and we define E_F as follows:

$$\begin{aligned} E_F = E_{F'} &\cup \bigcup_{1 \leq i \leq k} \{(u_i^1, u_i^f), (u_i^f, f), (f, u_i^1)\} \\ &\cup \bigcup_{1 \leq i \leq l} \{(v_i^0, v_i^f), (v_i^f, f), (f, v_i^0)\} \\ &\cup \bigcup_{1 \leq i \leq m} \{(w_i^{\frac{1}{2}}, w_i^f), (w_i^f, f), (f, w_i^{\frac{1}{2}}\} \end{aligned}$$

In the figure below we sketch this construction, depicting the pattern made up of the edges added in the induction step.

(8)

First let us note that Equation 7 holds for all $\mathsf{c} \in \mathcal{S}(E_F)$. Indeed, none of the edges that have been added interfere with the fact that for all $x_i \in V$, we have $\mathsf{c}(x_i^y) = 1$ if, and only if, $\mathsf{c}(x_i) = y$. It is then straightforward to establish that there is no $\mathsf{c} \in \mathcal{S}(E_F)$ such that $\mathsf{c}|_V = f$. In particular, if there was such a c it would follow that all arguments of the form $x_i^{f(x_i)}$ would be assigned 1, so all attackers of f would be labelled 0, which in turn would imply that the fresh argument f would be labelled 1. This would be contradiction, however, since f attacks all $x_i^{f(x_i)}$. On the other hand, it is easy to see that any other $f' \in F'$ is still permitted: as long as one or more arguments from V are labelled by something

different from their value under f, it follows from Equation (7) that the argument named f will be rejected, thus rendering all new attacks on existing arguments, which all come from f, irrelevant to the labelling of arguments from V.

Having demonstrated how to construct the desired AF E_F by induction, we conclude as follows.

Theorem 3.1. *For all finite $V \subseteq \Pi$, and all $F \subseteq \{1, \frac{1}{2}, 0\}^V$, there is a finite AF E_F such that for all $\mathcal{S} \in \{p, ss\}$ we have*

$$\{\mathsf{c}|_V \mid \mathsf{c} \in \mathcal{S}(E_F)\} = F$$

The proof of this result essentially consisted in an algorithm for computing E_F. To analyze the complexity of this construction, notice first that E_X has linear size in V. Moreover, remember that we needed $|V| + 1$ new arguments in each step of the procedure, and that the number of total steps required was equal to the number of forbidden labellings. In light of this, we obtain the following corollary.

Corollary 3.2. *For any finite $V \subseteq \Pi$ and any $F \subseteq \{1, \frac{1}{2}, 0\}^V$, we can construct E_F that enforces F under preferred and semi-stable semantics in time $\mathcal{O}(|V| \times |\{1, \frac{1}{2}, 0\}^V \setminus F|)$.*

Before we conclude, we comment briefly on the other semantics from Figure 2. It is easy to see, in particular, that Theorem 3.1 does not hold for any of the other semantics defined there. For the stable semantics this is trivial since it only permits boolean labellings.[6] For the other semantics, notice that all of them always prescribe a labelling such that all other permissible labellings extend it (the empty labelling for the admissible semantics, the grounded labelling for the others). This means, in particular, that no set of labellings can be enforced if it fails to include this labelling.

4 Conclusion

We have studied the finite signatures of the preferred and semi-stable semantics, in terms of the sets of finite labellings they may give rise to. As it turns out, any set of labellings is a possible outcome under these semantics, so in a sense we have indeed shown how to argue for anything. Moreover, while the construction we used takes exponential time to compute in general, it is linear in an interesting parameter: the number of labellings that are *not* supposed to be in the outcome.

This result provides theoretical insight concerning the preferred and semi-stable semantics and it also strengthens the connection between argumentation and three-valued Łukasiewicz logic. As observed in (Dyrkolbotn 2013), any semantics applied to an AF can be seen as a theory in this logic. Hence Theorem 3.1 serves to complete the picture by showing that any finite theory of Łukasiewicz logic can also be represented as an AF. That is, for any such theory there is a corresponding AF such that a three-valued assignment to atoms is a model of the theory if, and only if, it corresponds to a preferred/semi-stable labelling for the corresponding AF.

This is interesting in its own right, but also suggests the possibility of obtaining completeness results for modal logics that allow us to reason about skeptical and credulous acceptance under preferred and semi-stable semantics. It seems, in particular, that we are able to instantiate a canonical class of three-valued doxastic Kripke frames using AFs.[7] This will be explored further in future work.

[6] However, notice that the argument used to prove Theorem 3.1 can be easily adapted to show that the stable semantics is canonical for boolean theories.

[7] In particular, by taking labellings as worlds and letting belief sets be induced by an AF under an argumentation semantics.

Abstract

In this short note we give an overview of our research concerning cartography on the Web and its challenges. We present a mathematical formalism to capture the notion of map on the Web, which allows to automatize the construction of maps.

1 Introduction

Cartography is the art of making maps. Its essential aim is that of representing the characteristics of a region of interest. Cartography builds upon two main steps: *selection* and *abstraction* (Robinson et al. 1995). Selection enables to focus only on the particular pieces of information that will serve the map's purpose; in this phase the region of the space to be mapped is chosen. Abstraction is the fundamental property of a map, which states that a map should be smaller than the region it portraits. Thus, a map can be simply defined as an abstract representation of a region of interest.

The Web is a large and interconnected information space commonly accessed and explored via navigation. This space is simply too large and its interrelations too complex for anyone to grasp its content by direct observation. Hence, the possibility of applying cartographic principles to the Web space becomes a relevant matter. Knowledge maps can be useful cues that help to navigate, find routes and discover previously unknown connections between knowledge items on the Web. Effectively, they can play the role of *navigational charts* helping users to cope with the size of the Web (cyber)space (Dodge and Kitchin 2001). Users via knowledge maps can track, record, identify and abstract conceptual regions of information on the Web, for their own use, for sharing/exchanging with other users and/or for further processing (e.g., combination with other maps). Maps are also useful to analyze information. For instance, the availability of a series of chronologically sequential maps enables complex map analysis (e.g., longitudinal analysis) for the detection and forecasting of trends in specific domains (Garfield 1994). This is useful, for instance, in the analysis of the knowledge flows in scientific literature, which helps in understating how the interlinking between disciplines is changing (Rosvall and Bergstrom 2008). Maps of social networks

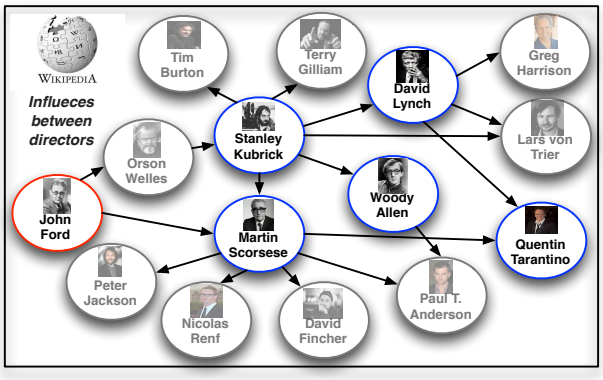

Figure 1: A region of the Web taken from Wikipedia.

can be analyzed to forecast friendship (Ledbetter, Griffin, and Sparks 2007).

The progresses in Web technologies and languages originating from the Semantic Web proposal and, in particular the availability of structured and machine-readable information (RDF data model and SPARQL language) open new perspectives toward the feasibility of knowledge maps of the Web. Now it is possible to leverage logical/algebraic methods to organize and specify in a formal, machine-understandable and reusable way regions and maps of the Web. In this short note we introduce the foundations of a formal notion of map for the Web that will enable the interpretation of maps not only by humans but also by machines, fostering in this way their exchange, combination and reuse at Web level. The following example gives an idea of how a knowledge map of the Web looks like.

Example 1 *(**Mapping favorite directors**). Syd is fond of cinema and wants to discover and keep track of his favorite directors and relations among them.*

The first step toward building the map of *Syd*'s favorite directors is to *select* the region of interest. This could be done by *tracking* the navigational activity of *Syd* on Wikipedia; Syd starting from the page of one of his favorite directors (i.e., J. Ford) has navigated toward directors influenced by J. Ford and manually (book)marked some of them, that is, S. Kubrick, W. Allen, D. Lynch, M. Scorsese and Q. Tarantino.

Note that the region besides these *distinguished* nodes also contains other (lighter) nodes that were visited during the navigation (see Fig. 1). Once the region in Fig. 1 has been obtained, it has to be *abstracted* in a knowledge map. Fig. 2 shows two possible maps of the region in Fig. 1. Which one is a "better" representation of the original region?

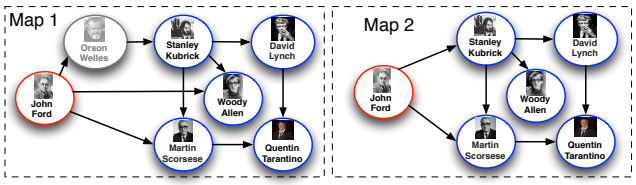

Figure 2: Two possible maps of the region in Fig. 1.

The challenge is to identify a suitable definition of knowledge map that provides an economic and informative representation of the region of interest. Essentially, a map must reflect in a *concise way* information in the region in terms of *connectivity* among some distinguished nodes. What are the formal property of knowledge maps of the Web? Answering these questions enables to have a clear understanding of the relations between regions and maps and also to define means to represent, exchange, reuse and combine different maps (i.e., via an algebra). In this short note we provide a formalization of the notions of region and map of the Web. We discuss several types of maps, present algorithms for constructing such maps and a concrete example of Web map.

2 Formalizing Maps

One of the main challenges toward building maps of the Web is how to move from human-readable maps towards maps that can also be understood and manipulated by machines. This requires the development of a formal notion of map and the investigation of its properties/relations with the region it represents. Let us introduce some notations and basic definitions. Let $\Gamma = (V, E)$ be a graph where V is the set of nodes and E is the set of edges. Then:

- $u \to v$ denotes an edge $(u, v) \in E$. As an example, S. Kubrick $\to$ W. Allen in Fig. 1.
- $u \twoheadrightarrow v$ denotes a path from u to v in Γ. As an example, J. Ford $\twoheadrightarrow$ S. Kubrick in Fig. 1.
- Let $N \subseteq V$. Then, $u \twoheadrightarrow_N v$ if and only if there is a path from u to v in Γ not passing through intermediate nodes in N. As an example, if $N = \{$M. Scorsese, W. Allen$\}$ then J. Ford $\twoheadrightarrow_N$ S. Kubrick but not J. Ford $\twoheadrightarrow_N$ P. T. Anderson in Fig. 1.

Definition 2 (Map) *Let $\Gamma = (V, E)$ be a graph. A* map *$M = (V_M, E_M)$ is a graph s.t. $V_M \subseteq V$ and each edge $(x, y) \in E_M$ implies $x \twoheadrightarrow y$ in Γ.*

By making a parallel with cartography, the graph Γ is the region (or "territory") to be represented/abstracted by the map M. The set of nodes V_M in M represent "points" relevant for the map; these are the *distinctive traits* used as the basis to *identity of the region*. The set of edges E_M in the map M represent the "directions", "routes" and signals connecting different points of interest. A basic (and highly used) example of maps of the Web are bookmarks. In this case, V_M is the set of nodes highlighted or marked, and $E_M = \emptyset$, that is, there is no connectivity recorded among them. More elaborate maps can be built from citation graphs (e.g., Google Scholar); here V_M is a set of URIs of papers of interest and E_M is the citation connectivity graph one can navigate.

Fig. 3 shows some possible maps obtained from the graph in Fig. 1. The map in Fig. 3 (a) is an example of bookmarks. Note that maps (a)-(c) do not capture connectivity among the distinguished nodes. For instance, J. Ford and S. Kubrick that are both distinguished nodes connected by a path in the original region, are not connected in these maps. This points to the notion of completeness of a map.

Definition 3 (Complete Map) *A* map *is complete if $\forall x, y \in V_M$, $x \twoheadrightarrow y$ in Γ implies $x \twoheadrightarrow y$ in M.*

In Fig. 3, maps (d)-(f) are examples of complete maps. However, even completeness is not enough to abstract information. Consider the map in Fig. 3 (d). In the region in Fig. 1 there is an edge connecting J. Ford and M. Scorsese. In the map, although there is a path connecting (via S. Kubrick) the two nodes, the fact that there is an alternative connection (not passing through nodes in V_M) between them is missing. The following notion captures this issue:

Definition 4 (Route-complete map) *A* map *M of Γ is route-complete iff $\forall x, y \in V_M$ $x \twoheadrightarrow_{V_M} y$ in Γ implies $x \to y$ in M.*

By looking at Fig. 3, map (d) is not route-complete while maps (e) and (f) are route-complete. Indeed, for each path between distinguished nodes not passing through any other distinguished node in the region, there is an edge in the map. As an example, maps (e) and (f), both introduce some direct edges like, for instance, J. Ford$\to$S. Kubrick (i.e., e_1) that were not present in the original region; the edge e_1 *abstracts* the path J. Ford$\to$O. Welles$\to$S. Kubrick.

But there are still some issues to address. Consider the edge e_2 between J.Ford and Q.Tarantino in map (f). All paths connecting J.Ford to Q.Tarantino in the region pass through some distinguished nodes (i.e., M.Scorsese, S.Kubrick, D.Lynch) and connectivity information between J.Ford and Q.Tarantino is already encoded in the map via the paths Ford $\to$ Scorsese $\to$ Tarantino, Ford $\to$ Kubrick $\to$ Scorsese $\to$ Tarantino and Ford $\to$ Kubrick $\to$ Lynch $\to$ Tarantino.
Thus, edge e_2 does not add new connectivity information, i.e., it is in some sense redundant.

Definition 5 (Non-redundant map) *A* map *M of Γ is non-redundant iff $\forall x, y \in V_M$ $x \to y$ in M implies $x \twoheadrightarrow_{V_M} y$ in Γ.*

Example of non-redundant maps are reported in Fig. 3 (d) and (e). However, recall that (d) does not satisfy the property of route-completeness. In order to capture completeness, route-completeness and non-redundancy we introduce *good maps*.

Definition 6 (Good map) *A* map *M of Γ is good if and only if it is complete, route-complete and non-redundant.*

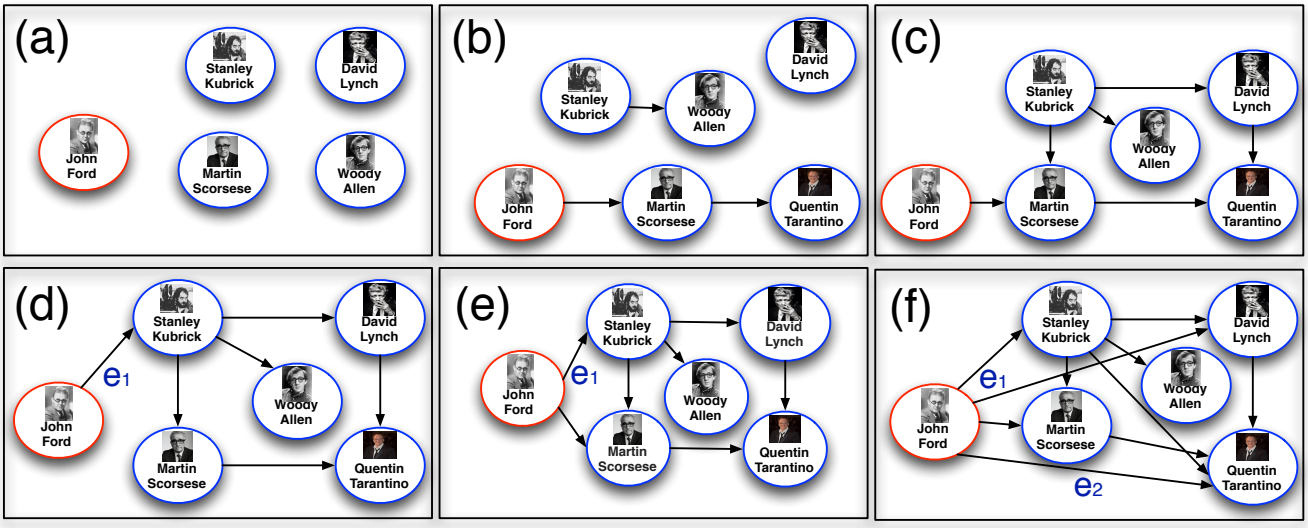

Figure 3: Examples of maps obtained from the region and the distinguished nodes (the set V_M) in Fig. 1.

Thus, good maps comprise the basic features we would like to have in a map in order to faithfully and economically capture connectivity. Fig. 3 (e) shows the good map of the region in Fig. 1. Indeed it is the *unique* good map of such a region. This is not a coincidence. Next theorem give a simple algorithmic characterization of good maps and shows that they are unique:

Theorem 7 *Let $\Gamma = (V_\Gamma, E_\Gamma)$ be a region. Then:*

1. A map M of Γ is good iff $\forall x, y \in V_M$, $x \to y$ in $M \Leftrightarrow x \twoheadrightarrow_{V_M} y$ in Γ.

2. Given $V_M \subseteq V_\Gamma$, there is a unique good map $M = (V_M, E_M)$ over Γ.

Good maps behave very well from algebraic and computationally point of views. In this short note we do not have space to exhibit further formal properties (operations between them, algorithms for computing, etc.), which will be presented in an extended version.

3 Maps for the Web of Data

Our motivation behind the formalism for maps is to develop knowledge maps of the Web graph. The availability of structured interlinked data on the Web (in the form of RDF) is evolving the traditional Web of Documents into a semantic distributed graph known as Web of Linked Data (WoD) (Heath and Bizer 2011), which we will denote as $\mathcal{W} = (V, E)$. Here, nodes are RDF data sources (identified by URIs) and edges RDF predicates. In this section we discuss how to instantiate the conceptual framework introduced in the previous section in the Web of Linked Data.

The problem of building maps in this scenario, given the machinery to build maps already presented, can be reduced to identify regions of interest:

Problem 1 *Given the WoD graph $\mathcal{W} = (V, E)$, construct a subgraph (region) $S = (V', E')$ of $\mathcal{W}$ that contains some distinguished nodes of interest $N \subseteq V'$.*

Graph navigational languages partially address this problem. Current navigational languages (e.g. XPath (W3C 1999), nSPARQL (Pérez, Arenas, and Gutierrez 2010), NautiLOD (Fionda, Gutierrez, and Pirrò 2012), etc.) enable to navigate a labeled graph essentially via matching some pattern (or navigational expression) expressed by means of a regular expression over the alphabet of edge labels. Their output is a set of nodes satisfying the matchings. For our purposes here, their drawback is that the information used during the navigation is forgotten, that is, the semantics uses the navigation only as the means to reach the resulting *set of nodes*. This is not enough for our goal: we need the missing information about connectivity in order to deal with regions and maps.

To cope with this problem, we extend the semantics of navigational languages to incorporate in their results not only the final set of nodes, but some of the paths followed during the evaluation. This allows to build regions instead of getting only sets of nodes. We consider the navigational language $\mathcal{L}$ that abstracts the core of most existing path languages. Its syntax is:

path::=<RDF predicate>| path[test] | (path)* | (path|path) | path/path

The core of $\mathcal{L}$ are regular expressions built upon RDF predicates and boolean tests used to drive the navigation. Tests can be of different types, for instance, ASK SPARQL queries (as in NautiLOD (Fionda, Gutierrez, and Pirrò 2012)) and/or nested regular expressions (Pérez, Arenas, and Gutierrez 2010). We are now ready to provide a concrete example of map.

Example 8 *Specify a region that contain scientists that have been influenced, directly or indirectly up to distance 6, by Tim Berners-Lee (TBL). Build the good map of the obtained region.*

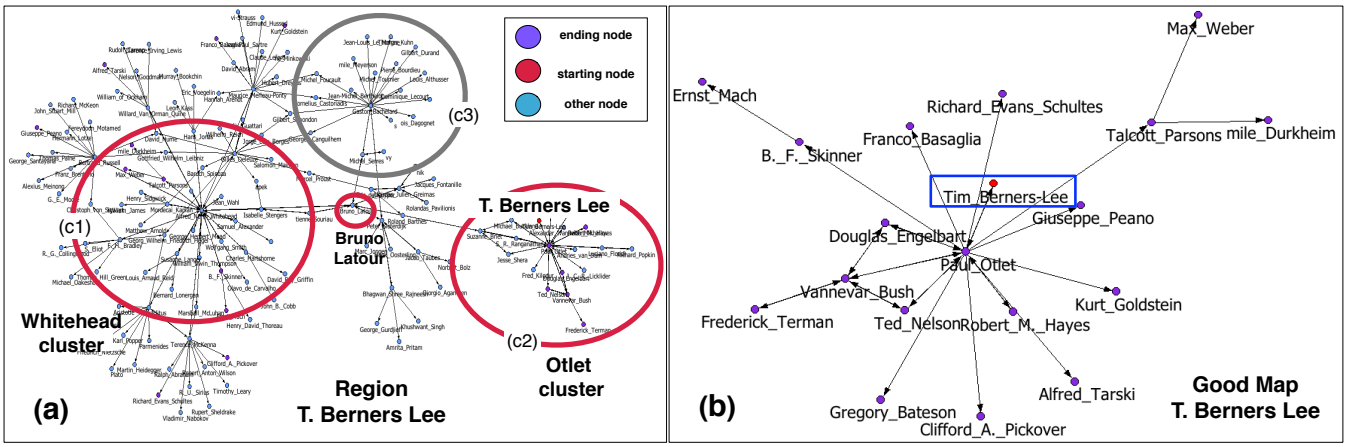

Figure 4: Region (a) and good map (b) for Example 8.

The region can be specified by considering the URI of TBL in DBpedia as starting node and the following $\mathcal{L}$ expression:

```
dbp:influenced<1-6>[test]
```

`test=` `ASK {?person rdf:type dbpedia:Scientist.}`

The notation `<1-6>` is a shorthand for the concatenation up to six steps of the predicate `dbp:influenced`, while the `test` is used to filter the endpoint nodes representing scientists. Fig. 4 (a) reports the region which contains 149 nodes and 236 edges. There are two main influence clusters; the first (c2) around Otlet and the second one (c1) around Whitehead. Note also that Latour is the bridge between the two clusters but (according to `dbpedia.org`) he is not a scientist. In the region there are several nodes that were visited during the evaluation of the expression but did not lead to any result (e.g., the cluster of nodes c3). Fig. 4 (b) shows the good map. It has 18 nodes and 43 edges and represents the connectivity information among scientists in the region.

4 Related Work

The development of our map framework share some characteristics with other approaches that focus on providing some form of "map" of the Web. Dodge (Dodge and Kitchin 2001) in the *Atlas of the Cyberspace*, provides a comprehensive overview of visual representations of *digital landscapes* on the Web. A recent information visualization paradigm used to summarize information is that of *metro maps* (e.g., (Shahaf, Guestrin, and Horvitz 2012)). Other strands of research related to ours are (visual) navigational histories, site maps and bookmarks. An approach enabling to create concept maps is described in Gaines and Shaw (Gaines and Shaw 1995). As for site maps, Li et al. (Li et al. 2001) investigated the problem of building multi-granular maps. Finally, bookmarking consists in marking and sharing (e.g., with Delicious) URIs for the purpose of future reuse.

The crucial difference with the present work is that these approaches are designed for human usage and are mainly oriented to visualization. Moreover, no formal/provable relations of connectivity between the URIs chosen are given.

Abstract

Many knowledge representation tasks involve trees or similar structures as abstract datatypes. However, devising compact and efficient declarative representations of such properties is non-obvious and can be challenging indeed. In this paper, we take acyclicity properties into consideration and investigate logic-based approaches to encode them. We use answer set programming as the primary representation language but also consider mappings to related formalisms, such as propositional logic, difference logic, and linear programming.

Introduction

Numerous hard computational tasks involve the construction of acyclic or tree structures. Constraint satisfaction and related methods are an important approach for solving many of these problems. Since acyclicity and the property of being a tree are no primitives in common constraint-based representation formalisms, the challenge of formulating such conditions in terms of more basic constraint expressions arises. Hence, in this work, we systematically investigate logic-based approaches to encode respective properties.

Construction of acyclic graphs, trees, or chordal graphs shows up in numerous applications. For instance, Bayesian network structure learning, where directed acyclic graphs provide solution candidates, can be reduced to constraint optimization (Jaakkola et al. 2010; Cussens 2011). Furthermore, chordal Markov network learning amounts to the task of optimizing maximum weight spanning trees induced by chordal graphs (Corander et al. 2013). Chordality is a relaxation of strict acyclicity in which cycles of length three are allowed in an otherwise tree-structured undirected graph. Constraint-based methods can also be used to infer phylogenetic trees (Brooks et al. 2007; Bonet and John 2009), describing the evolution of living organisms, languages, and other evolving systems.

The basic problem to be solved with constraint-based formalisms in the above and other applications is constructing an acyclic or a tree structure subject to further conditions. That the choice among underlying edge candidates actually results in some graph structure with the desired properties must be enforced by corresponding constraints. Straightforward formulations, however, can become impractically large and inefficient, and our work sheds light on ways to encode such constraints succinctly and efficiently.

Although we rely on answer set programming (ASP) (Brewka, Eiter, and Truszczyński 2011) as the primary representation language for encodings, respective formulations in related formalisms, such as propositional satisfiability (SAT), SAT extended with difference logic (DL), and linear programming (LP), can be obtained through automatic polynomial translations from ASP. Linear translations to SAT exist whenever ASP rules are *tight* (Erdem and Lifschitz 2003), i.e., if there are no circular positive dependencies through rules' prerequisites on the ground level. In the non-tight case, level mappings (Janhunen 2004) can be used to bridge the semantic gap between ASP and SAT. Compact linear representations of level mappings can be achieved by means of difference constraints available in DL (Niemelä 2008) or integer variables in LP (Liu, Janhunen, and Niemelä 2012).

In this short paper, we present encoding approaches for directed acyclic graphs. Their extensions to forests and trees, in the directed and undirected case, as well as chordal graphs are addressed in an extended version of this paper.[1]

Directed Graphs

As usual, a *directed graph* G is a pair $\langle V, E\rangle$, where V is a finite set of *vertices* and $E \subseteq V \times V$ is a set of directed *edges*. For some $v \in V$, we denote the number of incoming or outgoing edges, respectively, by $\deg^-(v) = |\{u \mid \langle u, v\rangle \in E\}|$ and $\deg^+(v) = |\{u \mid \langle v, u\rangle \in E\}|$; v is a *root* (or *leaf*) of G if $\deg^-(v) = 0$ (or $\deg^+(v) = 0$). A *path* of length $k-1$ in G is a non-empty sequence $v_1, \ldots, v_k$ of vertices from V such that $\langle v_i, v_{i+1}\rangle \in E$ and $v_i \neq v_j$ for all $1 \leq i < j \leq k$. A sequence $v_0, v_1, \ldots, v_k$ is a *cycle* of length k in G if $\langle v_0, v_1\rangle \in E$, $v_0 = v_k$, and $v_1, \ldots, v_k$ is a path in G.

A *directed acyclic graph* is a directed graph G such that there is no cycle in G. A directed acyclic graph $G = \langle V, E\rangle$ is a *directed forest* if, for every $v_k \in V$, there is exactly one path $v_1, \ldots, v_k$ in G from a root v_1 of G to v_k. Given

(a) Cyclic (b) Acyclic (c) Forest (d) Tree

Figure 1: Directed example graphs with five vertices each

```
1 #const n=5.
2 node(1..n).
3 pair(X,Y) :- node(X;Y), X != Y.
4 { edge(X,Y) } :- pair(X,Y).
```

Figure 2: Encoding part for generating directed graphs

that any incoming edge $\langle v_{k-1}, v_k \rangle$ can be extended to a path $v_1, \ldots, v_{k-1}, v_k$ from a root v_1, the former condition is equivalent to requiring $\deg^-(v) \leq 1$ for all vertices $v \in V$. Finally, a *directed tree* is a directed forest $G = \langle V, E \rangle$ with a unique root, i.e., $\deg^-(v) = 0$ holds for exactly one $v \in V$. Some directed example graphs illustrating the introduced acyclicity properties are depicted in Figure 1.

Encodings

We illustrate different encodings by means of first-order specifications in the input language of the ASP grounder GRINGO (Gebser et al. 2012). The underlying principles, however, are of general applicability, and we outline particularities of respective SAT, DL, and LP formulations.

Rules describing the (non-deterministic) generation of directed graphs are shown in Figure 2. The predicate `node`/1 provides the labels $1, \ldots, \mathbf{n}$ for vertices, where **n** is an integer constant standing for the number of vertices, and the symmetric predicate `pair`/2 represents the domain of directed edges given by all pairs of distinct vertices. Any subset of these pairs can be generated via the choice rule in line 4, permitting instances of `edge`/2 to hold without further preconditions. For instance, the atoms characterizing the directed graph in Figure 1(a) are `edge(1,2)`, `edge(1,3)`, `edge(2,4)`, `edge(3,2)`, `edge(4,5)`, and `edge(5,3)`.

Acyclicity Checking

To make sure that a generated directed graph $\langle V, E \rangle$ is acyclic, we may check whether there is a strict partial order $<$ over vertices in V such that $u < v$ if $\langle u, v \rangle \in E$. The rules in Figure 3 encode this approach in an inductive fashion. Given **n**=5, the following (simplified) ground instances are obtained when the label `3` is substituted for `X`:

```
order(3,1) :- not edge(3,1).
order(3,1) :- order(1).
order(3,2) :- not edge(3,2).
order(3,2) :- order(2).
order(3,4) :- not edge(3,4).
order(3,4) :- order(4).
order(3,5) :- not edge(3,5).
order(3,5) :- order(5).
```

```
5 order(X,Y) :- pair(X,Y), not edge(X,Y).
6 order(X,Y) :- pair(X,Y), order(Y).
7 order(X) :- node(X),
              order(X,Y) : pair(X,Y).
9 :- node(X), not order(X).
```

Figure 3: Inductive bottom-up encoding of acyclicity test

```
order(3)   :- order(3,1), order(3,2),
              order(3,4), order(3,5).
:- not order(3).
```

As expressed by `order(3,`v`)`, vertex `3` fulfills the condition of $<$ relative to a potential successor $v \in \{1,2,4,5\}$ if there is no edge from `3` to v or if v has no path to `3`. Then, `order(3)` is derived once the existence of a cycle through vertex `3` can be safely excluded for all potential successors v of `3`. In particular, the positive prerequisites of corresponding ground rules for other vertices along with well-foundedness of derivations, as required in ASP, prohibit `order(3)` to hold if `3` belongs to some cycle. Given this, the integrity constraint denying models such that `order(3)` is false rejects any directed graph with a cycle through `3`, and respective ground rules establish the same for other vertices.

Reconsidering the example graph in Figure 1(a), we have that `order(`u`,`v`)` can be derived for distinct vertices u and v such that $\langle u, v \rangle$ is not an edge. Since each vertex u has some successor v, there still is some atom `order(`u`,`v`)` for u that cannot be concluded in this way, e.g., `order(5,3)` for vertex `5`. Hence, `order(`u`)` remains underivable for all $u \in \{1,2,3,4,5\}$, and the cyclic graph in Figure 1(a) is rejected by means of the rules in Figure 3. Unlike this, vertex `5` has no successor in the acyclic graph shown in Figure 1(b), so that `order(5,`v`)` is derivable for $v \in \{1,2,3,4\}$. This in turn yields `order(5)`, `order(4,5)`, and `order(4)`, given that `5` is the only successor of vertex `4`. Similarly, the derivation of `order(2,4)` leads to `order(2)`, and the establishment of `order(3,2)`, `order(3,4)`, and `order(3,5)` for the successors of vertex `3` allows for deriving `order(3)`. Finally, `order(1)` can be concluded in view of `order(1,2)` and `order(1,3)`. As derivable atoms are compatible with (ground instances of) the integrity constraint in line 9 of Figure 3, the graph in Figure 1(b) passes the acyclicity test.

Encoding Variants

The encoding in Figure 3 is *non-tight*, i.e., it relies on well-foundedness in the presence of circular positive dependencies on the ground level. Level mappings (cf. (Janhunen 2004; Niemelä 2008; Liu, Janhunen, and Niemelä 2012)) furnish an alternative mechanism to express well-founded derivations, where difference constraints or integer variables allow for linear embeddings in DL and LP. A respective approach is taken by the *tight* ASP formulation of the predicate `order`/1 in Figure 4. In order to eliminate circular positive dependencies between rules' prerequisites and conclusions, the auxiliary predicates `order`/3 and `order`/2 include an additional argument for "step counting" that unfolds the derivation of a partial vertex order $<$ witnessing acyclicity. If such an order exists, its construction must be completed in at most **n** steps. For in-

```
5 order(X,Y,1..n) :- pair(X,Y),
                     not edge(X,Y).
6 order(X,Y,N-1)  :- pair(X,Y),
                     order(Y,N).
7 order(X,N) :- node(X), N = 2..n,
                order(X,Y,N) : pair(X,Y).
8 order(X)   :- node(X),
                order(X,Y,1) : pair(X,Y).
```

Figure 4: Unfolded bottom-up derivation of `order`/1

stance, the (total) order $1 < 3 < 2 < 4 < 5$ over vertices of the acyclic graph in Figure 1(b) is represented in terms of the atoms `order(5,2...5)`, `order(4,2...4)`, `order(2,2...3)`, and `order(3,2)` along with `order(`u`)` for $u \in \{1, 2, 3, 4, 5\}$. On the one hand, explicit step counting eliminates the potential of circular derivations, so that straightforward translations like completion (Clark 1978) can be used to map the encoding in Figure 4 to SAT, DL, or LP. In fact, the tight ASP formulation of `order`/1 can be viewed as a directed counterpart of the SAT encoding for the undirected case in (Corander et al. 2013). On the other hand, the step argument introduces an additional dimension increasing the number of atoms as well as constraints. For directed graphs $\langle V, E\rangle$, the size of ground instances grows from $\mathcal{O}(|E|)$ for the encoding in Figure 3 to $\mathcal{O}(|E|\times|V|)$, thus shifting from linear to quadratic space.

Variants of the encodings presented so far can be obtained by replacing the *unconditional* generation of edges in line 4 of Figure 2 by the following (non-deterministic) choice rule:

```
{ edge(X,Y) } :- pair(X,Y), order(Y).
```

The additional prerequisite `order(Y)` necessitates the absence of cycles through a vertex substituted for `Y` before admitting any edge from a predecessor substituted for `X`. Hence, the generation of edges with the above choice rule progresses successively from the leaves of a directed acyclic graph. Whether such *conditional* edge generation is advantageous or not is empirically investigated in the evaluation section below. While the *leaf encodings* in Figure 3 and 4 describe "bottom-up" traversals starting from the leaves of a directed graph, acyclicity tests can likewise be performed "top-down" from roots, and a successive choice rule similar to the one above can optionally be used in *root encodings* instead of line 4 in Figure 2. Without other side constraints, bottom-up and top-down traversals appear fully symmetric, but in extended contexts the orientation of acyclicity tests may interact or interfere.

Notably, the predicate definitions in Figure 3 and 4 are both *stratified* (cf. (Apt, Blair, and Walker 1988)). That is, when instances of the predicate `edge`/2 are fixed, there is at most one (well-founded) model that can be deterministically determined. In the absence of circular positive dependencies, as with ground instances of the rules in Figure 4, the unique model or unsatisfiability is also obtained by evaluating (via unit propagation) the rules' completion. Except for variants introducing prerequisites for conditional edge generation, all encoding parts in the sequel are stratified, so that the choice of edges is the only source of non-determinism.

directed acyclic graphs	**leaf encoding** non-tight	tight	**root encoding** non-tight	tight
CLASP	0.26	—	0.27	—
CLASP/SAT	2.41	1.59	1.55	1.16
LINGELING	5.65	2.53	5.19	2.49
Z3	1.69	—	1.67	—
CPLEX	682.54	623.17	639.38	687.46

Table 1: Average runtimes for directed acyclic graphs

Evaluation

To test our encodings, we ran CLASP (2.1.3) both as an ASP and SAT solver, the SAT solver LINGELING (ats-57807c8-131016), the DL solver Z3 (4.3.1), and the LP solver CPLEX (12.5.0.0) with default settings on a cluster of Linux machines. We used GRINGO (3.0.5) to ground first-order ASP formulations and the translators LP2SAT2 (1.18) (Janhunen and Niemelä 2011), LP2DIFF (1.33) (Janhunen, Niemelä, and Sevalnev 2009), and LP2MIP (1.18) (Liu, Janhunen, and Niemelä 2012) for converting ground instances to SAT, DL, or LP, respectively. In order to perturb the search space for directed acyclic graphs, we added randomly generated XOR-constraints over edges, systematically varying both the length and the number of such constraints.

Average runtimes in seconds for 25 instances with $\mathbf{n}$=25 vertices are given in Table 1. Runs exceeding 1000 seconds were counted as 1000 seconds, and an entry "—" marks that no run completed in time. We compare the performance of the considered solvers on four different encodings of directed acyclic graphs. The non-tight and tight variants of the *leaf encoding* consist of the rules shown in Figure 2 along with the inductive or unfolded bottom-up acyclicity test, respectively, encoded in Figure 3 and 4. Their counterparts denoted by *root encoding* swap the orientation of acyclicity tests by traversing vertices top-down from roots instead of bottom-up from leaves. The runtimes of CLASP on ASP formulations in the first row exhibit no significant differences between the symmetric leaf and root encodings. That is, instances relying on their non-tight variants were solved easily by CLASP (with default settings), whereas all runs on the tight variants timed out. Similar behavior is observed with the Z3 solver, for which non-tight instances are mapped to DL and tight ones to plain SAT. However, LINGELING and CLASP, run as a SAT solver, both perform well on the translations by LP2SAT2, where the tight ASP formulations have some advantage over the level mappings introduced when translating non-tight instances. The performance of the LP solver CPLEX (with default settings) is rather unstable on all of our encoding variants. In particular, CPLEX does not substantially benefit from the use of integer variables to represent level mappings for non-tight instances.

Conclusions

Graphs satisfying acyclicity properties are frequent in knowledge representation tasks. Since these properties do not appear as basic primitives in common constraint-based representation formalisms, formulating them compactly and efficiently is a recurring challenge. We have investigated

logic-based characterizations of directed acyclic graphs and developed encodings in the language of answer set programming. Directed forests and trees, their undirected variants, as well as chordal graphs are addressed in an extended draft.[1]

Experiments indicate the relevance of representation approaches and constraint formulations, with particular emphasis on well-foundedness. While the size of ground instances is linear for the acyclicity test in Figure 3, encodings based on the full transitive closure of edges (Rintanen, Heljanko, and Niemelä 2004; Brooks et al. 2007; Çaylı et al. 2007; Cussens 2008; Çelik et al. 2009; Brewka, Eiter, and Truszczyński 2011) yield quadratic space complexity, even for sparse graphs. As the discovery of a single "universal" encoding is highly unlikely, the alternatives investigated here provide a toolkit for representing graph structures in different applications. In fact, we believe that effective declarative means to specify such fundamental datatypes are important cornerstones for the development of robust constraint-based solving methods.

Abstract

We propose a model of belief and intention change over the course of a dialogue, in the case where the decisions taken during the dialogue affect the possibly conflicting goals of the agents involved. We use Situation Calculus to model the evolution of the world and an observation model to analyze the evolution of intentions and beliefs. In our formalization, utterances, that only change the beliefs and intentions, are observations. We illustrate our formalization with the game of Werewolf.

Introduction

Agents are engaged in dialogues according to goals they can satisfy by talking to other agents (Cohen and Perrault 1979),(Perrault and Allen 1980). A dialogue is a sequence of utterances, produced by agents based on their beliefs, in order to reach intended states of facts by causing other agents to change their beliefs and thus also their intentions. Our goal is to model this interaction between beliefs, intentions, and utterances. The ability to predict decisions resulting from the dialogue is used as a performance measure.

An example of such a domain is the *Werewolf* game. Here, players are assigned the roles of either villagers or werewolves. The game proceeds in alternating day and night stages, overlooked by an impartial judge. By night, unseen by villagers, the werewolves choose and kill a victim. The victim's identity is announced by the judge at the beginning of the next day. Then, the rest of the villagers discuss and vote to execute one person who they agree is a werewolf. The problem is to predict the outcome of each player's vote.

The game can be modeled with utterances as actions in Situation Calculus (McCarthy 1983), based on Austin's theory of performatives (Austin 1975). A problem is accounting for the indefinitely many perlocutionary acts, or possible effects an utterance may have on the hearer. Belief Revision (Alchourron, Gardenfors, and Makinson 1985) enables modeling and reasoning about changes of beliefs, including as a result of knowledge producing actions in Situation Calculus (Shapiro et al. 2000). Applying Belief Revision to our domain is hard because the agents need to do reasoning about beliefs over beliefs.

We present a new approach to Belief Revision in Situation Calculus. We overcome the need to represent perlocutions by assuming an 'observation model', describing what beliefs, intentions, and unknown properties the utterances expose. The agents' belief states are then filtered (Shirazi and Amir 2011) with the observed utterances, resulting in an updated Kripke structure.

Our new approach allows us to describe dialogues combined with actions. From a Kriple Structure perspective, we add an observation model of utterances, and a revision model, accounting for how the utterances are used to change beliefs. From a Situation Calculus perspective, we model beliefs over beliefs, belief change, and perlocutionary effects. From a Belief Revision perspective, we represent how utterances affect dialogue participants on an individual level, depeding on each agents' internal state.

Our model does not use any linguistic input. We assume the utterances are already parsed to logical formulas that encode both their propositional content and the speech act they function as. Utterances expressed in natural language may provide further insight into the agents' beliefs, encoded in presuppositions and propositional attitudes. We plan to embed those phenomena in our model as future work.

Related Work

Scherl and Levesque (Scherl and Levesque 2003) introduce a situation accessibility relation predicate for the knowledge modality, and a sensing result function for knowledge producing actions, in a single agent scenario. The knowledge of the agent changes only through sensing, and there is no discussion of actions that specifically change the possibly nested beliefs, leaving the world unchanged.

This work has been extended (Shapiro et al. 2000),(Delgrande and Levesque 2012) for Belief Revision and Update. The authors introduce plausabilty as a mapping from possible worlds to natural numbers, defining a total order on possible worlds in which one believes the most plausible possible world. Belief revision changes plausability.

R. Demolombe and P. P. Parra (Demolombe and del Pilar Pozos Parra 2000) define an epistemic logic for the multiagent case, using belief as a simple modality that qualifies sentences but does not allow nesting. Their fragment is tractable, but the fact that it does not allow nested belief makes it inapplicable to domains where agent's actions are

oriented mainly towards changing other agents' beliefs, both about the world and about themselves and other agents.

It is on this (Demolombe and del Pilar Pozos Parra 2000) tractable fragment that most of the work (Demolombe, Mara, and Fern 2005),(Parra, Nayak, and Demolombe 2004) on formalizing intentions or the BDI framework in Situation Calculus is built upon. These formalizations therefore inherit the limited expressing power of the fragment, also not allowing nested beliefs. Here, intentions are about actions, referring to plans, as sequences of actions that are intended, in that specific order, in order to reach the goals. We do not consider planning, our intentions refer to the states of the world currently most desirable to the agent.

None of these approaches can straightforwardly be used in our domain, by enconding utterances as actions, as we need to account for both the change in nested beliefs, and the variability in how an utterance affects the hearer. Early approaches to modeling speech acts as plan operators (Cohen and Perrault 1979) propose a solution to the latter problem by defining mediating acts between the speech acts and the perlocutionary effects. These acts describe the conditions in which the direct effects of the illocutionary act result in the intended effects. This amounts to defining perlocutionary effects as actions where the preconditions are defined on the hearer belief state, and illocutionary effects as actions where the preconditions are defined on the speaker belief state, the latter's effects being carried over to the mediating act's preconditions. A disadvantage is that the set of perlocutionary effects is virtually unbounded for any utterance.

Early work on dialogue modeling (Cohen and Levesque 1985), (Cohen and Levesque 1990) assumes that the dialogue participants are rational, intentional agents that hold beliefs and choose to intend actions according to their goals. This work builds upon earlier theories in pragmatics by Searle (Searle 1976) and Horn (Horn 1984). The authors axiomatize some speech acts as actions in an event calculus, with modal operators for beliefs and goals, and event operators such as *DONE* and *AFTER*. Intention in this framework refers to the intention to execute an action according to a plan in order to reach a goal, so an agent may intend an action, not a set of possible worlds described by a formula.

Formalization of the Observation Model

The observation axioms describe what each observation exposes. The propositional content and function of an utterance is modeled as an observation, rather than an action. The intuition is that utterances do not change the world itself, but change and provide evidence for agent beliefs.

Observation axioms play a similar role to the observation model in statistical models such as the HMM or the POMDP (Kaelbling, Littman, and Cassandra 1998). They also expose a hidden state, using the observed value of a model variable. In our case, the hidden state consists of beliefs, intentions, and unknown properties (roles), and the model variable is a predicate encoding an observable fact.

Preliminary Definitions and Notation

We build upon the framework of Situation Calculus (McCarthy 1983), using successor state axioms as introduced by Reiter (Reiter 1991) as a solution to the frame problem.

We have a set Ag of agents, a set R of roles, and a set S of situations. Some roles $R_u \subseteq R$ are unique. The set of unique roles for a certain game is known by all agents.

The signature specifies sorts α (agent) and σ (situation), a set M of modalities, a set F of fluents, a set C of constant symbols, and a set A of actions, where: $M = \{K, B, P, I\}$ (knowledge, belief, intention, persistent intention), $F = \{r : \alpha\sigma\}_{r\in R} \cup \{dead : \alpha\sigma, alive : \alpha\sigma, voted : \alpha\alpha\sigma\} \cup \{claim_r : \alpha\alpha\sigma\}_{r\in R} \cup \{claim_{\neg r} : \alpha\alpha\sigma\}_{r\in R}, C = \{c : \alpha\}_{c\in Ag} \cup \{s_0 : \sigma\}, A = \{vote(x)\} \cup \{round_n(x)\}_{3\leq n\leq |C|}$.

Modalities Modalities are ternary relations understood as each agent's accessibility relation on situations (Scherl and Levesque 2003). More specifically, for a modality $M \in \{K, B, P, I\}$, $M(x, s', s)$ is used for situation s' being accessible from situation s to agent x according to M.

For modality M, agent x, situation s, and formula ϕ_z with free situation variable z, we use the shorthand notation:

$M(x, \phi_z, s) \equiv \forall s' : \sigma.M(x, s', s) \rightarrow \phi_z[z/s']$

To improve readability, we will denote free situation variables with a single mention by symbol _.

Observation Axioms

Utterances are treated as observations, and are produced in the conditions specified by our axiom system.

An observation axiom is an axiom of the form:

$$\forall \vec{x} : \vec{\alpha}.l(\vec{x}, s) \wedge \wedge_{i\neq j\in I} x_i \neq x_j \rightarrow \vee_k(\phi_k \wedge \phi_k^M)$$

where: l is a literal, $\vec{x}$ is a vector of agent variables, I is a subset of the indices of $\vec{x}$, each ϕ_k is a formula with no modalities, and in each ϕ_k^M, every formula with no modalities appears in the scope of a modal formula.

Literal $l(\vec{x}, s)$ is the *observation* and encodes any fact that becomes available to all agents. Formulas ϕ_k encode facts that are not available to all agents. Formulas ϕ_k^M describe the intentions or beliefs that, in the conditions described by ϕ_k, resulted in the observed value of the predicate encoded by l. Formulas ϕ_k and ϕ_k^M describe the hidden state.

We assume only players can make and be the object of claims, for all roles $r \in R$, claims $c \in \{r, \neg r\}$, situations s:

$\forall x, y : \alpha.claim_c(x, y, s) \rightarrow \neg(judge(x, s) \vee judge(y, s))$

As a simplification, we consider as observations claims about the agents' roles. Other utterances only expose their propositional content. The observation model is known by all agents and consists of the following axioms:

- Accusing another player of being the werewolf:

$$\begin{aligned}&\forall x, y : \alpha.(claim_{wolf}(x, y, s) \wedge x \neq y) \rightarrow (wolf(x, s) \wedge \\ &\neg B(x, wolf(y, \_), s) \wedge B(x, B(y, wolf(x, \_))) \vee \\ &\neg wolf(x, s) \wedge B(x, wolf(y, \_), s)) \end{aligned} \quad (1)$$

- Defending another player or oneself:

$$\begin{aligned}&\forall x, y : \alpha.claim_{\neg wolf}(x, y, s) \rightarrow (wolf(x, s) \\ &\wedge B(x, \exists z : \alpha.z \neq x \wedge z \neq y \wedge B(z, wolf(y, \_), \_), s) \\ &\wedge B(x, \exists z : \alpha.z \neq x \wedge z \neq y \wedge \neg B(z, wolf(y, \_), \_), s) \\ &\wedge (x \neq y \vee \neg B(x, wolf(y, \_), s))) \vee (\neg wolf(x, s) \\ &\wedge B(x, \exists z : \alpha.z \neq x \wedge z \neq y \wedge B(z, wolf(y, \_), s), s) \\ &\wedge \neg B(x, wolf(y, \_), s))) \end{aligned} \quad (2)$$

- Claiming the role of seer:
$\forall x : \alpha.claim_{seer}(x, x, s) \rightarrow (wolf(x, s) \vee seer(x, s))$
$\forall x, y : \alpha.(claim_{seer}(x, y, s) \wedge x \neq y) \rightarrow (\neg wolf(x, s)$
$\wedge B(x, seer(y, \_), s) \wedge \neg B(x, wolf(y, \_), s)$
$\wedge B(x, \exists z : \alpha.I(z, dead(y, \_), \_), s))$ (3)

- Claiming that someone is not a seer:
$$\forall x, y : \alpha.claim_{\neg seer}(x, y, s) \rightarrow seer(x, s) \wedge B(x, \exists z : \alpha.B(z, seer(y, \_), s), s) \quad (4)$$

- Not only utterances can be seen as observations that alter beliefs and intentions. Executing an action such as voting can affect fluents such as $voted$, so those fluents can also be modeled as observations:
$$voted(x, y, do(z, a, s)) \rightarrow I(x, dead(y, \_), s) \quad (5)$$

Belief and Intention Axioms

A first set of axioms describe the end goal of each agent, which in the game of Werewolf is to stay alive.

$P(x, \neg dead(x, \_), s)$

Game rounds end with agents voting to have someone executed, which also reflects in the agents' intentions:

$P(x, \vee_{y \in C, y \neq x} dead(y, \_), s)$

Persistent intentions are intentions and are known by all.

In a reciprocal manner, any agent will intend another agent be dead if she concluded the latter intends her death:

$K(x, I(y, dead(x, \_), s), s) \rightarrow I(x, dead(y, \_), s)$

If an agent knows who the werewolf is, unless she is herself a werewolf, she will intend the werewolf be dead:

$K(x, wolf(y, \_), s) \wedge \neg wolf(y, s) \rightarrow I(x, dead(y, \_), s)$

The werewolf will have a similar approach to the seer.

Conversely, knowing an agent's intention will also give some insight into his belief regarding who the werewolf is:

$\forall x, y : \alpha.I(x, dead(y, \_), s) \rightarrow (\neg wolf(x, s) \wedge B(x, wolf(y, \_), s)) \vee (wolf(x, s) \wedge B(x, \neg wolf(y, \_), s))$

Initial Situation s_0

Initially, the agents are assigned and thus know their roles: $\forall x : \alpha.r(x, s_0) \rightarrow K(x, r(x, \_), s_0)$ for all roles r.

Since each agent has at most one role, for the unique roles $r \in R_u$ we have:
$$\forall x, y : \alpha.r(x, s) \rightarrow (y = x \vee (K(x, \neg r(y, \_), s_0)) \wedge K(x, \neg B(y, r(y, \_), \_), s_0))) \quad (6)$$

Each game will specify a role assignment. The roles will be assigned in the initial situation, but this assignment will not be available to the agents.

Belief Filtering

Observations are used in the process of logical filtering (Shirazi and Amir 2011) to select the situations to be believed or intended. We keep the original logical filtering notation and definition for formulas not containing modalities.

The result of filtering the belief relation with an observation is a new accessibility relation, where situations inconsistent with the observation are no longer accessible.

Definition 1 *Let M be a modality predicate and o an observation. Then, for any situations s, s' and agent $x \in Ag$:*

$Filter[o][M(x, s', s)] \equiv P(x, s', s)$, *if* $M \in \{P, I\}$

$Filter[o][M(x, s', s)] \equiv o_{[s/s']} \wedge M(x, s', s)$, *otherwise*

An agent will believe the consequences of her previous beliefs and the new observation:

Theorem 1 *For any modality $M \in \{K, B\}$, agent Ag, situation s, formulas ϕ, ψ, and observation o with $\{\psi, o\} \models \phi$:*

$$\{M(x, \psi, s)\} \models Filter[o][M(x, \phi, s)]$$

Conversely, only those consequences of previous beliefs that are consistent with the new observation are believed:

Theorem 2 *For any modality $M \in \{K, B\}$, agent x, situation s, formulas ϕ, ψ, and observation o with $\{\psi, \phi\} \models \neg o$:*

$$\{M(x, \psi, s), Filter[o][M(x, \phi, s)]\} \models \Box$$

This does not hold for intentions: as a result of refining her beliefs, an agent can drastically change her intentions.

Formalization of the Dynamic Model

We model actions that affect the world in Situation Calculus. The actions are voting and ending a round of game.

Voting is available to any player and any living player can vote for any living player she intends the death of:
$$Poss(x, vote(y), s) \equiv \neg judge(x, s) \wedge \neg judge(y, s) \wedge I(x, dead(y, \_), s) \quad (7)$$

Ending a game round of n players with x voted out ($round_n(x)$) is available to the judge:

$Poss(u, round_n(x), s) \equiv$
$\exists y_1 ... y_n : \alpha.(\wedge_{1 \leq i \leq n}(alive(y_i, \_) \wedge \neg judge(y_i, \_)) \wedge$
$\wedge_{1 \leq i \neq j \leq n} y_i \neq y_j \wedge (\forall z : \alpha.alive(z, \_) \wedge \neg judge(z, \_) \rightarrow$
$\vee_{1 \leq i \leq n} z = y_i)) \wedge judge(u, s) \wedge \neg dead(x, s) \wedge$
$\exists y_1 ... y_{1+n/2} : \alpha. \wedge_{1 \leq i \leq 1+n/2} voted(y_i, x, s)$

Ending a game round is also an *announcement* action, where the judge announces the identity of the player who was killed by werewolves during the night. Similarly to a sensing action (Scherl and Levesque 2003), it has associated an *announcement result* AR. This is a partial function as, depending on the roles, there may be rounds with no victims.

$AR(round_n(x), s, r) \equiv \vee_{c \in Ag}(r = c \wedge dead(c, s))$
$AR(round_n(x), s, r) \wedge AR(round_n(x), s, r') \rightarrow r = r'$

Successor State Axioms

The successor state axioms describe the effects of executing an action on any of the fluents:

- The roles do not change:
$r(x, do(y, a, s)) \equiv r(x, s) \wedge \neg dead(x, do(y, a, s))$
- Players are dead because they were either already dead, voted out at the end of the current round, or killed by werewolves at the end of the current round:
$dead(x, do(z, a, s)) \equiv dead(x, s) \vee (a = round_n(x) \wedge Poss(z, a, s)) \vee \exists y : \alpha.(a = round_n(y) \wedge Poss(z, a, s) \wedge AR(a, do(z, a, s), x))$

- A player's vote is counted when she performs the action of voting and does not change unless she votes for another player:

$$voted(x, y, do(u, a, s)) \equiv$$
$$(voted(x, y, s) \wedge (u \neq x \vee \forall z : \alpha.a \neq vote(z)))$$
$$\vee (a = vote(y) \wedge u = x \wedge Poss(x, a, s))$$

Note that belief filtering and action execution are orthogonal, in that the first only affects accessibility relations, whereas the latter only affects the current situation. Action execution results in a new situation, and new observations will lead to refining the accessibility of situations believed or intended from the new situation.

Conclusions

We presented a model for beliefs in dialogues where agents have conflicting intentions, and the Werewolf game in particular. Other domains can be formalized in a similar manner, by writing the appropriate observation model and belief and intention interaction axioms.

A possible line of future work is using the formalism for a richer domain, such as trials. Another extension is to probabilistic observation and dynamic models, and probabilistic belief and intention accessibility relations. This would allow better predictions of the voting outcomes, as an agent will no longer choose an action non-deterministically, but will have a preference over intended outcomes.

This formalization could be useful in computational pragmatics, for modeling complex conversations where some reasoning beyond text level is needed to follow and predict what the participants may say. In turn, linguistic cues exposing attitudes and polarity could result in a more accurate model of human interaction. Furthermore, in our example, we assumed the dialogue already parsed in a sequence of observations and relations. In the future, we would need to extract these logical formulas from text.

Representing and Reasoning about Time Travel Narratives: Foundational Concepts

Leora Morgenstern

leora.morgenstern@leidos.com

Abstract

The paper develops a branching-time ontology that maintains the classical restriction of forward movement through a temporal tree structure, but permits the representation of paths in which one can perform inferences about time-travel scenarios. Central to the ontology is the notion of an agent embodiment whose beliefs are equivalent to those of an agent who has time-traveled from the future.

1 Introduction

This paper explores the development of a formal theory of time travel, in which one would be able to represent and reason with time travel narratives. This is part of a long-term research program in developing formal models of narrative (Morgenstern 2008). A longer version of this paper is available at (Morgenstern 2014).

2 Working Example

Our working example is adapted and simplified from the Tapestry episode of *Star Trek: The Next Generation*. When Jean-Luc Picard was young, he was involved in a brawl with the Nausicaans, in which he defended the honor of a friend. Picard's heart was irreparably injured, and he was given an artificial, damage-prone heart instead. When he is a middle-aged captain of the Enterprise, he is injured. The artifical heart malfunctions, and Picard dies. While he is waiting to enter the afterlife, the superbeing Q offers him the chance to change his life. Picard returns to the past and avoids the brawl. However, Picard has now become overly cautious and thus never amounts to anything. When Picard realizes the consequences of avloiding the brawl, he asks Q to revert to his old life: he would rather live a meaningful, even if shortened, life.

3 Temporal Ontology

3.1 Representing Backward Time

AI temporal ontologies are generally founded on linear time, as in the event calculus (Miller and Shanahan 1994) or branching time, as in the situation calculus (Reiter 2001). Because linear time does not facilitate reasoning about alternate possibilities, it seems unsuitable as the underlying ontology for time travel. Branching time seems to have better potential. but we are left with a basic conceptual problem: time goes forward, not back.

To solve this problem, we first move away from the implicit assumption in time-travel accounts that there is a path in the time tree that "really" or "first" occurs; Rather, at any point in the time tree, certain sets of paths are accessible by certain agents. Some of these subtrees intuitively correspond to how the world might be if time travel were allowed.

Second, we introduce the idea of different *embodiments* of agents. Intuitively, an agent changes as he goes through different experiences, most notably by gaining beliefs. Specifically, we talk about the embodiment of an agent $A(Sj, Si)$, where there is a path segment from Si to Sj; this represents someone who has the memories of an agent who has lived from Si to Sj. $A(Sj, Si)$ corresponds to the agent A who has time-traveled back from Sj to Si.

Third, we introduce sets of time-travel (or *departure*) points and re-entry points for particular agents. In general, the path between a re-entry point and a departure point is called a *reversible path segment*. An embodiment of an agent will be characterized by the pair (departurel point, re-entry point), indicating that the agent in this embodiment will have beliefs about what has happened in the reversible path segment.

3.2 Preformal development of the model

Consider the working example (Figure 1).

At S1, Picard can choose to get involved in the brawl (path from S1 to S3), or to withdraw from the brawl (path from S1 to S2). Picard gets involved in the brawl and is stabbed. Picard continues along the path whose initial segment is (S1,S3). Assume that he is injured again between S4 and S7 and is dead at S7. S7 is a time-travel point: Picard has the choice to "time-travel." The re-entry point available to him is S1, the point at which he decided to get involved in the brawl.

We represent time travel as a triple consisting of the departure and the re-entry point, together with the agent who is intuitively doing the time-travel along portions of the subtree rooted at S1, These portions of the subtree are accessible to a more experienced *embodiment* of Picard, Picard(S7,S1), who

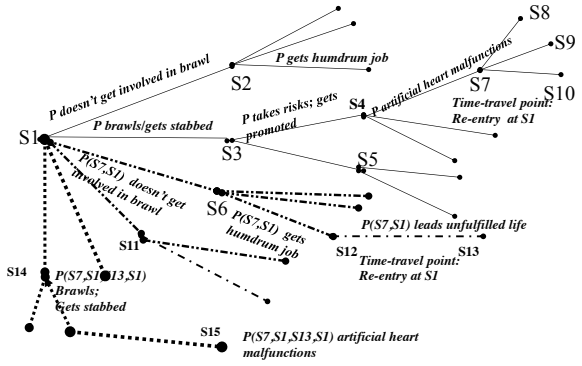

Figure 1: *Star Trek TNG Tapestry Example.*

chooses now to follow a different path. He can no longer follow the path from S1 to S2 but he follows a similar path in which he avoids the brawl (S1,S6).

Nested Time Travel and Embodiments: The time-travel process can be repeated along the path segment of an embodied agent, leading to nested embodiments. E.g., the embodiment of Picard who is aware that brawling will shorten his life realizes, when middle-aged, that he never amounted to anything because he *avoided* the brawl. This embodiment then has a possibility of time travel at S13 and an associated re-entry point at S1. (See Fig. 1.)

Embodiment along a path stays the same or grows deeper, but does not grow shallower. An agent is marked by the path segments that he believes he has lived.

4 Formal Model

4.1 The Time-Travel Tree Structure

Definition 4.1.1 A time-travel tree structure *TTT* is a tuple (S,Act,DP,RP,AG, τ, T), whose elements are described below: [1]

S: S is an infinite set of situations, arranged into a partial order under the precedes relation $<$. The function *time* maps a situation onto its date-clock-time. If $s1 < s2$, then $time(s1) < time(s2)$. There is a path between any two ordered situations. $start$ and end are functions giving the start and end situations of any finite path segment.

Act: A set of actions of the form $do(ag, ac)$ where ag is an agent (see below) and ac is an *actional*, intuitively, an unanchored action type. *Occurs(do(ag,act),s1,s2)* means that the action of ag performing ac occurs between situations $s1$ and $s2$.

DP: A set *DP* $\subset$ *S* of *departure points*, intuitively corresponding to those situations in which an agent can decide to travel to the past, or is involuntarily dispatched to a point inthe past. (Or to the future, in models permitting such time travel.)

RP: A set *RP* $\subset$ *S* of *re-entry points*, intuitively corresponding to those situations to which an agent time travels.

AG: A set of agent embodiments ag. An agent embodiment (AE) ag may be primary, intuitively an agent who has not (yet) time traveled, or secondary, intuitively one who has time traveled.

A primary AE is represented as a, possibly subscripted; a secondary AE is represented as a $2n + 1$-tuple $(a, dp_1, rp_1, \ldots, dp_n, rp_n)$ where a is a primary agent, each $dp_i \in DP$, each $rp_i \in RP$, and (for backward time travel), for each dp_i, rp_i , it is the case that $dp_i > rp_i$.

For $n \geq 1$, we can represent the AE as $(a, dp_1, rp_1, \ldots, dp_{n-1}, rp_{n-1})(dp_n, rp_n)$.The AE $(a, dp_1, rp_1, \ldots, dp_{n-1}, rp_{n-1})$ is the *generating* AE, while $(a, dp_1, rp_1, \ldots, dp_n, rp_n)$ is the *generated* AE. Primary agents can only be generating AEs; secondary agents can be both generating and generated AEs.

Notation 4.1.2: $\hat{a}$ or *a'* is used to range over the primary AE a as well as secondary AEs who are recursively generated by a. This notation is useful when we wish to speak about various embodiments of a specific primary agent. (See the Proof in Example 4.5.2.)

τ: $\tau \subseteq AG \times DP \times RP$. That is, τ is the set of all triples of the form (ag, dp_i, rp_i) which give all the possible ways agent embodiments can travel through the time-travel tree structure. If (ag, dp_i, rp_i) is an element of τ, we say that rp_i is the re-entry point associated with dp_i, from ag's point of view. Note that there may be several re-entry points for a particular departure point of an AE, and several departure points for a re-entry point of a particular AE. Fig. 1 gives an example of the latter scenario.

T: A set of subtrees of S, one for each AE. Assume e is an AE $(a, dp_1, rp_1, \ldots, dp_n, rp_n)$.$T_e$ denotes the subtree rooted at rp_n, the time at which e is first active.

Isomorphisms between subtrees: For each primary AE a, T_a is the subtree of S during which a is active. Let Pa_s denote the subtree of T_a that is rooted at s. If e = $(a, dp_1, rp_1, \ldots, dp_n, rp_n)$, then there is an isomorphism between Pa_s and T_e. Let $\sigma(s)$ denote the image in T_e under this isomorphism. Note that if Pa_s and T_e share the root rp_i, then $\sigma(rp_i) = rp_i$. The existence of this isomorphism is what makes it possible to represent the secondary AE being faced with the same choices that the primary AE faced, and (possibly) making different choices.

4.2 Belief

We use a standard possible worlds semantics of belief as in (Fagin et al. 1995) Thus we have the standard definition of belief in terms of belief-accessible worlds:

Definition 4.2.1:

Holds(s,Bel(ag,p)) $\Leftrightarrow$ $\forall$ *s B(ag,s,s')* $\Rightarrow$ *Holds(s',p)*

We need to be able to say that the more an AE has time traveled, the more an agent believes. Equivalently, fewer possible worlds are belief-accessible to him. Recall that a generating AE and the corresponding generated AE inhabit separate worlds. This is built into the structure of the *TTT*: there are separate, isomorphic structures for generated AEs. We can use the mapping σ between the situations in the isomorphic structures to give us precisely what we need:

Axiom4.2.2:

$B(a(dp_1, rp_1, \ldots, dp_n, rp_n), \sigma(s), \sigma(s'))$
$\Rightarrow B(a(dp_1, rp_1, \ldots, dp_{n-1}, rp_{n-1}), s, s')$

[1] What follows is based on the theory of knowledge and action in (Davis and Morgenstern 2005); however, belief is used here instead of knowledge.

We add the usual KD45 axioms on belief.

E.g., consider the statements P,"If someone gets involved in a barroom brawl, he will have a shortened life span," and Q "If someone avoids a brawl, he becomes a wimp and will not have a meaningful life." Then Picard does not believes either statement in S1; as far as he believes, he can have both a long and meaningful life. At S7, Picard believes that in any branch in which someone brawls, he will not have a long life. That is, any world which is belief accessible to Picard and which is a successor situation to an AE brawling will be on a path in which the AE has a shortened life. Now, consider all such worlds W, and consider the image of such worlds under the isomorphism σ which maps T_{Picard} to $T_{Picard(S7,S1)}$, denoted $\sigma(W)$. Then, by Axiom 4.2.2, the worlds that are belief accessible to Picard(S7,S1) are a subset of $\sigma(W)$. That is, Picard(S7,S1) believes at least as much as Picard. Therefore, at S1, and in all subsequent situations for Picard(S7,S1), he believes P.

Similarly, at S13, having lived the meaningless wimpy life of the non-brawler, Picard(S7,S1) believes Q; we can show via application of Axiom 4.2.2 that in S1, and in all subsequent situations for Picard(S7,S1,S13,S1), Picard(S7,S1,S13,S1) believes Q as well.

4.3 Time Travel Narratives

We define a time travel narrative (TTN) from the perspective of a primary AE A. Intuitively, a TTN describes the intervals of time through which the AE lives. In our approach, this corresponds to a sequence of path segments in the *TTT*, with one path segment ending in a departure point, and the next path segment in the sequence beginning with its associated re-entry point.

Defining the TTN is a bit tricky, since a different AE is associated with each path segment. The following notation is helpful: If PS_i is a path segment, then $A(PS_i)$ is the active agent of PS_i.

Definition 4.3.1: A time travel narrative TTN_A is a sequence of path segments $PS_1 \ldots PS_n$ of the *TTT* that satisfy the following

1. PS_1 is a path segment of T_A.
2. The start and endpoints of the PS_i are characterized recursively as follows:
   (a) The end situation of PS_i is a departure point of A; the starting situation of PS_{i+1} is its associated re-entry point.
   (b) For any PS_i, $i > 2$, if $A(PS_{i-1}) = A(dp_1, rp_1, \ldots, dp_{i-2}, rp_{i-2})$, and dp_{i-1} is the end point of PS_{i-1}, then
      i. the starting point of PS_{i-1} is rp_{i-1}, where rp_{i-1} is dp_{i-1}'s associated re-entry point;
      ii. $A(PS_i) = A(dp_1, rp_1, \ldots dp_{i-1}, rp_{i-1})$.

Example 4.3.2: In Fig. 1, TTN_{Picard} is the sequence of path segments ((S1,S7),(S1,S13), (S1,S15)). (S1,S7) represents Picard's involvement in the brawl, leading to his premature death. S7 is a departure point; the associated re-entry point is S1. (S1,S13) represents the path segment in which Picard(S7,S1) avoids the brawl. S13 is the departure point whose associated re-entry point is S1.

4.4 Goals

For any TTN_A, A may have a goal or set of goals. A goal is represented as a fluent. Let G_j be a goal. G_j is achievable iff it holds in some future situation:

Definition 4.4.1:
Holds(s1,Achievable(G_j)) $\Leftrightarrow \exists s2 > s1(Holds(s2, G_j))$

We are interested in the cases where it is consistent with an agent's beliefs that a goal is achievable. It is straightforward to show that *Holds(s1,¬ Bel(A, ¬ Achievable(G_j)))* $\iff$ *∃ s2 B(A,S1,s2)* $\wedge \exists s3 > s2(Holds(s3, G_j))$.

A set of goals $G = \{G1 \ldots Gn\}$ is said to be achievable if the conjunction of the goals is achievable. An AE has a set of goals only if it is consistent with his beliefs that the conjunction is achievable:

Axiom 4.4.2: *Holds(s, Goalset(A,G))* $\Rightarrow$
Holds(s,¬Bel(A,¬Achievable($\bigwedge_{G_j \in G} G_j$*)))*

Frequently, a goal set is not achievable, leading to the question of which individual goals should be abandoned. We posit an ordering $<_g$ on subsets of G. A preferred subset of G is one that is minimal under this ordering.

4.5 Motivated Time-Travel Narratives

Intuitively, a time-travel narrative is motivated if an AE time travels only when he is in a serious bind and needs to revise history in order to achieve his goals. In this model, this can be expressed by saying that a TTN_A is motivated with respect to the time travel tree if each departure point is taken only after $\hat{A}$ comes to believe that one of his goals can no longer be realized. The associated re-entry point must be chosen so that it is consistent with $\hat{A}$'s beliefs that this life goal, or at least some preferred subset of his goals, can be realized in that re-entry point's future.

Definition 4.5.1
Let *TTT* be a time-travel tree. Let A be be a primary AE and let $TTN_A = PS_1 \ldots PS_n$. Assume that *Holds(start(PS1), Goalset(G))*. Then TTN_A is motivated with respect to *TTT* if the following condition holds:

For all $1 < i \leq n-1$,
if *Holds(end(PS_i), ¬Bel(A(PS_i),Achievable(G)))*, then one of the following is true:
(a) *Holds(start(PS_{i+1}),¬Bel(A(PS_{i+1}),¬Achievable(G)))*
(b) There is some G' that is a preferred subset of G such that *Holds(end(PS_i), ¬Bel(A(PS_i),¬Achievable(G')))*
(c) There is some G' that is a preferred subset of G such that *Holds(start(PS_{i+1}),¬Bel(A(PS_{i+1}),¬Achievable(G')))*

Condition (a) holds when it is consistent with one's beliefs that one can achieve all one's goals by starting over (i.e., re-entering the TTT); condition (b) holds when it is consistent with one's beliefs that one's preferred subset of goals can be achieved in the future (thus negating the need to do time travel at all); condition (c) holds when it is consistent with one's beliefs that a preferred subset of goals is achievable at some re-entry point.

Example: One can show that TTN_{Picard} (Example 4.3.2) is motivated with respect to the *TTT* of the example. Proof in (Morgenstern 2014).

5 Supplementary Examples

In the full paper (Morgenstern 2014), we distinguish between voluntary and involuntary time travel, and give formal characterizations of Second Chance narratives, in which a protagonist has the chance to fix a mistake in his past, and Serendipitous Nnarratives, in which a protagonist unexpectedly has a chance to improve his chances or circumstances. Examples of involuntary time travel are in *Peggy Sue Got Married* and *Groundhog Day*; *Peggy Sue* is a Second Chance narrative, while *Groundhog Day* is a Serendipitous narrative. Only some serendipitous narratives are time-travel stories; examples that are not time-travel narratives include many of the novels of Jane Austen, including *Persuasion*, *Emma*, and *Pride and Prejudice*.

6 Time-Travel Paradoxes

Time travel is subject to a number of well-known paradoxes and puzzles. Some of the best known are the grandfather/autoinfanticide paradox (Barjavel 1943; Horwich 1987), in which an agent travels back to the time when he was an infant, and kills his grandfather or the infant version of himself; the predestination paradox (Novikov 1998), in which no matter what an agent does, he cannot fix the past to prevent some disaster occurring; and closed loop and ontological paradoxes. In the full paper, we show that an advantage of the model proposed here is that these classic paradoxes of time travel do not occur, or occur in a less severe form, within our model.

7 Related Work

Modern theories of narratology, such as (Bal 2009) and (Abbot 2008), discuss representations of non-standard time within narratives. Their focus has generally been on narrative constructs such as flashbacks. None of the work in this field attempts to develop formal theories in which a story can be represented and reasoned about.

The interest of physicists in time travel dates back to the development of Einstein's theory of relativity, and his contention that spacetime is locally curved. Examples of discussions of time travel's feasibility include (Gödel 1949; Malament 1985; Friedman et al. 1990).

8 Evaluation and Future Work

We have classified dozens of time-travel stories (from fiction, film, and TV) with regard to several features and have evaluated whether our theory can handle such features and/or the extent of modification that would be necessary. A sample of this analysis is show in figure 2.

Future work includes extending the theory to handle more cases, especially that of interacting time-traveling agents, and exploring the connection between time-travel and Second Chance narratives.

Acknowledgements

I am grateful to Ernie Davis, Hojjat Ghaderi, Gerhard Lakemeyer, Stephanie Lewis, Sheila McIlraith, Barbara Partee, and Robert Sloan for their helpful comments and suggestions,and to MZ for his indefatigable reading and viewing of hundreds of time-travel stories and episodes, which has helped greatly with this research.

Feature	Example in Fiction	Handles?
Travel to past within lifetime	*Christmas Carol, Peggy Sue, Groundhog*	yes
Travel to any time in past	*Conn. Yankee*	yes
Future time travel	*Time Machine*	minor
Agent travels with object	*Story of the Amulet*	yes
Agent embodiment inhabits self	Star Trek Tapestry	yes
Agent embodiment observes self	*Prisoner of Azkaban*	moderate
Agent emobdiment interacts w. self	*Back to the Future2*	moderate
Multi-agent time travel	*Wizards of Waverly Place*	major
One predetermined future	*Slaughterhouse-Five*	no
Agent cannot change future or past but can bring knowledge back and forth	*Time Traveler's Wife*	no

Aggregative Deontic Detachment for Normative Reasoning

Xavier Parent and Leendert van der Torre
University of Luxembourg
6, rue Richard Coudenhove-Kalergi
L-1359 Luxembourg

Abstract

Aggregative deontic detachment is a new form of deontic detachment that keeps track of previously detached obligations. We argue that it handles iteration of successive detachments in a more principled manner than the traditional systems do. To study this new form of deontic detachment, we introduce a 'minimal' logic for aggregative deontic detachment, and we discuss various properties of the logic.

Aggregative Deontic Detachment

The *Handbook of Deontic Logic and Normative Systems* (Gabbay et al. 2013) reports on-going development of new standards for the formal study of normative reasoning. In his chapter "Alternative semantics for deontic logic", Hansson writes:

> "Deontic logic has ... a strong semantic tradition. Using possible worlds and orderings (preference relations) as their major building-blocks, deontic logicians have constructed models that can be used to determine the validity of deontic sentences. ... But, unfortunately, deontic logic also has a long history of getting stuck in semantic principles that support blatantly implausible deontic postulates. This is probably a major reason why the influence of deontic logic ... has been rather weak." (Hansson 2013, p. 447)

In the past, deontic logic seems to have been heavily, perhaps one-sidely, influenced by the modal logic paradigm, to which Hansson alludes here. However, given all the difficulties the traditionel systems face, deontic logic is currently undergoing a paradigm shift from modal logic to what may be called "norm-based semantics" (Hansen 2014). The core idea is to explain the truths of deontic logic not by some set of possible worlds among which some are ideal or at least better than others, but with reference to an explicit set of given norms or existing moral standards. The present short paper embraces such a paradigm shift.

To study aggregative deontic detachment we introduce a new logic for normative reasoning. It builds on so-called input/output (I/O) logic − one of the candidate systems for a new standard described in the *Handbook* (Parent and van der Torre 2013). Detachment (or modus-ponens) is the core mechanism of the semantics being used. The law of detachment (or modus-ponens) is well-known from propositional logic: from a conditional statement and its antecedent, the consequent of the conditional statement is inferred. In the deontic logic literature, this is referred to as "factual" detachment. The rule may be given the following form, where the conditional obligation for x given a is written as $\bigcirc(x \mid a)$:

$$\text{FD}\ \frac{\bigcirc(x \mid a) \qquad a}{\bigcirc x}$$

Van Eck asked, "How can we take seriously a conditional obligation if it cannot, by way of detachment, lead to an unconditional obligation?" (van Eck 1982, p. 263). Thus, it is no wonder that factual detachment is accepted as valid in many traditional systems of deontic logic, either in its plain form or in a qualified one. However, the traditional systems make some extra assumptions that are potentially controversial.

This can be illustrated with the Danielsson-Hansson-Lewis logic for conditional obligation (Danielsson 1968; Hansson 1969; van Fraassen 1972; Lewis 1973), which until recently was mainstream. First, it shares with the so-called classical theory of rational choice the assumption that an individual has (well-defined) preferences, and that a normative judgment is based on a maximization process. Advocates of −as Simon (1957) terms it−"bounded rationality" have argued that an approach to rationality in terms of maximization is not realistic, because human beings lack the cognitive resources to optimize. Second, such a logic takes the so-called trichotomy thesis for granted. It is the assumption that comparable items (worlds) can only be better than, worse than, or equal to each other in overall value. The trichotomy view has been challenged more than once. Some have argued that these three value relations do not exhaust the space of possibilities. The best-known proposal for a fourth *sui generis* relation is Chang's argument for "on a par"−see Chang (2002).

The best way to avoid potential objections is to make as few assumptions as possible. We believe that the assumption that conditionals obey the detachment rule is one that can hardly be challenged. Obligations and permissions are

Copyright © 2014, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

contextual and vary based on the setting. Consequently, a norm always takes the form of a conditional statement. Some philosophers like Boghossian (2000) think (rightly, in our view) that the disposition to reason according to detachment is constitutive of the possession of the concept of conditional, and thus of the concept of norm. The idea is that, if some agent says "if a then x", and if he truly means it, then he commits himself to detaching x given a. If this agent refuses to acknowledge that he is justified in employing detachment, this will be good evidence that he fails to understand what is meant by "if ... then". Accepting detachment and acquiring an implication are two sides of the same coin.

The present paper focuses on the question of how to handle iterations of successive detachments. The standard I/O systems handle them, by injecting the following rule, known as "deontic detachment":

$$\text{DD}\ \frac{\bigcirc(y \mid x) \qquad \bigcirc x}{\bigcirc y}$$

That is fully in line with the tradition in deontic logic. For instance, the Danielsson-Hansson-Lewis semantics for conditional obligation validates such a law. However, potential counterexamples to DD may be found in the literature (McLaughlin 1955; Hansson 1997; Makinson 1999). They all rely on the intuition that the obligation of y ceases to hold when the obligation of x is violated. This can be illustrated with the following example, due to Broome (2013, §7.4):

> You ought to exercise hard everyday
> If you exercise hard everyday, you ought to eat heartily
> ?* You ought to eat heartily

Intuitively, the obligation to eat heartily no longer holds, if you do not take exercise. Like the others, this counterexample suggests an alternative (call it "aggregative") form of detachment, which keeps track of what has been previously detached:

$$\text{ADD}\ \frac{\bigcirc(y \mid x) \qquad \bigcirc x}{\bigcirc(x \wedge y)}$$

This form of detachment has been overlooked in the literature.

To study aggregative deontic detachment we define a system supporting ADD, but not DD. Accepting ADD, but not DD, implies rejecting the rule known as "weakening". This is the rule, where $\vdash$ stands for the deducibility relation in propositional logic:

$$\text{W}\ \frac{\bigcirc(x \mid a) \qquad x \vdash y}{\bigcirc(y \mid a)}$$

ADD and W together imply DD.[1]

We provide not only a suitable semantics, but also a sound and complete axiomatization for the new logic. Due to space limitations we do not give the soundness and completeness proofs here, but we do present some properties of the new logic.

[1](van der Torre and Tan 1998) define a system PDL validating ADD, but not DD. However, PDL has a preference-based semantics.

Logic for Aggregative Deontic Detachment

In input/output logic, a normative code is a set N of conditional obligations. A conditional obligation is a pair (a, x), where a and x are two formulae of classical propositional logic. We use this notation instead of $\bigcirc(x \mid a)$, because the latter has distinct interpretations in the literature. In the notation (a, x), the first element a is called the body of the rule, and is thought of as an input, representing some condition or situation. The second element x is called the head of the rule, and is thought of as an output, representing what the norm tells us to be obligatory in that situation. We use the standard notation $(\top, x)$ for the unconditional obligation of x, where $\top$ is a zero-place connective standing for 'tautology'.

Some further notation. $\mathcal{L}$ is the set of all formulae of classical propositional logic. Given an input $A \subseteq \mathcal{L}$, and a set of generators N, $N(A)$ denotes the image of N under A, i.e., $N(A) = \{x : (a, x) \in N \text{ for some } a \in A\}$. $Cn(A)$ denotes the set $\{x : A \vdash x\}$, where $\vdash$ is the deducibility relation used in classical propositional logic. The notation $x \dashv\vdash y$ is short for $x \vdash y$ and $y \vdash x$. We use PL as an abbreviation for (classical) propositional logic. For the sake of conciseness, we denote by $h(M)$ the set of all the heads of elements of M. Moreover, $\mathcal{B}_A^M$ denotes the set of all B such that $A \subseteq B = Cn(B) \supseteq M(B)$. Intuitively, $\mathcal{B}_A^M$ gathers all the Bs that contain A and are closed under both Cn and M.

Definition 1 (Semantics). *$x \in \mathcal{O}(N, A)$ if and only if there is some finite $M \subseteq N$ such that,*

- *$M(Cn(A)) \neq \emptyset$, and*
- *for all B, if $B \in \mathcal{B}_A^M$, then $x \dashv\vdash \wedge M(B)$.*

We call such a M an A-witness for x. $\mathcal{O}$ is a variation of the operation *out*$_3$ defined by Makinson and van der Torre (2000). We have *out*$_3(N, A) = \cap\{Cn(N(B)) : B \in \mathcal{B}_A^N\}$.

While *out*$_3$ validates DD, $\mathcal{O}$ does not, as illustrated below.

Example 1 (Deontic Detachment). *Consider the two norms $N = \{(\top, a), (a, x)\}$. We have obligation $a \in \mathcal{O}(N, \top)$, since $M = \{(\top, a)\}$ is a $\top$-witness for a. We also have $x \in \mathcal{O}(N, a)$, since $M = \{(a, x)\}$ is an a-witness for x. But we do not have $x \in \mathcal{O}(N, \top)$. To see this, it suffices to go through all the non-empty subsets of N, and check that, for each of them, the smallest relevant B does not deliver heads whose conjunction is equivalent to x:*

M	B	$M(B)$
$\{(\top, a)\}$	$Cn(a)$	$\{a\}$
$\{(a, x)\}$	$Cn(\emptyset)$	$\emptyset$
$\{(\top, a)(a, x)\}$	$Cn(a, x)$	$\{a, x\}$

We define $\mathcal{O}(N) = \{(A, x) : x \in \mathcal{O}(N, A)\}$. This definition leads to an axiomatic characterization that is much alike those used for conditional logic.

Given a set R of rules, (a, x) is said to be derivable from N if (a, x) is in the least superset of N that is closed under the rules in R. This may be written as $(a, x) \in \mathcal{D}(N)$, or equivalently $x \in \mathcal{D}(N, a)$. The specific rules of interest here are described below. They are formulated for a singleton input set A (for such an input set, curly brackets will be omitted). SI, EQ and ACT abbreviate "strengthening of the input," "equivalence" and "aggregative cumulative transitivity."

Definition 2 (Proof system). $(a, x) \in \mathcal{D}(N)$ *if and only if* (a, x) *is derivable from* N *using the rules* {*SI, EQ, ACT*}.

$$SI\ \frac{(a,x) \qquad b \vdash a}{(b,x)} \qquad EQ\ \frac{(a,x) \qquad x \dashv\vdash y}{(a,y)}$$

$$ACT\ \frac{(a,x) \qquad (a \wedge x, y)}{(a, x \wedge y)}$$

ACT yields ADD as a special case (a is $\top$).

Where A is a set of formulae, $(A, x) \in \mathcal{D}(N)$ means that $(a, x) \in \mathcal{D}(N)$, for some conjunction a of elements in A. Moreover, $\mathcal{D}(N, A)$ is $\{x : (A, x) \in \mathcal{D}(N)\}$.

Theorem 1 (Completeness). $\mathcal{O}(N, A) = \mathcal{D}(N, A)$

Below is an illustration.

Example 2 ("Change your mind!"). *Hansson (1997) gives the following example, with credit to Pörn:*

> *"Consider the hoary example of the man who ought to go to a meeting on August 5 and who ought to send, on August 2, a note explaining his absence, if and only if he is in fact going to be absent." (1997, p.425-6)*

The example is structurally identical to the Chisholm example (Chisholm 1963). The norms involved may be rendered as $N = \{(\top, m), (m, s)(\neg m, \neg s)\}$*, where* m *and* s *are for attending the meeting and sending a note, respectively. Given input* $\top$*,* $m \wedge s$ *is outputed, but not* s*. This is as it should be. The obligation of* s *will not be triggered unless the agent is going to fulfil his primary obligation of* m*. In the violation context* $\neg m$*,* $m \wedge s$ *is still outputed. If not, then the following intuitive deontic reasoning pattern would not be supported:*

> *"August 2 arrives, and though he is able to attend the meeting, he has no intention of doing so. He argues: 'I ought to change my mind, forbear note-writing, and attend the meeting. ... My present fulfillment of this obligation will help make up for my sinfully staying at home on the fifth!'." (Hansson 1997, p. 426)*

In the remainder of this paper, we consider some properties of this new logic.

Properties

Deontic properties

Exact factual detachment (EFD) and violation detection (VD) characterise what is special about *deontic* logic.

$$\text{EFD} \quad (x, y) \in N \Rightarrow y \in \mathcal{O}(N, x)$$
$$\text{VD} \quad (A, y) \Rightarrow (A \cup \{\neg y\}, y)$$

Exact factual detachment represents that if there is a norm with precisely the context as body, then the output contains the head. On the one hand, exact factual detachment is relatively weak, as the context has to be *precisely* the body. The much stronger factual detachment principle (FD) discussed in the introduction imposes detachment when the body is *implied* by the context. On the other hand, exact factual detachment principle is already quite strong, as in context a from the norm $(a, \bot)$ the contradiction $\bot$ is detached, and in case of a dilemma of (a, x) and $(a, \neg x)$, in context a both x and $\neg x$ are detached.

Violation detection says that violations are explicit. The distinctive feature of norms and obligations with respect to other types of rules and modalities is that they can be violated. For example, dilemma examples arise because some obligation has to be violated, and contrary-to-duty examples arise because some obligation has been violated. Modal logic offers a useful representation for violations. An obligation for x has been violated if and only if we have $\neg x \wedge \bigcirc x$. In our notation with explicit norms, this is $x \in \mathcal{O}(N, A)$ with $\neg x \in Cn(A)$.

Theorem 2. $\mathcal{O}$ *satisfies* EFD, FD *and* VD.

Logical properties

Substitution (SUB), replacements of logical equivalents (RLE), implication (IMP) and paraconsistency (PC) say something about *logic*.

$$\begin{array}{ll} \text{SUB} & x \in \mathcal{O}(N, A) \Rightarrow x[\sigma] \in \mathcal{O}(N[\sigma], A[\sigma]) \\ \text{RLE} & N \approx M \Rightarrow \mathcal{O}(N) \subseteq \mathcal{O}(M) \\ \text{IMP} & \mathcal{O}(N, A) \subseteq Cn(m(N) \cup A) \\ \text{PC} & x \in \overline{V}(N, A) \Rightarrow \exists M \subseteq N : x \in \mathcal{O}(M, A) \\ & \text{and } \mathcal{O}(M, A) \cup A \text{ consistent} \end{array}$$

Substitution is well known from classical propositional logic. We use the notation $x[\sigma]$ to denote a substitution instance of x. Thus, $x[\sigma]$ is obtained from x by replacing uniformly, in x, all occurrences of a propositional letter by the same propositional formula. $A[\sigma]$ and $N[\sigma]$ extend the notion of substitution instance to sets of formulae, and sets of norms in the straightforward way.

Replacement for logically equivalent expressions expresses a principle of irrelevance of syntax. For $N \approx M$, read "N is (logically) equivalent to M". The simplest way to define $\approx$ is as follows: $N \approx M$ whenever M is obtained from N, by replacing each $(b, y) \in N$ with some (c, z) such that b is equivalent with c, and y is equivalent with z.

Implication makes use of the so-called materialisation of a normative system, which means that each norm (a, x) is interpreted as a material conditional $a \rightarrow x$, i.e. as the propositional sentence $\neg a \vee x$. The implication property says that if the materializations of N, written as $m(N)$, do not imply $a \rightarrow x$, then $(a, x) \notin \mathcal{O}(N)$. This represents the idea that we cannot derive more than we can derive in propositional logic. In general, implication in the base logic is the upper bound.

To prevent explosion we do not want to derive the whole language, unless maybe in pathological cases in which the normative system contains a norm for each propositional formula. A consequence relation may be said to be paraconsistent if it is not explosive, though there are various ways to make this formal.

To define our paraconsistency property, we distinguish obligations representing violations from other obligations. That is, we decompose an operator $\mathcal{O}(N, A)$ into two operators $V(N, A)$ and $\overline{V}(N, A)$, such that

- $V(N, A) = \{x \in \mathcal{O}(N, A) \mid \neg x \in Cn(A)\}$
- $\overline{V}(N, A) = \mathcal{O}(N, A) \setminus V(N, A)$

Trivially, we have

$$\mathcal{O}(N, A) = V(N, A) \cup \overline{V}(N, A)$$

The basic idea of our paraconsistency property is that obligations in $\overline{V}$ can be derived from a set of norms M in N, such that this set of norms M does not explode.

The underlying intuition to restrict to a set of norms is raised in the following example. If we can derive $\bigcirc(y \wedge z)$ from $\bigcirc(x \wedge y)$ and $\bigcirc(\neg x \wedge z)$, and we have substitution and replacements of logical equivalents, then we also derive $\bigcirc y$ from $\bigcirc x$ and $\bigcirc \neg x$, in other words, we have deontic explosion. This can be verified by replacing y by $x \vee y$ and z by $\neg x \vee y$. Therefore, we restrict the set of norms we use to a set of norms which is in some sense "consistent" with the input A.

Theorem 3. *$\mathcal{O}$ satisfies* SUB*,* RLE*,* IMP *and* PC*.*

Norm change properties

The next two properties are: norm monotony (NM) and norm induction (NI). We call them "norm change properties", because the N is no longer held constant.

NM $\quad \mathcal{O}(N) \subseteq \mathcal{O}(N \cup M)$

NI $\quad M \subseteq \mathcal{O}(N) \Rightarrow \mathcal{O}(N) = \mathcal{O}(N \cup M)$

The most interesting property is norm induction. It says that if there is an output x for an input a, and we add the norm (a, x) to the normative system, then for all inputs, the output of the normative system stays the same. This is called "norm induction", because the norm is induced from the relation between facts and obligations.

Theorem 4. *$\mathcal{O}$ satisfies* NM *and* NI*.*

Together, exact factual detachment, norm monotony and norm induction are equivalent to saying that $\mathcal{O}$ is a closure operator.

Reusability properties

The reusability properties relate the system to standard I/O logic. Their formulation appeals to some key notions of so-called constrained input/output logic, developed by Makinson and van der Torre (2001) in order to reason about norm violation:

$conf(N, A) = \{N' \subseteq N \mid out(N', A) \cup A \text{ consistent } \}$

$maxf(N, A) = \{N' \in conf(N, A) \mid N' \subseteq \text{-maximal } \}$

$outf(N, A) = \{out(N.A) \mid N' \in maxf(N, A)\}$

The first property listed below represents inclusion in reusable output (IO). The following two properties define redundancy R and strong redundancy SR.

IO $\quad \mathcal{O}(N, A) \subseteq out_3(N, A)$

R $\quad outf_3(N, A) = outf_3(\mathcal{O}(N), A)$

SR $\quad outf_3(N \cup M, A) = outf_3(\mathcal{O}(N) \cup M, A)$

Redundancy is worth a mention, because it makes a bridge to constrained input/output logic.

Summary

This paper has introduced a 'minimal' logic for aggregative deontic detachment, with a sound and complete axiomatization. Various properties of the logic have been discussed. Summarizing, the operator $\mathcal{O}(N)$ is a closure operator, which means that it satisfies factual detachment, norm monotony and norm induction. In addition, it satisfies substitution and replacement of logical equivalents. Finally, the operator satisfies violation detection, implication, and paraconsistency.

Action Theories over Generalized Databases with Equality Constraints (Extended Abstract)

Fabio Patrizi and Stavros Vassos
Department of Computer, Control, and Management Engineering (DIAG)
Sapienza University of Rome
Rome, Italy

Abstract

In this work we study action theories of the situation calculus such that the initial KB is a generalized database with equality constraints (GFDBs). We show that GFDBs characterize the class of definitional KBs and that they are closed under progression. We also show that, under conditions, generalized projection queries can be decided based on an induced transition system and evaluation of local conditions over states.

Introduction

Situation calculus basic action theories (BATs) (Reiter 2001) consist of a first-order knowledge base (KB) which describes the initial state of a given domain, and a set of first-order axioms that specify how the properties of the domain change under the effects of actions. Two important reasoning problems are *projection*, i.e., *predicting* whether a condition would hold if a series of actions were to be performed, and *progression*, i.e., *updating* the KB by a new description that reflects the current state after actions have been performed.

For the general case it has been shown that second-order logic may be required to capture the updated KB (Lin and Reiter 1997; Vassos and Levesque 2013) and an overview of some special cases where it becomes first-order is studied in (Vassos and Patrizi 2013). Similarly, answering projection queries is in the general case undecidable and a few decidable cases have been studied, e.g., when the KB is a regular database (Reiter 2001) or the case of a modified version of the situation calculus language built using a two-variable fragment of first-order logic (Gu and Soutchanski 2007).

Notably, the case when the KB has the form of a *generalized database with constraints* (Kanellakis, Kuper, and Revesz 1995), which allows to specify relations with possibly *infinitely many tuples*, has not been investigated. In this work we show that for a special type of BATs whose KB is a generalized database with equality constraints, projection is decidable and a first-order progression can always be computed. We then look into richer forms of projection that may refer to more than one possible evolution of the initial KB, e.g., capturing properties of the form "after execution of $\alpha_1, \ldots, \alpha_n$ condition ϕ always holds in the future" and specify a condition that ensures decidability also for them.

BATs with generalized fluent databases

The situation calculus as presented by Reiter (2001) is a three-sorted first-order language with equality (and some limited second-order features). The sorts are used to distinguish between actions, situations, and objects. A *situation* represents a world history as a sequence of actions. S_0 is used to denote the initial situation where no actions have occurred. Sequences of actions are built using the function symbol *do*, such that $do(a, s)$ denotes the successor situation resulting from performing action a in situation s. A (relational) *fluent* is a predicate whose last argument is a situation, whose value can change from situation to situation. We also assume a finite number of fluent and action symbols, $\mathcal{F}$ and $\mathcal{A}$, and an infinite number of constants $\mathcal{C}$.

Reiter (2001) investigates the case where the initial knowledge base (KB) is a *definitional theory* characterized as follows: $\bigwedge_{F_i \in \mathcal{F}} \forall \vec{x}_i . F(\vec{x}_i, S_0) \equiv \phi_i(\vec{x}_i)$, where $\phi_i(\vec{x}_i)$, called the *definition* for F_i, is an unrestricted first-order formula mentioning no situations. Definitional KBs express *complete* information for fluents under the assumption of the unique-name axioms for constants captured in a set $\mathcal{E}$. For example the following axiom states that there are exactly two atoms true for $In(x_1, x_2, S_0)$, namely $In(box, it_1, S_0)$ and $In(box, it_2, S_0)$:

$$\forall x \forall y (In(x, y, S_0) \equiv (x{=}box \wedge (y{=}it_1 \vee y{=}it_2))).$$

Nonetheless, the definition for a fluent can be any unrestricted first-order formula built over the constants in $\mathcal{C}$ and equality. For instance, it could have the following form implying an infinity of ground atoms that are true in S_0:

$$\forall x \forall y (In(x, y, S_0) \equiv (x{\neq}box \wedge (y{=}it_1 \vee y{=}it_2))).$$

More complicated definitions can be formed also using quantification which is actually not adding to the expressiveness as first-order theories of equality admit quantifier elimination (Enderton and Enderton 2001).

We now present definitions from (Kanellakis, Kuper, and Revesz 1995) in the context of the situation calculus.

Definition 1. An *equality constraint* is a literal formula $x\theta y$ or $x\theta c$, where $c \in \mathcal{C}$ and θ is $=$ or $\neq$. A *generalized k-tuple* over variables $x_1, \ldots, x_k$ is a finite conjunction ψ of equality constraints whose all variables are free and among $x_1, \ldots, x_k$. A *generalized relation of arity k* is a finite set

$R = \{\psi_1, \ldots, \psi_q\}$, of generalized k-tuples over $x_1, \ldots, x_k$. The *formula corresponding to a generalized relation* R is the disjunction $\psi_1 \vee \cdots \vee \psi_q$. We will use ϕ_R to denote the quantifier-free formula corresponding to relation R.

We will be dealing with the so-called *basic action theories* of the form $\mathcal{D} = \mathcal{D}_{ap} \cup \mathcal{D}_{ss} \cup \mathcal{D}_{una} \cup \mathcal{D}_0 \cup \Sigma$, where: $\mathcal{D}_{ap}$ is a set of action precondition axioms (APs) and $\mathcal{D}_{ss}$ is a set of successor state axioms (SSAs), one per fluent symbol $F_i \in \mathcal{F}$, $\mathcal{D}_{una}$ is the set of unique-names axioms for actions, $\mathcal{D}_0$ describes the initial situation S_0, and Σ is a set of foundational axioms which formally define legal situations. We identify BATs over generalized databases as follows.

Definition 2. A set $\mathcal{D}_0$ of first-order sentences uniform in S_0 is a *generalized fluent database (GFDB)* iff it has the form $\bigwedge_{F_i \in \mathcal{F}} \forall \vec{x}_i . F(\vec{x}_i, S_0) \equiv \phi_i(\vec{x}_i)$, where $\phi_i(\vec{x}_i)$ corresponds to a generalized relation over $\vec{x}$, i.e., is a disjunction of conjunctions of equality constraints. A basic action theory $\mathcal{D}$ is a *basic action theory over a generalized fluent database (BAT-GFDB)* iff it also includes the set of unique-names axioms for constants $\mathcal{E}$, and $\mathcal{D}_0$ is a GFDB.

Theorem 1. *Let ϕ be a definitional KB. There exists a generalized fluent database ϕ' such that $\mathcal{E} \models \phi \equiv \phi'$.*

Kanellakis *et. al* (1995) show that for such KBs there is also a decidable procedure for evaluating queries. Note also that equivalence of generalized fluent databases can also be decided, formed as an appropriate query. With these tools available we now proceed to show how solutions for progression and projection can be obtained for BAT-GFDBs.

Progression of BAT-GFDBs

In order to do a one-step progression of a BAT $\mathcal{D}$ with respect to a ground action α we need to replace $\mathcal{D}_0$ in $\mathcal{D}$ by a suitable set $\mathcal{D}_\alpha$ of sentences uniform in $do(\alpha, S_0)$ so that the original theory $\mathcal{D}$ and the theory $(\mathcal{D} - \mathcal{D}_0) \cup \mathcal{D}_\alpha$ are equivalent with respect to how they describe the situation $do(\alpha, S_0)$ and the situations in the future of $do(\alpha, S_0)$.

In a seminal paper Lin and Reiter (1997) gave a model-theoretic definition for the progression $\mathcal{D}_\alpha$ of $\mathcal{D}_0$ wrt α and $\mathcal{D}$ that achieves this goal. Finding such a $\mathcal{D}_\alpha$ is a difficult task and it has been shown that second-order logic may be required in the general case (Lin and Reiter 1997; Vassos and Levesque 2013). Nonetheless, for the definitional KBs, and as a consequence also for the special case of generalized fluent databases, there is a simple way to progress. Note that an SSA, that has the form $F(\vec{x}, do(a, s)) \equiv \Phi(\vec{x}, a, s)$, characterizes the conditions under which F has a specific value at situation $do(a, s)$ as a function of situation s and action a. A progression can then be obtained by replacing fluent atoms $F(\vec{o}, S_0)$ in the right-hand side of the SSA by their definition in the KB (Reiter 2001). It is interesting to look into how this method works when $\mathcal{D}_0$ is a GFDB.

Note that since each $\Phi(\vec{x_i}, \alpha, S_0)$ in the right-hand side of SSAs is in general unrestricted, e.g., may include quantifiers, $\mathcal{D}_\alpha$ is not guaranteed to be in the form of a generalized fluent database even though $\mathcal{D}_0$ is. The point in using a form like the generalized fluent database is that it allows us to perform query evaluation using the methods and existing technologies in constraint databases instead of performing more general theorem proving. Therefore, we want progression to preserve the form of $\mathcal{D}_0$. The previous substitution method does well in preserving the form of a *definitional KB* but does not preserve the form in the case of a GFDB.

The idea then is to consider generalized tuples as the "base" formulas that we use to express any generalized fluent relation. This is similar to a regular database where we would update $\mathcal{D}_0$ into a $\mathcal{D}_\alpha$ such that for every fluent a finite list of tuples is specified. Theorem 1 then provides a way to transform, by means of quantifier elimination, the resulting $\mathcal{D}_\alpha$ of the substitution method into the form of a GFDB.

Theorem 2. *Let $\mathcal{D}$ be a BAT over a generalized fluent database and α a ground action. Then there exists a first-order progression $\mathcal{D}_\alpha$ of $\mathcal{D}_0$ wrt α and $\mathcal{D}$ that is in the form of a generalized fluent database.*

As a result, we can *iteratively* progress a BAT-GFDB and characterize the state of any ground situation as a GFDB.

Finally, since every definitional KB can be expressed as a generalized fluent database, this also illustrates a subtle detail about progression. Both a progression $\mathcal{D}_\alpha$ according to the substitution method and a progression $\mathcal{D}'_\alpha$ according to Theorem 2 qualify as logically correct progressions of $\mathcal{D}_0$ and are logically equivalent (under the assumption of $\mathcal{E}$). Nonetheless, $\mathcal{D}_0$ is more of a *logical specification of the changes* that need to be made due to action α and $\mathcal{D}'_\alpha$ more of a *materialized update* of these changes.

Another way to look at it is that the progression based on the substitution method is purely syntactic (linear to the size of $\mathcal{D}_0$) and does not involve any form of evaluation; in a sense, the fluents are not updated to a new truth value but, rather, the new truth values are still specified with respect to the initial situation. As there are to date no implemented systems for performing progression, this difference is less easy to identify because, as far as the logical specification is concerned, $\mathcal{D}_0$ is a well-behaved progression. In practice, though, we would expect that unless a method that goes along the lines of Theorem 2 is followed, the progressed theory would in fact look much similar to the original theory $\mathcal{D}$, and queries over the current state would perform similar to using a *regression* technique over the original theory $\mathcal{D}$.

Projection over BAT-GFDBs

The *(simple) projection problem* is the task of *predicting* whether a condition holds at a particular time in the future after a series of ground actions have been executed (Reiter 2001). The following is a straightforward result.

Theorem 3. *Let $\mathcal{D}$ be a BAT-GFDB, $\alpha_1, \ldots, \alpha_n$ a sequence of ground actions, and $\phi(s)$ a first-order formula uniform in s. Then determining whether or not the following holds is decidable: $\mathcal{D} \models \phi(do(\alpha_n, \cdots do(\alpha_1, S_0)))$.*

This is not a new result and can be proven by means of regression and the fact that $\mathcal{E}$ is decidable. Our previous analysis also shows that simple projection queries over a BAT-GFDB can be decided by iteratively progressing $\mathcal{D}_0$ wrt $\alpha_1, \ldots, \alpha_n$ according to Th. 2 and then evaluating the query over the resulting generalized fluent database following the

method of (Kanellakis, Kuper, and Revesz 1995). Depending on the type of queries, and the frequency that actions occur, either approach may be preferred under conditions.

We now proceed to show a major result about the decidability of richer projection queries over BAT-GFDBs that may also quantify over future situations. A *generalized* version of the projection problem is when ϕ may refer to any number or combination of future situations. For example, $\forall s(do(\alpha, S_0) \sqsubseteq s \supset \psi(s))$ states that after executing action α condition $\psi(s)$ will hold in all situations s in the future, i.e., that it will always remain true.

We consider the language $\mathcal{L}_p$ of *generalized projection queries* φ. $\mathcal{L}_p$ is defined on top of the language $\mathcal{L}_n$, whose formulas ϕ are as follows: $\phi := x = c \mid x = y \mid F(\vec{x}, s) \mid F(\vec{x}, \sigma) \mid \neg\phi \mid \phi \wedge \phi \mid \exists x.\phi$, for F a fluent symbol, c a constant, and σ a ground situation term. $\mathcal{L}_p$ formulas are defined as: $\varphi := \phi \mid \neg\varphi \mid \varphi \wedge \varphi \mid \exists s.\sigma \sqsubseteq s \wedge \varphi$, where $\phi \in \mathcal{L}_n$ is any formula uniform in s or in a ground situation term σ, whose free variables (if any) are only of sort situation.

We also consider a class of BAT-GFDBs which we call C-bounded. To define it, let T_V be the (finite) set of all generalized tuples ψ that use equality constraints with (only variable) symbols from the finite set of variables V, and s.t. ψ does not contain multiple occurrences of some equality constraint. Notice that since generalized tuples are conjunctions (thus multiple occurrences of a conjunct do not change their semantics), T_V essentially contains all the possible generalized tuples one can build using symbols from V.

Definition 3. Let $\mathcal{D}$ be a BAT-GFDB and B a natural number. A ground situation term σ is said to be *constant-bounded by B in $\mathcal{D}$*, C-bounded by B for short, iff for every fluent $F_i(\vec{x}, s) \in \mathcal{F}$, it is the case that $\mathcal{D} \models \bigvee_{\Psi \in 2^{T_V}} \exists \vec{y}.F(\vec{x}, \sigma) \equiv \bigvee_{\psi \in \Psi} \psi$, where: V is partitioned into X and Y, with X the set of variables occurring in $\vec{x}$, Y any set of variable symbols such that $|Y| = B$, and $\vec{y}$ are the free variables of ψ coming from Y. $\mathcal{D}$ is said to be *constant-bounded by a finite bound B*, C-bounded by B for short, iff every ground situation term of $\mathcal{D}$ that is executable is also C-bounded by B.

Notice that Ψ above is a set of generalized tuples, thus the formula $\bigvee_{\psi \in \Psi} \psi$ is a generalized relation. Intuitively, Def. 3 requires that the definition of each fluent in σ is a generalized relation mentioning at most B distinct constants.

For this class of theories, we have the following result.

Theorem 4. *Given a BAT-GFDB $\mathcal{D}$ that is C-bounded by some B, and a generalized projection query φ that is a sentence in $\mathcal{L}_p$, it is decidable to check whether $\mathcal{D} \models \varphi$.*

The proof starts by introducing the notion of *transition system over generalized fluent databases (GFDB-TS)*. These are transition systems with states labelled by generalized fluent databases and transitions labelled by ground actions. The aim of GFDB-TSs is to capture the information, represented as GFDBs, about both the states associated with the executable situations of an action theory, and their transitions, together with the respective actions. In particular the GFDB-TS $T_{\mathcal{D}}$ *induced* by an action theory $\mathcal{D}$ can be defined, which accounts for the evolution of the states of the theory starting from S_0.

Then, a definition of satisfaction of $\mathcal{L}_p$ sentences wrt GFDB-TSs is provided, and it is proven that, for any generalized projection query φ, $\mathcal{D} \models \varphi$ iff $T_{\mathcal{D}} \models \varphi$. Thus, one can check whether $\mathcal{D} \models \varphi$ by using the induced GFDB-TS $T_{\mathcal{D}}$ instead of the theory $\mathcal{D}$. However, this does not guarantee decidability, as $T_{\mathcal{D}}$ is infinite-state, in general.

The final step of the proof consists in defining a procedure to build a finite-state GFDB-TS $\hat{T}_{\mathcal{D}}$ such that, for any sentence $\varphi \in \mathcal{L}_p$, $T_{\mathcal{D}} \models \varphi$ iff $\hat{T}_{\mathcal{D}} \models \varphi$. The construction exploits the key observations that if $\mathcal{D}$ is C-bounded then: *(i)* it is first-order progressable; and *(ii)* its states can be partitioned into finitely many equivalence classes of logically equivalent GFDBs. Essentially, the procedure amounts to iteratively progressing $\mathcal{D}$ from S_0, by executing all possible ground actions obtained using a finite subset $H \subseteq \mathcal{C}$ of constants, until a state whose label is logically equivalent to that of some state visited in the past is generated. Once $\hat{T}_{\mathcal{D}}$ is available, checking whether $\hat{T}_{\mathcal{D}} \models \varphi$ can be done by applying a straightforward recursive procedure.

Conclusions

In this paper we looked into situation calculus action theories over generalized fluent databases with equality constraints (GFDB), connecting the situation calculus with constraint query languages. We showed that GFDBs characterize the class of definitional KBs with fluent predicates only, and that for action theories over such KBs (BAT-GFDBs), the KBs are *closed under progression*. Our results show that simple projection queries over BAT-GFDBs are decidable in general. Also, extending the notion of *boundedness* proposed in (De Giacomo, Lespérance, and Patrizi 2012), we introduced the notion of *C-boundedness* and showed that, under this, a wide class of generalized projection queries that include quantification over situations is decidable.

Abstract

The tendency to accept or reject arguments based on own beliefs or prior knowledge rather than on the reasoning process is called the belief-bias effect. A psychological syllogistic reasoning task shows this phenomenon, wherein participants were asked whether they accept or reject a given syllogism. We discuss one case which is commonly assumed to be believable but not logically valid. By introducing abnormalities, abduction and background knowledge, we model this case under the weak completion semantics. Our formalization reveals new questions about observations and their explanations which might include some relevant prior abductive contextual information concerning some side-effect. Inspection points, introduced by Pereira and Pinto, allow us to express these definitions syntactically and intertwine them into an operational semantics.

Keywords: Abductive Reasoning; Side-effects; Inspection Points; Human Reasoning; Belief-Bias Effect

1 Introduction

Whenever discovering abductive explanations for some given primary observation, one may wish to check too whether some other given additional secondary observations are logical consequences of the abductive explanations found for the primary observation. The primary explanations may be used to explain the secondary observations, whereas the secondary explanations cannot be used to explain the primary observations. We show this type of reasoning requires the characterization of a new abduction concept and mechanism, that of *contextual abduction*. We formalize contextual abduction and employ it to understand and justify the belief-bias effect in human reasoning by addressing syllogisms.

Evans, Barston, and Pollard (1983) made a psychological study showing possibly conflicting processes in human reasoning. Participants were presented syllogisms and had to decide whether they were logically valid. Consider S_{add}:

PREMISE1 *No addictive things are inexpensive (not costly).*
PREMISE2 *Some cigarettes are inexpensive (not costly).*
CONCLUSION *Therefore, some addictive things are not cigarettes.*

Although the conclusion does not necessarily follow from the premises, participants assumed the syllogism to be logically valid. Evans, Barston, and Pollard (1983) concluded that they have been unduly influenced by their own beliefs. In the following, we explain the belief-bias effect by abductive reasoning and its side-effects.

2 Preliminaries

We restrict ourselves to datalog (first-order) programs, ie. the set of terms consists only of constants and variables. A logic program $\mathcal{P}$ is a finite set of clauses of the form

$$A \leftarrow A_1 \wedge \ldots \wedge A_n \wedge \overline{B_1} \wedge \ldots \wedge \overline{B_m},$$

where A and A_i, $1 \leq i \leq n$, are atoms and $\overline{B_j}$, $1 \leq j \leq m$, are negated atoms. A is the head and $A_1 \wedge \ldots \wedge A_n \wedge \overline{B_1} \wedge \ldots \wedge \overline{B_m}$ is the body of the clause. We abbreviate the body of a clause by $body$. $A \leftarrow \top$ and $A \leftarrow \bot$ are special cases of clauses denoting positive and negative facts, respectively. If an argument is written with an upper case letter, it is a variable; otherwise it is a constant. In the sequel, we assume $\mathcal{P}$ to be ground, containing all the ground instances of its clauses. The set of all atoms occurring in $\mathcal{P}$ is $\mathsf{atoms}(\mathcal{P})$. An atom is undefined in $\mathcal{P}$ if it is not the head of some clause in $\mathcal{P}$ and the corresponding set of these atoms is $\mathsf{udef}(\mathcal{P})$.

2.1 Three-Valued Łukasiewicz Semantics

Table 1 shows the three-valued Łukasiewicz (1920) semantics. Interpretations are represented by pairs $\langle I^\top, I^\bot \rangle$, where

$$I^\top = \{A \in B_\mathcal{P} \mid A \text{ is mapped to } \top\},$$
$$I^\bot = \{A \in B_\mathcal{P} \mid A \text{ is mapped to } \bot\}.$$

$\mathcal{B}_\mathcal{P}$ is the Herbrand base wrt $\mathcal{P}$. A model of $\mathcal{P}$ is an interpretation which maps each clause occurring in $\mathcal{P}$ to $\top$.

2.2 Weak Completion Semantics

Weak completion semantics (Hölldobler and Kencana Ramli 2009a) seems to adequately model Byrne's (1989) suppression task (Dietz, Hölldobler, and Ragni 2012) and Wason's (1968) selection task (Dietz, Hölldobler, and Ragni 2013). Consider the following transformation for $\mathcal{P}$:

1. Replace all clauses with the same head $A \leftarrow body_1, \ldots, A \leftarrow body_n$ by $A \leftarrow body_1 \vee \ldots \vee body_n$.
2. For all atoms A, if $A \in \mathsf{udef}(\mathcal{P})$ then add $A \leftarrow \bot$.
3. Replace all occurrences of $\leftarrow$ by $\leftrightarrow$.

$\leftrightarrow_{Ł}$	$\top$	U	$\bot$
$\top$	$\top$	U	$\bot$
U	U	$\top$	U
$\bot$	$\bot$	U	$\top$

Table 1: $\top$, $\bot$, and U denote *true*, *false*, and *unknown*, respectively.

The resulting set of equivalences is called the *completion* of $\mathcal{P}$ (Clark 1978). If Step 2 is omitted, then the resulting set is called the *weak completion* of $\mathcal{P}$ ($\mathsf{wc}\,\mathcal{P}$).

Hölldobler and Kencana Ramli (2009b) showed that each weakly completed program admits a least model. Stenning and van Lambalgen (2008) devised an operator which has been generalized for first-order programs by Hölldobler and Kencana Ramli (2009a): Let I be an interpretation in $\Phi_{\mathcal{P}}(I) = \langle J^{\top}, J^{\bot}\rangle$, where
$J^{\top} = \{A \mid$ there exists $A \leftarrow body \in \mathcal{P}$ with $I(body) = \top\}$,
$J^{\bot} = \{A \mid$ there exists $A \leftarrow body \in \mathcal{P}$ and
for all $A \leftarrow body \in \mathcal{P}$ we find $I(body) = \bot\}$.
As shown by Hölldobler and Kencana Ramli, the least fixed point of $\Phi_{\mathcal{P}}$ is identical to the least model of the weak completion of $\mathcal{P}$ ($\mathsf{lm}_{Ł}\mathsf{wc}\,\mathcal{P}$). Starting with the empty interpretation $I = \langle \emptyset, \emptyset\rangle$, $\mathsf{lm}_{Ł}\mathsf{wc}\,\mathcal{P}$ can be computed by iterating $\Phi_{\mathcal{P}}$.[1]

3 Reasoning in an Appropriate Logical Form

We follow the approach of Stenning and van Lambalgen (2005; 2008), who proposed to model human reasoning by a two step process: Firstly, human reasoning is to be modeled by setting up an *appropriate representation* and, secondly, *reasoning* wrt this representation.

3.1 Integrity Constraints

One should observe that the first premise *no addictive things are inexpensive* is equivalent to *if something is inexpensive, then it is not addictive*. As weak completion semantics does not allow negative heads in clauses, for every negative conclusion $\overline{p(X)}$ we need to introduce an auxiliary formula $p'(X)$ together with the clause $p(X) \leftarrow \overline{p'(X)}$. We obtain a (preliminary) representation of the first premise of S_{add}:

$$\begin{aligned} add'(X) &\leftarrow inex(X), \\ add(X) &\leftarrow \overline{add'(X)}, \end{aligned}$$

where $add(X)$, $add'(X)$, and $inex(X)$ denote that X is addictive, not addictive, and inexpensive, respectively.

With the introduction of these auxiliary atoms, the need for integrity constraints arises. An interpretation which maps both, $add(a)$ and $add'(a)$, to true for some constant a should not be a model. This can be represented by a specific type of *integrity constraint* (IC), a logical formula of the form $\bot \leftarrow IC\_body$, where IC_body is a conjunction of atoms. For our running example we obtain the integrity constraint:

$$\bot \leftarrow add(X) \wedge add(X)'.$$

However, the Φ operator does not consider clauses of this form. We need to apply a two step approach: firstly, compute the least model and secondly, verify whether it respects the IC, where an interpretation I respects IC iff for each $\bot \leftarrow IC\_body$ in IC, we find that $I(IC\_body) \in \{\bot, \mathsf{U}\}$.[2]

For the following examples, whenever there is a $p(X)$ and its $p(X)'$ counterpart, we implicitly assume its corresponding integrity constraint, IC_p: $\bot \leftarrow p(X) \wedge p(X)'$.

3.2 Abnormalities

Stenning and van Lambalgen proposed the idea to implement conditionals by default licenses for implications. This can be achieved by adding an *abnormality predicate* to the antecedent of the implication and initially assuming that the abnormality predicate is false. Following this idea, the initial program representing PREMISE1 in S_{add} is extended to:

If something is inexpensive and not abnormal,
then it is not addictive.
Nothing (by default) is abnormal (regarding PREMISE1*).*

3.3 Background Knowledge and Belief-Bias

A direct first-order representation of PREMISE2 is

There exists a cigarette which is inexpensive. (1)

which includes two pieces of information. Firstly, a more specific one, namely that there exists something, say a, which is a cigarette. Secondly, as Evans et al. have discussed, it contains background knowledge or belief that humans seem to have, which, in this context, we assume to be

Cigarettes are inexpensive (2)

compared to other addictive things, which implies (1) and biases the reasoning towards a representation. This belief bias together with the idea to represent conditionals by default licenses for implication leads to

If something is a cigarette and not abnormal,
then it is inexpensive.
Nothing (by default) is abnormal (regarding PREMISE2*).*

Additionally, we have a second piece of background knowledge, viz. it is commonly known that

Cigarettes are addictive. (3)

This belief together with (2), leads to

If something is a cigarette,
then it is abnormal (regarding PREMISE1*).*

The information contained in the two premises of S_{add} is encoded as the program $\mathcal{P}_{add}$ as follows:

$$\begin{aligned} cig(a) &\leftarrow \top, \\ add'(X) &\leftarrow inex(X) \wedge \overline{ab_1(X)}, \\ add(X) &\leftarrow \overline{add'(X)}, \\ ab_1(X) &\leftarrow \bot, \\ ab_1(X) &\leftarrow cig(X), \\ inex(X) &\leftarrow cig(X) \wedge \overline{ab_2(X)}, \\ ab_2(X) &\leftarrow \bot. \end{aligned}$$

[1] Dietz, Hölldobler, and Wernhard (2014) showed that the weak completion semantics corresponds to the well-founded semantics (Van Gelder, Ross, and Schlipf 1991) for tight logic programs.

[2] This corresponds to the definition applied for the well-founded semantics in (Pereira, Aparício, and Alferes 1991).

Finally, we impose $IC_{add} : \bot \leftarrow add(X) \wedge add'(X)$.

4 Abductive Framework

Following Kakas, Kowalski, and Toni (1993) we consider an *abductive framework* consisting of a program $\mathcal{P}$ as knowledge base, a collection of atoms $\mathcal{A}$ of abducibles syntactically represented by the set of the (positive and negative) facts for each undefined ground atom in $\mathcal{P}$, a set of integrity constraints IC, and the logical consequence relation $\models_{Ł}^{lmwc}$, where $\mathcal{P} \models_{Ł}^{lmwc} F$ if and only if $\mathsf{lm}_{Ł}\mathsf{wc}\,\mathcal{P}(F) = \top$ for a formula F. An *observation* is a non-empty set of literals. An explanation $\mathcal{E}$ is a consistent subset of $\mathcal{A}$.

Definition 1 *Let* $\langle \mathcal{P}, \mathcal{A}, IC, \models_{Ł}^{lmwc} \rangle$ be an abductive framework, $\mathcal{O}$ an observation, $\mathcal{E}$ an explanation, IC a set of integrity constraints, and $\models_{Ł}^{lmwc}$ the consequence relation defined for all formulas F.

- $\mathcal{O}$ is **explained by** $\mathcal{E}$ **given** $\mathcal{P}$ **and** IC iff $\mathcal{P} \cup \mathcal{E} \models_{Ł}^{lmwc} O$, where $\mathcal{P} \not\models_{Ł}^{lmwc} \mathcal{O}$ and $\mathsf{lm}_{Ł}\mathsf{wc}\,(\mathcal{P} \cup \mathcal{E})$ respects IC.
- $\mathcal{O}$ is **explained given** $\mathcal{P}$ **and** IC iff there exists an $\mathcal{E}$ such that $\mathcal{O}$ is explained by $\mathcal{E}$ given $\mathcal{P}$ and IC.

We distinguish between two forms of reasoning:

- F **follows skeptically from** $\mathcal{P}$**,** IC **and** $\mathcal{O}$ iff $\mathcal{O}$ can be explained given $\mathcal{P}$ and IC, and for all minimal (or otherwise preferred) explanations $\mathcal{E}$ we find that $\mathcal{P} \cup \mathcal{E} \models_{Ł}^{lmwc} \mathcal{O}$.
- F **follows credulously from** $\mathcal{P}$**,** IC **and** $\mathcal{O}$ iff there exists a minimal (or otherwise preferred) explanation $\mathcal{E}$ such that $\mathcal{P} \cup \mathcal{E} \models_{Ł}^{lmwc} \mathcal{O}$.

An important extension of abduction pertains to the issue that, whenever discovering explanations for some given primary observation, one may wish to check too whether some other given additional secondary observations are true, being a logical consequence of the abductive explanations found for the primary observation.[3]

5 Contextual Abductive Explanations

Let's consider again $\mathcal{P}_{add}$, where its weak completion consists of the equivalences:

$$\begin{array}{lcl} cig(a) & \leftrightarrow & \top, \\ add'(a) & \leftrightarrow & inex(a) \wedge \overline{ab_1(a)}, \\ add(a) & \leftrightarrow & \overline{add'(a)}, \\ ab_1(a) & \leftrightarrow & cig(a), \\ inex(a) & \leftrightarrow & cig(a) \wedge \overline{ab_2(a)}, \\ ab_2(a) & \leftrightarrow & \bot. \end{array}$$

Its least model, $\mathsf{lm}_{Ł}\mathsf{wc}\,\mathcal{P}_{add}$, is

$\langle \{cig(a), inex(a), add(a), ab_1(a)\}, \{add'(a), ab_2(a)\}\rangle$,

from which we cannot derive the CONCLUSION in S_{add}. Obviously, the CONCLUSION is something about an object which is not a. The first part of this conclusion is an observation, let's say about b: $\mathcal{O}_{add(b)} = \{add(b)\}$, which we need to explain as described in Section 4. The set of abducibles is: $\mathcal{A}_{(\mathcal{P}_{add} \cup \mathcal{O}_{add(b)})} = \{cig(b) \leftarrow \top, cig(b) \leftarrow \bot\}$.

We have the following minimal explanations for $\mathcal{O}_{add(b)}$:

$\mathcal{E}_{\overline{cig(b)}} = \{cig(b) \leftarrow \bot\}$ and $\mathcal{E}_{cig(b)} = \{cig(b) \leftarrow \top\}$.

[3] Reuse of contextual abductions, by resorting to an implementation of tabled abduction for well-founded semantics, is reported in (Saptawijaya and Pereira 2013).

The corresponding least models of the weak completion are:

$\mathsf{lm}_{Ł}\mathsf{wc}\,(\mathcal{P}_{add} \cup \mathcal{E}_{\overline{cig(b)}}) = \langle \{add(b)\}, \{cig(b), inex(b), ...\}\rangle$,

$\mathsf{lm}_{Ł}\mathsf{wc}\,(\mathcal{P}_{add} \cup \mathcal{E}_{cig(b)}) = \langle \{add(b), cig(b), inex(b), ...\}, ...\rangle$.

Under credulous reasoning we conclude, given explanation $\mathcal{E}_{\overline{cig(b)}}$ that the CONCLUSION of S_{add} is true, as there exists something addictive which is not a cigarette.

However, $\mathcal{O}_{add(b)}$ can also be explained by $\mathcal{E}_{cig(b)}$. We would prefer to reflect that the first explanation describes the usual case and the second describes the exceptional one.

6 Inspection Points

In the example we can easily identify from the context what is the exceptional case. But this is not stated in our program yet. For this purpose we apply inspection points, originally presented in (Pereira and Pinto 2011). We now discuss this approach and show how inspection points can be modeled in our example, concerning its abducibles. Given an atom A, we introduce the following two reserved (meta-)predicates:

$$\mathsf{inspect}(A) \qquad \text{and} \qquad \mathsf{inspect}_{\neg}(A),$$

that are special cases of abducibles. They differ from usual abducibles in the way that they can only be abduced whenever A or $\neg A$ have been abduced somewhere else already: an abductive solution or explanation $\mathcal{E}$ is only valid when for each $\mathsf{inspect}(A)$ it contains, respectively $\mathsf{inspect}_{\neg}(A)$, it also contains a corresponding A, respectively $\neg A$.

One should observe that for a treatment of inspection points for all literals in a program and not just the abducible ones, we would simply need to adopt the program transformation technique in (Pereira and Pinto 2011), which recursively relays inspection of non-terminal literals to the base inspection of terminals.

6.1 Usual Contextual Abduction

Let us modify our previous example with inspection points. The new program, $\mathcal{P}_{add}^{insp}$, has a new ab_1-clause:

$$\begin{array}{l} (\mathcal{P}_{add} \setminus \{ab_1(X) \leftarrow cig(X)\}) \cup \\ \qquad \{ab_1(X) \leftarrow inspect(cig(X))\}. \end{array}$$

Suppose again that b is addictive, i.e. $\mathcal{O}_{add(b)} = \{add(b)\}$. As $cig(b)$ is unknown, $inspect(cig(b))$ is false, and $ab_1(b)$ is false rather than unknown that is, its falsity is obtained because nothing is known about $cig(b)$, and there exists no observation to be explained and which abduces $cig(b)$. The only minimal explanation for $\mathcal{O}_{add(b)}$ is generated by $inex(b)$ being false, achieved by $\mathsf{lm}_{Ł}\mathsf{wc}\,(\mathcal{P}_{add}^{insp} \cup \mathcal{E}_{\overline{cig(b)}})$:

$\langle \{add(b)\}, \{add'(b), cig(b), ab_1(b), inex(b), ab_2(b)\}\rangle$.

Now, even under skeptical reasoning, we conclude that there exists an addictive thing which is not a cigarette.

6.2 Contextual Side-effects

Let us extend S_{add} with the conditional:

If something is sold in the streets and there is no reason to believe it is cigarettes, then it is illegal.

Accordingly, our new program $\mathcal{P}_{ill}^{insp}$ is defined as:

$\mathcal{P}_{add}^{insp} \cup \{ill(X) \leftarrow streets(X) \wedge inspect_{\neg}(cig(X))\}$.

We only conclude that something is illegal when we have abduced somewhere else that it is not a cigarette. Note, that we can abduce $\mathcal{E}_{streets(b)} = \{streets(b) \leftarrow \top\}$ to

partly explain $\mathcal{O}_{ill(b)} = \{illegal(b)\}$. Assume additionally, we observe $\mathcal{O}_{add(b)}$ which is explained by $\mathcal{E}_{\overline{cig(b)}}$. The $\mathsf{lm}_{\text{Ł}}\mathsf{wc}\,(\mathcal{P}^{insp}_{ill} \cup \mathcal{E}_{\overline{cig(b)}} \cup \mathcal{E}_{streets(b)})$ is:

$$\langle\{add(b), streets(b), illegal(b), inspect_{\neg}(cig(b))\}, \{add'(b), cig(b), ab_1(b), inex(b), ab_2(b)\}\rangle$$

thus, $illegal(b)$ is true. We define side-effects as follows:

Definition 2 *Given a background knowledge $\mathcal{P}$ and two observations $\mathcal{O}_1$ and $\mathcal{O}_2$, both explained given $\mathcal{P}$ and IC.*

- *$\mathcal{O}_2$ is a **necessary contextual side-effect of** $\mathcal{O}_1$ **given** $\mathcal{P}$ **and** IC iff for all explanations $\mathcal{E}_1$ for $\mathcal{O}_1$, there exists some explanation $\mathcal{E}_2$ for $\mathcal{O}_2$ containing abducibles of the form $inspect(A)$, or respectively $inspect_{\neg}(A)$, and for all such abducibles for which abducible A, respectively $\neg A$, is not in $\mathcal{E}_2$, and at least one exists, then it is in $\mathcal{E}_1$.*
- *$\mathcal{O}_2$ is a **strict necessary contextual side-effect of** $\mathcal{O}_1$ **given** $\mathcal{P}$ **and** IC iff $\mathcal{O}_2$ is a necessary contextual side-effect of $\mathcal{O}_1$ given $\mathcal{P}$ and IC and all explanations $\mathcal{E}_1$ for $\mathcal{O}_1$ are also all the explanations for $\mathcal{O}_2$.*
- *$\mathcal{O}2$ is a **possible contextual side-effect of explained** $\mathcal{O}_1$ **given** $\mathcal{P}$ **and** IC iff there exists an explanation $\mathcal{E}_1$ for $\mathcal{O}_1$ and an explanation $\mathcal{E}_2$ for $\mathcal{O}_2$ containing abducibles of the form $inspect(A)$, or respectively $inspect_{\neg}(A)$, and for all such abducibles for which abducible A, respectively $\neg A$, is not in $\mathcal{E}_2$, at least one exists, then it is in $\mathcal{E}_1$.*
- *$\mathcal{O}_2$ is a **strict possible contextual side-effect of** $\mathcal{O}_1$ **given** $\mathcal{P}$ **and** IC iff $\mathcal{O}_2$ is a possible contextual side-effect of $\mathcal{O}_1$ given $\mathcal{P}$ and IC and there exists an explanation $\mathcal{E}_1$ for $\mathcal{O}_1$ such that $\mathcal{E}_1$ is also an explanation for $\mathcal{O}_2$.*

The idea behind necessary contextual side-effects, is, that every explanation $\mathcal{E}_1$ for $\mathcal{O}_1$ affords us with one *complete* explanation under which some *incomplete* explanation $\mathcal{E}_2$ for $\mathcal{O}_2$ is necessarily completed. The idea behind possible contextual side-effects, is, that there is at least one explanation $\mathcal{E}_1$ for $\mathcal{O}_1$ which affords us with one *complete* explanation under which some *incomplete* explanation $\mathcal{E}_2$ for $\mathcal{O}_2$ can be completed. Summing up, $\mathcal{O}_{add(b)}$ is a strict necessary contextual side-effect of explained $\mathcal{O}_{inex(b)}$ given $\mathcal{P}^{insp}_{add}$ and IC_{add} and $\mathcal{O}_{ill(b)}$ is a possible contextual side-effect of $\mathcal{O}_{add(b)}$ given $\mathcal{P}^{insp}_{ill}$ and IC_{add} but not vice versa.

7 Conclusion

Taking weak completion semantics as starting point, we showed with a running example the need for possible extensions in abductive reasoning. Introducing the concept of inspection points in our framework by applying reserved (meta-)predication for all abductive ground atoms, gives us the possibility to distinguish between different kinds of abducibles in a logic program. This distinction allows to straightforwardly implement the concepts of contextual side-effects. Torasso et al. (1991) do abduction with the completion semantics and do not address side-effects.

Minimal Change in AGM Revision for Non-Classical Logics

Abstract

In this paper, we address the problem of applying AGM-style belief revision to non-classical logics. We discuss the idea of minimal change in revision and show that for non-classical logics, some sort of minimality postulate has to be explicitly introduced. We also present two constructions for revision which satisfy the AGM postulates and prove the representation theorems including minimality postulates.

Introduction

Belief revision is a sub-field of knowledge representation that studies the dynamics of epistemic states. Alchourrón, Gärdenfors and Makinson (1985) set the basis of a tradition in this field which became known as the *AGM paradigm* due to the authors initials.

Following the AGM tradition, the *epistemic state* of a rational agent is represented as a set of sentences closed under a consequence operator ($K = Cn(K)$) called *belief set*. Three main operations over belief sets are studied: *expansion*, *revision* and *contraction*. The former is the simplest and is defined as $K + \alpha = Cn(K \cup \{\alpha\})$. We can extend it to deal with expansion by a set of formulas in a natural way by defining $K + A = Cn(K \cup A)$.

Contraction ($-$) is the operation used when one intends to open his mind over some proposition and *revision* ($*$) is the operation used when one intends to consistently incorporate a new piece of knowledge to his belief set. Both are typically defined via sets of rationality postulates. Furthermore, revision can be defined in terms of the two other operations using the following equation, known as the *Levi identity*:

$$K * \alpha = (K - \neg\alpha) + \alpha$$

This identitiy assumes the underlying logic to be closed under negation. However, this is not the case for many interesting logics which are used in practice. In the last decade, there was an effort to adapt the AGM paradigm to non-classical logics of interest in Artificial Intelligence, notably Description Logics (Flouris, Plexousakis, and Antoniou 2005) and Horn logics (Delgrande 2008). The use of the Levi identity in order to define constructions for revision has induced the common practice of concentrating on contraction operators and not revision. It should be noted, however, that on early AI work, the focus was on revision, and not on contraction:

> "To choose their actions, reasoning programs must be able to make assumptions and subsequently revise their beliefs when discoveries contradict these assumptions."(Doyle 1979)

The main goal of this work is to generalize AGM revision for a wide class of logics. Our first attempt in this direction, presented in (Ribeiro and Wassermann 2009; 2010), was applicable only for a certain class of logics, which does not include most Description Logics (DLs) and Horn logic.

After presenting the motivation and formal preliminaries, we investigate the role of minimality postulates for AGM revision in non-classical logics, the main result being that, for non-classical logics, AGM postulates for revision fail to guarantee even the weakest form of minimality. We argue that some minimality postulates such as relevance or core-retainment must be added to the list of rationality postulates for AGM revision in non-classical logics.

Before presenting the main results, we introduce some new postulates and argue that these are the adequate postulates for non-classical AGM belief revision.

Two general approaches for belief revision in non-classical logics that satisfy some minimality postulate are presented. They are general in the sense that they are applicable to a wide class of logics, but also in the sense that they do not take advantage of any singularity of a specific logic. We provide representation results for both approaches.

Finally, we briefly comment on related work, present some conclusions and point towards future work.

Formal Preliminaries

For the purposes of this article, a logic is a pair $\langle \mathscr{L}, Cn \rangle$ such that $\mathscr{L}$ is any enumerable set called *language* whose elements are called *sentences* and $Cn : 2^{\mathscr{L}} \rightarrow 2^{\mathscr{L}}$ is a function called *consequence operator* that is considered to be Tarskian i.e. for every $A, B \in 2^{\mathscr{L}}$ if $A \subseteq B$ then $Cn(A) \subseteq Cn(B)$ (*monotonicity*), $A \subseteq Cn(A)$ (*inclusion*) and $Cn(A) = Cn(Cn(A))$ (*idempotence*).

Throughout this paper, sentences will be denoted by lower case Greek letters (α, β etc), sets of sentences will be denoted by upper case letters (A, B etc) and the letter K will be reserved for *belief sets*.

A logic is called *supra-classical* if it contains every valid inference of Classical Propositional Logic (CPL); it is called *compact* if for every $A \cup \{\alpha\} \in 2^{\mathscr{L}}$ it follows that if $\alpha \in Cn(A)$ then there is a finite subset A_F of A such that $\alpha \in Cn(A_F)$. Most work in belief revision literature assumes the underling logic $\langle \mathscr{L}, Cn \rangle$ to satisfy certain properties: the language $\mathscr{L}$ is supposed to be closed under the standard connectives $\wedge$, $\vee$, $\rightarrow$ and $\neg$; the consequence operator is supposed to be compact, supra-classical and to satisfy the deduction theorem.[1] This set of properties are called the *AGM assumptions*.

Minimal Change in AGM Revision

In this section, we discuss AGM revision and the concept of minimal change.

In their seminal work, Alchourrón, Gärdenfors and Makinson (1985) proposed the following set of postulates for revision:

closure: $K * \alpha = Cn(K * \alpha)$.

success: $\alpha \in K * \alpha$.

inclusion: $K * \alpha \subseteq K + \alpha$

vacuity: If $K + \alpha \neq \mathscr{L}$ then $K + \alpha \subseteq K * \alpha$.

consistency: If $K * \alpha = \mathscr{L}$ then $Cn(\alpha) = \mathscr{L}$.

extensionality: If $Cn(\alpha) = Cn(\beta)$ then $K * \alpha = K * \beta$.

Examining these postulates one may notice the lack of a *minimality postulate* i.e. a postulate that states the principle of informational economy: "one should not give up beyond necessity" (Harman 1986). This principle, certainly desirable for revision, seems to be missing in the AGM paradigm.

Consider the following trivial construction for revision, where in case of inconsistency, one throws away everything but the new input:

$$K * \alpha = \begin{cases} Cn(\alpha) \textit{ if } K + \{\alpha\} = \mathscr{L} \\ K + \alpha \textit{ otherwise} \end{cases}$$

Alchourrón and Makinson (1982) have already argued that the AGM postulates for revision are not enough to prevent this trivial revision. Here, we get back to the original AGM notion of minimal change. In AGM contraction, minimality is given by the *recovery* postulate:

(recovery) $K \subseteq (K - \alpha) + \alpha$

This postulate does not say anything about the size of the resulting set, or that it should be maximal with respect to inclusion. It only states that whatever is given up in a contraction should be recoverable by expanding with the same formula. The AGM postulates for contraction (including recovery) allow for the (full) meet contraction (Alchourrón and Makinson 1982), which by using the Levi identity, yields the trivial revision.

[1] $\beta \in Cn(A \cup \{\alpha\})$ if and only if $\alpha \rightarrow \beta \in Cn(A)$.

On the context of contraction operations, Makinson and Hansson staged a significant debate on the importance of a minimality postulate. Makinson (Makinson 1987) argued that the postulate of recovery has several odd properties and should be removed from the list of AGM postulates for contraction. He proposed an alternative operation called *withdrawal* that satisfies all AGM postulates for contraction but recovery. Hansson (Hansson 1991), on the other hand, argued that withdrawal suffers from the lack of a minimality postulate. That is, giving up recovery altogether would mean to abandon the desirable principle of informational economy for contraction. Agreeing with the disadvantages of recovery, Hansson proposed to exchange it with some new postulate that stated minimality directly. Two postulates were proposed, relevance and core-retainment, and both were proved to be equivalent to recovery in classical propositional logic. In (Ribeiro et al. 2013) the authors reassembled this controversy and showed that this equivalence does not hold in general (e.g. it fails for Horn logic and most DLs). Hence, in general, minimality of change has to be guaranteed by either relevance or core-retainment, but not recovery. Actually, Flouris (2006) has shown that several logics are not *AGM-compliant*, i.e., they do not admit any contraction operation satisfying recovery together with the other AGM contraction postulates.

In the belief bases literature (Hansson 1991), one can find two postulates for minimality in revision analogous to the ones for contraction. Because of the strong analogy they have the same names as the their contraction counterpart:

(core-retainment) If $\beta \in K \setminus K * \alpha$ then there is $X \subseteq K$ such that $X + \alpha \neq \mathscr{L}$ and $X + \{\alpha, \beta\} = \mathscr{L}$.

(relevance) If $\beta \in K \setminus K * \alpha$ then there is X such that $K \cap (K * \alpha) \subseteq X \subseteq K$ and $X + \alpha \neq \mathscr{L}$, but $X + \{\alpha, \beta\} = \mathscr{L}$.

It is trivial to see that core-retainment follows from relevance, but the converse is not necessarily the case.

Although these minimality postulates can be found in the belief base literature, in AGM revision they are not mentioned. In fact, AGM revision does not state any postulate similar to any of these postulates of minimality explicitly. However, we can show that for logics satisfying the AGM assumptions, both relevance and core-retainment follow from the other AGM postulates.

Theorem 1. *If the underlying logic satisfies the AGM assumptions (i.e. be supra-classical, compact and satisfy the deduction theorem), relevance and core-retainment follow from the AGM postulates for revision.*

Corollary 2. *For logics satisfying the AGM assumptions, relevance does not prevent the trivial revision.*

Since most of the belief revision literature deals with supra-classical logics, formulating relevance explicitly does not bring anything new. However, for many non-classical logics this is not the case:

Theorem 3. *In general neither core-retainment nor relevance follow from the AGM postulates for revision.*

Following Hansson (Hansson 1991) and Harmann (Harman 1986) we argue that the principle of informational economy is desirable for a revision.

Surprisingly enough, the proof above shows that adding core-retainment to the AGM postulates blocks the trivial revision for some non-classical logics.

Besides introducing some postulate for minimality, we will introduce two postulates:

(strong inclusion) $K * \alpha \subseteq (K \cap K * \alpha) + \alpha$

(uniformity) If for all $X \subseteq K$, $X + \alpha = \mathscr{L}$ iff $X + \beta = \mathscr{L}$ then $K \cap K * \alpha = K \cap K * \beta$

The former is a stronger version of inclusion related to Harper identity and the latter is for syntactic independence. In the presence of these postulates vacuity, extensionality and inclusion became superfluous. Hence, we suggest the following set of postulates for revision in non-classical logics: *success*, *closure*, *strong inclusion*, *consistency*, *uniformity* and either *relevance* or *core-retainment*. Results from next section corroborate this choice of postulates.

Revision Constructions in Non-classical Logics

Following the AGM tradition, we will present in this section two constructions for revision. The first one is based on remainder sets, maximal subsets of the original belief set that together with the input are inconsistent. The second construction is based on the idea of kernels, minimal subsets of the original belief set that are inconsistent with the input. We will prove representation theorems for both constructions.

Partial Meet Revision

This section presents a construction for revision called *negation free partial meet revision*. It is an adaptation of partial meet revision (Alchourrón, Gärdenfors, and Makinson 1985) for logics that are not closed under negation and it was first introduced in (Ribeiro and Wassermann 2009), but with severe limitation on applicability. It will be reintroduced here together with a new, more general, representation theorem.

A *negation free remainder set* $K \downarrow \alpha$ is defined as the set of all maximal subsets of K that are consistent with the input α.[2] Formally:

Definition 4 (negation free remainder set). $X \in K \downarrow \alpha$ *iff:*

1. $X \subseteq K$
2. $X + \alpha \neq \mathscr{L}$
3. *If* $X \subset X' \subseteq K$ *then* $X' + \alpha = \mathscr{L}$

A *selection function* γ selects a non-empty subset of $K \downarrow \alpha$ if possible i.e. if $K \downarrow \alpha \neq \emptyset$. Otherwise it returns $\{K\}$.

Any selection function induces the following revision operation called *negation free partial meet revision*:

$$K *_\gamma \alpha = \bigcap \gamma(K \downarrow \alpha) + \alpha$$

For any compact logic that satisfies inconsistent explosion (i.e. that contains a formula $\bot$ such that $Cn(\bot) = \mathscr{L}$) this construction is fully characterized by a certain set of postulates.

Representation Theorem 5 (negation free partial meet revision). *For any compact logic that satisfies inconsistent explosion, $*$ is a negation free partial meet revision if and only if it satisfies* closure*,* success*,* strong inclusion*,* consistency*,* relevance *and* uniformity.

Kernel Revision

In the literature of belief base revision, we can find an alternative approach for constructing revision operation based on what is called kernels. Instead of finding the maximal subsets of the belief set that are consistent with the input, the kernel approach depends on finding the minimal subsets that are inconsistent with the input.

Formally, the *negation free kernel* $K \Downarrow \alpha$ is defined as follows:

Definition 6 (negation free kernel). $X \in K \Downarrow \alpha$ *iff:*

1. $X \subseteq K$.
2. $X + \alpha = \mathscr{L}$.
3. *If* $X' \subset X$ *then* $X' + \alpha \notin \mathscr{L}$.

Each element of $K \Downarrow \alpha$ will be called here an α*-kernel*. An *incision function* σ is a function that selects at least one element of each non-empty α-kernel. Formally it is any function such that $\sigma(K \Downarrow \alpha) \subseteq \bigcup K \Downarrow \alpha$ and if $\emptyset \neq X \in K \Downarrow \alpha$ then $X \cap \sigma(K \Downarrow \alpha) \neq \emptyset$.

Any incision function induces the construction of a revision operation:

$$K *_\sigma \alpha = (K \setminus \sigma(K \Downarrow \alpha)) + \alpha$$

In words, the incision function selects at least one element of each α-kernel in $K \Downarrow \alpha$. The elements selected by this function are removed from K and the result is expanded by α. This construction is the revision induced by σ.

One of the main differences between this and the previous representation theorem is the underlying minimality postulate. While relevance is the minimality postulate associated with negation free partial meet revision, core-retainment is the minimality postulate associated with negation free kernel revision.

Representation Theorem 7 (negation free kernel revision). *For any compact logic that satisfies inconsistent explosion, $*$ is a negation free kernel revision if and only if it satisfies* closure*,* success*,* strong inclusion*,* consistency*,* core-retainment *and* uniformity.

Related Work

There have been several proposals in the literature to adapt the AGM framework to non-classical logics, almost all of them dealing with very specific logics. Most of the recent work was concentrated around DLs and Horn Logics.

[2] This was called an *inconsistency-based remainder set* in (Delgrande 2008).

Delgrande and Peppas (2011) have proposed a construction for model-based revision of Horn theories and proved that it can be characterized by the eight AGM postulates (they include the supplementary postulates) together with an extra postulate for acyclicity of derivations, needed in the Horn case. It is interesting to note that they do not propose any minimality postulate. Zhuang, Pagnucco and Zhang (2013) show that they can obtain a revision characterized by the same postulates using a variation of the Levi identity and an operation for contraction of Horn theories. Their construction uses the idea of Horn strengthening and is thus specific for Horn Logics.

Qi, Liu and Bell (2006) have worked on revision operators for DLs based on the idea of weakening axioms to avoid inconsistencies. Again, this is a very specific method, tailored for specific logics. Qi et al. (2008) have proposed a kernel construction for revision in DLs, but they work with bases and not theories. Their operation satisfies a variant of core-retainment. There is, however, no proof that the postulates fully characterize the operation. More recently, Wang, Wang, and Topor (2010) have also proposed constructions for revision which satisfy most of the AGM postulates, but they focus on a very restricted logic of the DL-Lite family.

Conclusion

Traditional constructions for revision are based on contraction and the Levi identity. These constructions are not useful for logics that are not closed under negation. In this paper, we have shown two alternative constructions that do not depend on negation: negation free kernel revision (NFK) and negation free partial meet revision (NFPM).

Each of these constructions is associated to a certain minimality postulate: core-retainment and relevance respectively. For classical logics, both postulates follow from the other AGM revision postulates and, hence, are typically omitted. In general, however, they must be explicitly introduced.

Besides the postulates for minimality, we introduced two other postulates: uniformity (for syntactic independence) and a stronger version of inclusion.

NFPM revision had been already considered in a previous paper, but the representation theorem for NFPM proved in (Ribeiro and Wassermann 2009) depended on the logic being distributive. The version of the representation theorem for NFPM in this paper, on the other hand, is applicable to a wide class of logics, namely, any compact logic that satisfies inconsistent explosion. This is a much wider class of logics that includes, for example, Horn Logic and most DLs.

Besides fixing the representation theorem for NFPM, a construction based on kernel revision (NFK revision) was presented and the representation theorem was proved for the same class of logics.

Differently from related work, our approach solves the revision problem in non-classical logic from a general perspective. Our constructions and characterizations are applicable to a wide class of logics and do not rely on particularities of any specific one.

Future work includes a deeper study of the relation between contraction and revision in non-classical logics, as well as applying our results to Horn and DLs and comparing them with the specific proposals found in the literature for these logics.

Predicting Performance of OWL Reasoners: Locally or Globally?

Viachaslau Sazonau and **Uli Sattler** and **Gavin Brown**

{*sazonauv, sattler, gbrown*}*@cs.manchester.ac.uk*

Abstract

We propose a novel approach for performance prediction of OWL reasoners that selects suitable, small ontology subsets, and then extrapolates reasoner's performance on them to the whole ontology. We investigate intercorrelation of ontology features using PCA and discuss various error measures for performance prediction.

Introduction

An ontology is a machine-processable representation of knowledge about a domain of interest. Ontologies are encoded in knowledge representation languages which are formally based on logic. A common ontology language is the Web Ontology Language (Horrocks, Patel-Schneider, and Van Harmelen 2003), OWL. We consider only OWL ontologies. Since an ontology is essentially a set of logical formulae, one can reason over it. As a result, one can derive inferences, or entailments, encoding implicit knowledge. Tools that implement reasoning services are called *reasoners*. A standard service invoked by ontology engineers is *ontology classification*, i.e. the computation of an inferred class hierarchy.[1] We focus on ontology classification.

Although there exist many reasoners, there is no single reasoner that performs best on all given inputs. The same ontology may take just several seconds to reason over for some reasoners and require hours to process for others (Gonçalves, Parsia, and Sattler 2012). Recent results of the competition between 14 reasoners taking place at the OWL Reasoner Evaluation Workshop, ORE 2013,[2] show that there is no single winner in all ontology categories. The huge difference in performance of reasoners on a given input often surprises ontology designers.

During ontology design and maintenance, reasoning performance may vary significantly and in surprising ways: axiom additions or removals may cause a significant increase or decrease of classification time, often in contrast to intuitive expectations (Gonçalves, Parsia, and Sattler 2012). Recent studies of performance variability suggest that there are ontologies which are *performance homogeneous* and others are *performance heterogeneous* for a reasoner (Gonçalves, Parsia, and Sattler 2012). An ontology $\mathcal{O}$ is performance heterogeneous if classification time of $\mathcal{O}' \subset \mathcal{O}$ is not linearly correlated with its relative size. The latter suggests that interaction effects come into play when certain axioms are part of the ontology and, consequently, loose their impact on reasoner's performance when those axioms are removed.

These observations make performance prediction of a reasoner on a given input challenging and often impossible even for experienced and skilled ontology engineers. However, the ability to predict performance is attractive. Firstly, reasoner developers equipped with a predictor would be able to find out which ontologies are harder for a reasoner. This can speed up tests of reasoners and facilitate new optimizations. Secondly, an estimate of classification time might allow an ontology engineer to decide whether the reasoning task is worth waiting for or not. As a practical example, the progress bar of an ontology editor, such as Protégé 4,[3] could be made more reliable with a good performance predictor. It could also supply auto-picking the fastest reasoner for a given ontology from the list of available reasoners.

The contributions of this work are three-fold. Firstly, we suggest an approach to analyse intercorrelation of ontology features using PCA, given a corpus of ontologies, and observe that ontology features are highly intercorrelated so that 57 features can be "faithfully" replaced by one or two features. Secondly, we introduce a new method for performance prediction which is competitive with existing performance predictors. Thirdly, we discuss different prediction accuracy measures. All details can be found in the technical report (Sazonau, Sattler, and Brown 2013).

Feature Analysis

There exist recent attempts to apply supervised machine learning to performance prediction of a reasoner on a given ontology. In (Kang, Li, and Krishnaswamy 2012), the authors define 27 ontology features, or *metrics*, of 4 types: ontology level (*ONT*), class hierarchy level (*CH*), anonymous class expressions (*ANE*) and properties (*PRO*). A feature vector $\mathbf{x}_i$ is extracted from each ontology $\mathcal{O}_i$, $i = 1, ..., N$ in the corpus. It is assigned a label $y_i = b(\mathcal{O}_i, \mathcal{R})$, $i =$

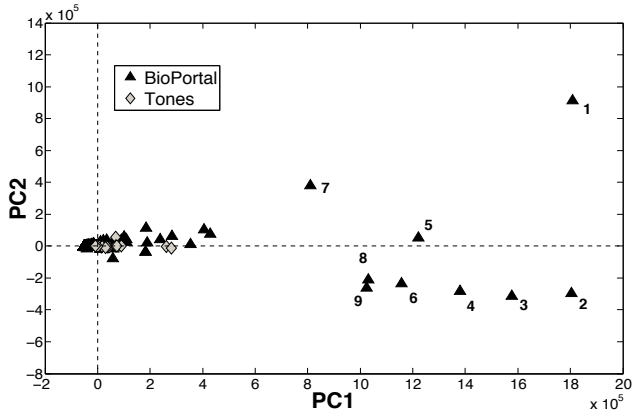

Figure 1: Comparing BioPortal and Tones using PCA

$1 \dots N$, which is the performance bin of $\mathcal{O}_i$ given a reasoner $\mathcal{R}$. Kang et al. attempt to predict the performance bin $\hat{y} = \hat{b}(\mathcal{O}, \mathcal{R})$ for an ontology $\mathcal{O}$ based on its feature vector $\mathbf{x}$, or "profile".[4] To do so, they train a model using feature vectors $\mathbf{X}$ of *all training ontologies* in the corpus with their *labels* $\mathbf{y} = (y_1, y_2, ..., y_N)$ per reasoner, i.e. the "global" corpus view $[\mathbf{X} \mid \mathbf{y}^T]$. We call such a technique a *global approach*. For basics of predicting algorithm runtime, we refer the interested reader to a survey of machine learning methods for three NP-complete problems (Hutter et al. 2014).

As we will see, it is considerably hard or even impossible to define the "ideal" set of ontology features for performance prediction of reasoners. Nonetheless, we need to take features of different scales into account, e.g. EOG and SOV,[5] used by Kang et al. Competing approaches exist in machine learning to address this problem (Tuv, Borisov, and Torkkola 2006). Another problem that should be noticed is that a corpus of ontologies should be selected carefully. A corpus, significantly biased towards easy ontologies, may cause misleading generalizations. Although dealing with such bias is generally difficult due to the lack of hard ontologies, we need to take this into account.

We skip some features from Kang et al. and add our own features. The inferred SubClass relationships are not included because this requires classification and, thus, makes little sense for performance prediction. Overall, we consider $d = 57$ ontology features including 33 new features. Intuitively, more features should allow us to capture more information about the object. However, a smaller set of features can produce a more accurate model in practice (Guyon and Elisseeff 2003). It can be achieved either by eliminating weakly useful features from the original set, hence, *selecting* features, or by transforming the features into a lower dimensional space minimizing information loss, known as *constructing* features (Guyon and Elisseeff 2003). A common feature construction method is *Principal Component Analysis*, PCA (Jolliffe 2002). In a nutshell, PCA helps to identify the presence of *intercorrelation* of features and provides a new, smaller set of uncorrelated features.

We have chosen the NCBO BioPortal[6] as an ontology corpus for experiments since it is a natural set of ontologies primarily maintained by biomedical domain experts. We exclude empty ontologies, duplicates, multiple versions of the same ontology, and ontologies with loading errors. As a result, we obtain the BioPortal corpus of 357 ontologies of various sizes. We also examine an additional corpus, the Tones Ontology Repository.[7] We filter it out via exactly the same procedure. As a result, we obtain the Tones corpus of 196 ontologies.

Given a data set $[\mathbf{X} \mid \mathbf{y}^T]$, PCA deals only with a set of feature vectors $\mathbf{X}$ and *ignores* labels $\mathbf{y}$. It produces a set of PCs, PC_j, with respective variances, λ_j. We apply PCA to BioPortal and obtain a set of PCs, PC_j^B. To check our findings, we also apply PCA to Tones, which induces another set of PCs, PC_j^T, and compare the results. We use PC_j^X to denote both PC_j^B and PC_j^T. As a result, we found out that the first 3 out of 57 components explain ≈99% of all variance for both data sets. Hence, we can hypothesize that the original 57 features are *highly intercorrelated*. Another important thing to notice is that PC_1^B explains $\approx 87\%$ and PC_1^T explains $\approx 96\%$ of total variance for BioPortal and Tones, respectively.

An additional advantage of PCA is that it allows us to visualise a data set in a lower dimensional space. Since just few components have significant variances, we can reasonably visualise the corpora in two dimensional space (PC_1^X, PC_2^X) and explore their spread in the projection space. This way, we preserve $\approx 94\%$ of total variance for BioPortal and $\approx 98\%$ of total variance for Tones. As Figure 1 shows, ontologies of both corpora are mainly spread along the first coordinate with smaller deviations along the second coordinate and even smaller along others.

BioPortal has more outliers, i.e. ontologies which differ from the main cluster of similar ontologies. There are 9 evident outliers out of 357 ontologies. They include 9 out of 10 biggest ontologies in the corpus. In addition, these outliers are amongst the computationally hardest ontologies for all three reasoners. None of them are the heterogeneous ontologies from (Gonçalves, Parsia, and Sattler 2012). It is important to note that the outliers have been identified *without any performance measurements*.

It is worth noticing that the same 6 original features are the only ones that contribute significantly to PC_1^X for both corpora. Moreover, these features have similar contribution coefficients for both corpora. This implies that PC_1^B is *approximately equal* to PC_1^T. Exploring feature vectors, we observe that these features significantly correlate with ontology size.[8] Hence, one can be interested how PC_1^X is affected by it. To measure this, we calculate the correlation coefficient between the first component and ontology size. It turns out that the first component correlates surprisingly well with ontology size and no other components do. As a conse-

[8] In the following, ontology size is the number of axioms

quence, one can ask an interesting question: is ontology size a good performance indicator? Can we predict performance better with 57 features or with size alone? We will answer these questions below.

A Local Approach to Performance Prediction

Here we sketch an approach for predicting performance of a reasoner on a given ontology, given classification time of that reasoner on some of the ontology subsets, ideally few and small, which we call *samples*. We call such a technique a *local approach*.

A reasonable way to construct samples is to represent an ontology as a directed graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V}$ is a set of vertices and $\mathcal{E}$ is a set of directed edges. Each vertice $v \in \mathcal{V}$ is labelled with some set of axioms, called a *clump*. Edges $\mathcal{E}$ represent relationships between clumps. From such a representation we can assemble sets of clumps in many possible ways and use these sets as samples for predictions.

Obviously, the quality of such performance prediction depends on our notion of clumps, their relations, and the assembling mechanism used. For example, a trivial way is to take small arbitrary ontology subsets as samples without any relations between them. However, they are not suitable performance indicators because they can be so only by chance, which is low, given that the size of an ontology is sufficiently large. A more informed way to define clumps is Atomic Decomposition, AD (Del Vescovo 2013). In this case, we ensure cohesion of samples.

Given $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, sampling starts from a single atom. A next sample is constructed by extending the current sample with a new atom. A sensible way of choosing a next atom can cause significant increases of classification time of a sample. The sampling algorithm is described in (Sazonau, Sattler, and Brown 2013). It produces a set of samples with their classification times per ontology.

This local data is then used to make predictions for the whole ontology via regression analysis. Thus, where a global approach gathers data from many ontologies and interpolates for unseen ontologies, a local approach collects data only from part of a given ontology and extrapolates to its full size. In contrast to a global approach, it does not rely on the global view of a corpus to exploit similarities/dissimilarities between ontologies and it uses no features except sample sizes.

Performance Prediction Experiments

In this work, we investigate three commonly used reasoners: Hermit 1.3.8 (Motik, Shearer, and Horrocks 2007), Pellet 2.3.0 (Sirin et al. 2007), and JFact 1.0.0, a Java version of FaCT++ (Tsarkov and Horrocks 2006). In addition to the performance bins specified by Kang et al., we add one more bin E in order to distinguish the hardest ontologies with classification times longer than 1,000 seconds. Thus, we consider the following 5 bins: $A \in (0s, 1s)$, $B \in [1s, 10s)$, $C \in [10s, 100s)$, $D \in [100s, 1,000s)$, $E \in [1,000s, +\infty)$. The performance statistics on BioPortal is shown in Table 1, where the "Exception" bin means that a reasoner raises an exception on those ontologies and does not finish its job.

Bins	JFact	Hermit	Pellet
A	250	222	247
B	50	53	48
C	16	21	21
D	11	13	11
E	23	16	28
Exception	7	32	2

Table 1: Performance statistics on BioPortal (number of ontologies per bin)

We aim to test a global and local performance predictor and compare them. Consequently, we need a procedure to evaluate a performance predictor. The first possibility is based on performance bins. The model predicts a bin for each ontology from the testing set. Whenever it predicts a wrong bin for an ontology, this is counted as an error. Once the model is tested on all ontologies, an average error is calculated which we call the *average classification error*, ACE. Kang et al. use the classification accuracy, $1 - ACE$, to evaluate a model. When predicting performance bins, we suggest to additionally consider a more precise way of evaluation - the *confusion matrix* (Fawcett 2006), which is especially useful for unbalanced data sets. It essentially counts the number of ontologies of actual bin b which are classified to bin $\hat{b}$ for each possible pair $(b, \hat{b})$.

A third way to assess a model is to measure raw differences between the actual and predicted classification time for each testing ontology. The *mean absolute error*, MAE, is a common measure that can be used for this purpose. Nonetheless, hard ontologies, which are rare, can contribute more to MAE than all remaining ontologies together. Thus, all aforementioned measures have their disadvantages, no single measure is enough for predictor evaluation, and we should rather consider them all.

We conduct two performance prediction experiments for the global approach. In the first one, we extract all 57 features from each ontology in BioPortal and train a model, *Glob.57f*, using the resulting data set. In the second one, we record the ontology size (in number of axioms) per ontology and use it as the only feature to train a model, *Glob.1f*. The latter is based on our earlier observations and PCA results. For the local approach we construct samples per ontology as explained above. We restrict samples to have relative sizes $\leq 10\%$ of the full ontology considering the following tradeoff: higher size limits should give more accurate predictions but take longer to compute. Prediction results of the global and local approach are gathered in Table 2.

As Table 2 shows, the local approach delivers better prediction accuracy than the global one in all cases, for both ACE and MAE (the lowest errors are in bold). Extracting 57 ontology features makes surprisingly little sense, especially for bin predictions (ACE): the differences in errors between Glob.57f and Glob.1f are small. One can also notice that Pellet is harder to predict than others for all approaches via either ACE or MAE. It is also worth mentioning that all reasoners are mostly *linearly* predictable.

The confusion matrices, the one for JFact is given by Table 3, show that Glob.57f and Glob.1f are slightly more accurate than the local approach on the easiest bin A, while the

Reasoner	ACE		
	Glob.57f	**Glob.1f**	**Local**
JFact	0.230 (0.048)	0.211 (0.045)	**0.169**
Hermit	0.231 (0.053)	0.237 (0.047)	**0.224**
Pellet	0.301 (0.048)	0.301 (0.048)	**0.250**
	MAE, sec		
JFact	61 (24)	69 (18)	**43**
Hermit	70 (25)	89 (23)	**42**
Pellet	106 (31)	127 (27)	**69**

Table 2: Comparison of global and local approaches on BioPortal (error deviations are in brackets where appropriate)

Real bin	**Predicted bin**				
	A	B	C	D	E
A	**245/242/232**	4/7/16	0/0/1	0/0/0	1/1/1
B	31/23/15	**19/27/28**	0/0/7	0/0/0	0/0/0
C	2/0/0	9/9/0	**3/2/11**	0/0/3	2/5/2
D	1/1/0	2/2/0	3/4/1	**0/0/6**	5/4/4
E	2/2/1	5/4/1	4/5/3	0/3/4	**12/9/14**

Table 3: Confusion matrix for bin predictions of JFact on BioPortal (Glob.57f/Glob.1f/Local)

latter is more correct on all harder bins B, C, D, E; especially on bins C, D. If easy ontologies (bin A) are excluded, it turns out that the remaining ontologies cause extremely higher errors of performance predictions for all approaches.

Discussion of Results and Future Work

To conclude, we have observed that performance prediction of reasoners is a hard and interesting problem. In this work, we propose a novel approach, called local, to solve it. It is based on carefully selecting ontology samples, ideally small, and then using them to predict reasoning performance on the full ontology. The AD, as an ontology graph, is useful to construct such samples: samples of sizes $\leq 10\%$ allow us to obtain good predictions via simple extrapolations. In comparison to a global approach, a local approach gives more accurate performance predictions, does not rely on an ontology corpus and, therefore, cannot be biased by it. Moreover, a local approach reveals interesting information about reasoners' behaviour: linear/nonlinear predictability on the corpus. However, it requires reasoning over samples to make a prediction.

Although selecting an unbiased corpus remains a difficult problem (Matentzoglu, Bail, and Parsia 2013), we definitely need to acknowledge the bias and interpret observations correctly. Moreover, the error measures for evaluating predictors should be chosen carefully because there is no single best measure. A reasonable way is to use several measures evaluating different aspects of prediction accuracy.

One of our main findings is that, for both BioPortal and Tones, multiple ontology features are efficiently represented by ontology size. Predictions using ontology size alone are comparable to predictions using all 57 ontology features. Therefore, ontology features for performance prediction should be defined and used cautiously. Firstly, we should not mix features of different scales in the feature vector because low-scale features can be "hidden" by others. Nonetheless, if these features are informative, suitable techniques, able to handle different scales, must be used. Secondly, we have to investigate intercorrelation of features because the features may turn out to carry little useful information and even degrade the accuracy.

As future work, we consider local approach improvements. The maximal sample size can be estimated for each ontology separately because 10% samples are not indicative enough to make good predictions for some ontologies. In addition, there may exist more suitable regression models for extrapolation. One can also study appropriate methods to cope with ontology features of different scales with respect to performance prediction, e.g. ensemble learning. Finally, we can work on assembling "good" corpora using dimensionality reduction techniques such as PCA.

Canonical Logic Programs Are Succinctly Incomparable with Propositional Formulas

Abstract

Canonical (logic) programs (CP) refer to the class of *normal* programs (LP) augmented with connective *not not*, and are equally expressive as *propositional formulas* (PF). In this paper we address the question of whether CP and PF are *succinctly incomparable*. Our main result shows that the PARITY problem *only* has exponential CP representations, while it can be polynomially represented in PF. In other words, PARITY *separates* PF from CP. Simply speaking, this means that exponential size blowup is generally inevitable when translating a set of PF formulas into a (logically) equivalent CP program (without introducing new variables). Furthermore, since it has been shown by Lifschitz and Razborov that there is also a problem which separates CP from PF (assuming $\mathsf{P} \not\subseteq \mathsf{NC}^1/\mathsf{poly}$), it follows that the two formalisms are indeed succinctly incomparable.

1 Introduction

The relationship between *(logic) programs* under *answer set semantics* (ASP) (Lifschitz 2008; Brewka, Eiter, and Truszczynski 2011) and *propositional satisfiability* (SAT) (Biere et al. 2009) gains a lot of attention in the literature. In 2006, Lifschitz and Razborov proved that an exponential size blowup is generally inevitable when translating a *normal program* (LP) to a (logically) equivalent set of *propositional formulas* (PF) (without introducing additional variables). More precisely, they showed that (a variant of) the P-complete problem PathSystem (PATH) has polynomial size LP representations, however, it *cannot* be polynomially represented in PF (assuming $\mathsf{P} \not\subseteq \mathsf{NC}^1/\mathsf{poly}$) (Lifschitz and Razborov 2006), i.e., PATH *separates* LP from PF.

As noted in (Lifschitz and Razborov 2006), PF can be considered as a special case of the class of *(nondisjunctive) nested programs* (NLP, without classical negation $\neg$) (Lifschitz 1999). Therefore, NLP is *stronger* than PF in terms of the *succinctness* criterion (or the *"comparative linguistics" approach*) (Gogic et al. 1995):

> That is, we consider formalism A to be stronger than formalism B if and only if any knowledge base (KB) in B has an equivalent KB in A that is only polynomially longer, while there is a KB in A that can be translated to B only with an exponential blowup.

So the following footnote in (Lifschitz 2008) seems convincing:

> ...ASP appears to be stronger than SAT in the sense of the "comparative linguistics" approach to knowledge representation...

However, ASP involves many kinds of programs, the above statement probably needs further clarification. Particularly, the class of so-called *(nondisjunctive) canonical programs* (CP[1]) (Lifschitz 1999; Lee 2005; Lee, Lifschitz, and Yang 2013), is a minimal form of ASP that is equally expressive as PF, but looks more likely *not* succinctly stronger. So a question naturally arises: *Does there exist a problem that separates PF from CP?* If there is such a problem, then CP and PF are *succinctly incomparable* (assuming $\mathsf{P} \not\subseteq \mathsf{NC}^1/\mathsf{poly}$).

In this paper we address the question and give a *positive* answer. Our main result shows that the PARITY problem separates PF from CP. Simply speaking, this means exponential size blowup is generally inevitable when translating a set of PF formulas into an equivalent CP program. The PARITY problem asks whether a binary string contains an odd number of 1's, and it is well-known that (i) PARITY$\in \mathsf{NC}^1/\mathsf{poly}$[2], i.e., it has polynomial PF representations; (ii) PARITY$\notin \mathsf{AC}^0$, i.e., it cannot be represented by *polynomial* size (boolean) circuits with *constant depth* and *unbounded fan-in* (Arora and Barak 2009; Jukna 2012).

To show PARITY separates PF from CP, we provide a procedure that simplifies every PARITY program Π into a shorter program Π' s.t. Π' is equivalent to its *completion* $Comp(\Pi')$ (Erdem and Lifschitz 2003). Such completions are essentially constant depth, unbounded fan-in circuits. According to PARITY$\notin \mathsf{AC}^0$, these circuits must be of exponential size, consequently, there are no polynomial size PARITY programs in CP. In the rest of the paper, we shall introduce the basic concepts, key steps of our proof and discuss the importance of succinctness research in the theory and practice of Knowledge Representation (KR).

[1] Extends LP with connective *not not*.

[2] $\mathsf{NC}^1/\mathsf{poly}$ (or *non-uniform* NC^1) *exactly* contains languages computable (representable) by polynomial size PF formulas.

2 Background

Canonical Programs

The following notations are adopted from (Lifschitz 1999; Lee 2005). A *rule element* e is defined as

$$e := \top \mid \bot \mid x \mid not\ x \mid not\ not\ x$$

in which $\top, \bot$ are 0-ary connectives, x is a *(boolean) variable* (or an *atom*) and not is a unary connective[3]. A *(nondisjunctive canonical) rule* is an expression of the form

$$H \leftarrow B \tag{1}$$

where the *head* H is either a variable or the connective $\bot$, and the *body* B is a finite set of rule elements. A *canonical program* Π is a finite set of rules. E.g., the following is a canonical program:

$$\begin{array}{ll} x_1 \leftarrow not\ not\ x_1, & x_3 \leftarrow not\ x_1, not\ x_2, \\ x_2 \leftarrow not\ not\ x_2, & x_3 \leftarrow x_1,\ x_2. \end{array} \tag{2}$$

A canonical program Π is *normal* if it contains no connectives $not\ not$. A normal program Π is *basic* if it contains no occurrences of connective not.

The *satisfaction relation* $\models$ between a set of variables I and a rule element is defined as follows:

- $I \models \top$ and $I \not\models \bot$,
- $I \models x$ iff $I \models not\ not\ x$ iff $x \in I$,
- $I \models not\ x$ iff $x \notin I$.

Say I satisfies a set of rule elements B if I satisfies each rule element in B. We say I is *closed* under a program Π, if I is closed under every rule in Π, i.e., for each rule $H \leftarrow B \in \Pi$, $I \models H$ whenever $I \models B$. Let Π be a basic program and let $Cn(\Pi)$ denotes the *minimal* set (in terms of set inclusion) closed under Π, we say I is an *answer set* of Π if $I = Cn(\Pi)$. Note that a basic program has exactly one answer set.

The *reduct* Π^I of a program Π w.r.t. I is a set of rules obtained from Π via: (i) Replacing each $not\ not\ x$ with $\top$ if $I \models x$, and with $\bot$ otherwise; (ii) Replacing each $not\ x$ with $\top$ if $I \not\models x$, and with $\bot$ otherwise. Observe that Π^I must be a basic program. We say I is an answer set of Π if $I = Cn(\Pi^I)$, i.e., I is an answer set of Π^I. E.g., the following single rule program:

$$x \leftarrow not\ not\ x \tag{3}$$

has two answer sets $\emptyset$ and $\{x\}$.

For a set of rule elements B, define $var(B) = \{e \in B : e \text{ is a variable}\}$. E.g., $var(\{x_1, not\ x_2, not\ not\ x_3\}) = \{x_1\}$. The *signature* $sig(\Pi)$ of a program Π is the set of all involved variables in Π. By $Ans(\Pi)$ we denote the set of all answer sets of Π. E.g., if Π is (2), then $sig(\Pi) = \{x_1, x_2, x_3\}$ and $Ans(\Pi) = \{\{x_1, x_2, x_3\}, \{x_1\}, \{x_2\}, \{x_3\}\}$. The *size* $|\Pi|$ of Π is the number of its rules. As a convention, Π_n refers to a program with signature $\{x_1, \ldots, x_n\}$, i.e., $sig(\Pi_n) = \{x_1, \ldots, x_n\}$.

It is easy to see that by using rules of the form (3) and appropriate *constraints* of the form $\bot \leftarrow B$, it is easy to give an arbitrary set of answer sets over $sig(\Pi_n)$, in other words, CP has exactly the same expressive power as PF.

[3]By (Lifschitz 1999), $not\ not\ not\ x$ can be replaced by $not\ x$.

Problem Representation and Succinctness

A *(binary) string* is a finite sequence of *bits* from $\{0, 1\}$. A string w of length n (i.e., $w \in \{0, 1\}^n$) defines a subset of variables $\{x_1, \ldots, x_n\}$. E.g., 1010 stands for $\{x_1, x_3\}$. Therefore, a set of variables I and a string w can be regarded as the same. A *problem* (or *language*) L is a set of strings.

Definition 2.1 (Problem Representation). *A problem L can be* represented *in a class of programs (or formulas, etc) $\mathcal{C}$ (i.e., $L \in \mathcal{C}$), if there exists a* sequence *of programs $\{\Pi_n\}$ ($n = 1, 2, \ldots$) in $\mathcal{C}$ that* computes *L, i.e., for every string $w \in \{0, 1\}^n$,*

$$w \in L \Leftrightarrow w \in Ans(\Pi_n).$$

Say L has polynomial representations in $\mathcal{C}$ (i.e., $L \in$ Poly-$\mathcal{C}$), if $L \in \mathcal{C}$ and $|\Pi_n|$ is bounded by a polynomial $p(n)$.

Recall that the PARITY problem is the set of binary strings with an odd number of 1's. By PARITY_n we denote PARITY strings of length n. Clearly, (2) represents PARITY_3 since its answer sets are $111, 100, 010$ and 001.

Definition 2.2 (Succinctness (Gogic et al. 1995; French et al. 2013)). *Let $\mathcal{C}, \mathcal{C}'$ be two classes of programs such that for every problem L, $L \in \mathcal{C} \Leftrightarrow L \in \mathcal{C}'$. Say $\mathcal{C}$ is* at least as succinct as *$\mathcal{C}'$ (i.e., $\mathcal{C}' \preceq \mathcal{C}$), if for every problem L,*

$$L \in \text{Poly-}\mathcal{C}' \Rightarrow L \in \text{Poly-}\mathcal{C}.$$

If $L \in$ Poly-$\mathcal{C}$ but $L \notin$ Poly-$\mathcal{C}'$ (i.e., $\mathcal{C} \not\preceq \mathcal{C}'$), then L separates *$\mathcal{C}$ from $\mathcal{C}'$. If $\mathcal{C}' \preceq \mathcal{C}$ and $\mathcal{C} \not\preceq \mathcal{C}'$, then $\mathcal{C}$ is* strictly more succinct than *$\mathcal{C}'$ (i.e., $\mathcal{C}' \prec \mathcal{C}$). Moreover, $\mathcal{C}, \mathcal{C}'$ are* succinctly incomparable *if there is a problem L that separates $\mathcal{C}$ from $\mathcal{C}'$, and vice versa (i.e., $\mathcal{C} \not\preceq \mathcal{C}'$ and $\mathcal{C}' \not\preceq \mathcal{C}$).*

PARITY Representations and Completion

Note that (2) suggests a "pattern" for PARITY_n: The first part of the program (e.g., the "*not not*" rules in (2)) generates all possible strings of length $n-1$, the second part identifies the last bit to form an odd string of length n. Following the pattern, we can give a sequence of *exponential* size CP programs for PARITY, i.e., PARITY$\in$CP.

On the other hand, it is a textbook result that PARITY has polynomial size PF representations with classical connectives $\{\wedge, \vee, \neg\}$, i.e., PARITY$\in \mathsf{NC}^1/\mathsf{poly}$ (or Poly-PF). Remind that the size of a formula is the number of its connectives. E.g., $(x_1 \wedge \neg x_2) \vee (\neg x_1 \wedge x_2)$ represents PARITY_2, and the formula can be recursively applied for arbitrary PARITY_n. It is also well-known that PARITY$\notin \mathsf{AC}^0$, i.e., PARITY cannot be represented by a sequence of polynomial size circuits $\{C_n\}$ in which these circuits C_n have unbounded fan-in and constant depth.

Simply speaking, a sequence of polynomial size PF formulas $\{\phi_n\}$ represents an AC^0 language, if the number of variables occur in a *conjunction* or *disjunction* of ϕ_n is *unrestricted*, and the distance of the longest path from the root to a leaf in the tree structure of each ϕ_n is *fixed*. E.g., PARITY cannot be represented by a sequence of polynomial size CNFs $\{\psi_n\}$ since $\{\psi_n\}$ represents an AC^0 language. For more details about circuits, please see (Arora and Barak 2009; Jukna 2012).

The *completion* $Comp(\Pi)$ (Erdem and Lifschitz 2003) of a CP program Π consists of a set (or a conjunction) of PF formulas (we slightly abuse the connective $\equiv$): (i) $x \equiv \tilde{B}_1 \vee \tilde{B}_2 \vee \cdots \vee \tilde{B}_m$, where $x \leftarrow B_1, \ldots, x \leftarrow B_m$ are all rules in Π with head x, and each $\tilde{B}_i$ is the conjunction of rule elements in B_i with connective *not* replaced by $\neg$; (ii) $x \equiv \bot$, if x is not a head of any rule in Π; (iii) $\neg\tilde{B}$, if a rule $\bot \leftarrow B$ is in Π.

Proposition 2.1. *The completion $Comp(\Pi)$ of an arbitrary canonical program Π is a constant depth, unbounded fan-in circuit whose size is polynomially bounded by $|\Pi|$.*

It is well-known that an answer set of Π is also a model of its completion, but the inverse generally does not hold. E.g., the completion $\{x_1 \equiv \neg x_2 \vee (x_2 \wedge x_1), x_2 \equiv \neg x_1 \vee (x_1 \wedge x_2)\}$ of the PARITY$_2$ program:

$$\begin{array}{ll} x_1 \leftarrow not\ x_2, & x_2 \leftarrow not\ x_1, \\ x_1 \leftarrow x_2, not\ not\ x_1, & x_2 \leftarrow x_1, not\ not\ x_2, \end{array} \quad (4)$$

has an even string model 11, i.e., (4) is not *completion-equivalent*. In the next section, we will show how to simplify a PARITY program to be completion-equivalent.

3 Simplifying PARITY Programs

Let B be a finite set of rule elements built on signature $V = \{x_1, \ldots, x_n\}$. By $S(B)$ we denote the set $\{I \subseteq V : I \models B\}$. E.g., let $V = \{x_1, x_2, x_3, x_4\}$ and $B = \{x_2, not\ x_3, not\ not\ x_4\}$, then $S(B) = \{\{x_1, x_2, x_4\}, \{x_2, x_4\}\} = \{1101, 0101\}$. We say B is *consistent* if there is a set of variables I s.t. $I \models B$. We say B *covers* a variable $x \in V$ iff $x \in B$ or $not\ x \in B$ or $not\ not\ x \in B$. If B covers every variable in V then B *fully covers* V. E.g., $B = \{x_1, not\ x_2, not\ not\ x_3\}$ fully covers $V = \{x_1, x_2, x_3\}$. Clearly, B is consistent and fully covers V iff $S(B)$ contains a unique string.

In the following we assume that all rules $x \leftarrow B$ have consistent body B and $x \notin var(B)$. It is easy to see that the assumption does not affect the generality.

Lemma 3.1. *Let Π_n be a PARITY$_n$ program. If there is a rule $x \leftarrow B$ in Π_n s.t. $not\ not\ x \in B$ and $S(B)$ contains a unique even string, then dropping $x \leftarrow B$ from Π_n results in a PARITY$_n$ program Π'_n.*

E.g., by Lemma 3.1, (4) can be simplified to:

$$x_1 \leftarrow not\ x_2, \quad x_2 \leftarrow not\ x_1. \quad (5)$$

Lemma 3.2. *Let Π_n be a PARITY$_n$ program. If there is a rule $x \leftarrow B$ in Π_n s.t. $not\ not\ x \in B$ and $S(B)$ contains a unique odd string, then dropping $not\ not\ x$ from B results in a PARITY$_n$ program Π'_n.*

Standard Programs and the Main Theorem

A PARITY$_n$ program Π_n is *standard* if for each rule $x \leftarrow B \in \Pi_n$, $not\ not\ x \notin B$ whenever $S(B \cup \{x\})$ contains a unique string. E.g., (2) and (5) are standard programs. By Lemma 3.1 and 3.2, it is not hard to see:

Proposition 3.1. *Let Π_n be a PARITY$_n$ program. Then there is a standard PARITY$_n$ program Π'_n s.t. $|\Pi'_n| \leq |\Pi_n|$.*

Moreover, note that (2) and (5) are completion-equivalent PARITY programs. This is guaranteed by the following proposition:

Proposition 3.2. *Let Π_n be a standard PARITY$_n$ program. Then Π_n is equivalent to its completion $Comp(\Pi_n)$.*

The proof idea of Proposition 3.2 is that every standard PARITY$_n$ program Π_n can be equivalently rewritten to Π'_n by replacing each $x \in var(B)$ with $not\ not\ x$ for every rule body B in Π_n. By the Lin-Zhao Theorem (Lin and Zhao 2004) or the (generalized) *Fages Theorem* (Erdem and Lifschitz 2003; You, Yuan, and Zhang 2003), Π'_n is equivalent to its completion $Comp(\Pi'_n)$. And then the Proposition follows from the fact that $Comp(\Pi'_n) = Comp(\Pi_n)$.

Lemma 3.3 (Main Lemma). *Let Π_n be a PARITY$_n$ program. Then there is a PARITY$_n$ program Π'_n s.t. Π'_n is equivalent to $Comp(\Pi'_n)$ and $|\Pi'_n| \leq |\Pi_n|$.*

Theorem 3.1 (PARITY$\notin$Poly-CP). *PARITY has no polynomial size CP representations.*

Proof. Assume the contrary that there is a sequence of PARITY$_n$ programs $\{\Pi_n\}$ s.t. $|\Pi_n|$ is bounded by a polynomial $p(n)$. By Lemma 3.3, there is a sequence of completion-equivalent PARITY$_n$ programs $\{\Pi'_n\}$ in which $|\Pi'_n|$ is also bounded by the polynomial $p(n)$. By Proposition 2.1, $\{\Pi'_n\}$ represents a language in AC^0. This contradicts PARITY$\notin \mathsf{AC}^0$. □

Corollary 3.1. *PARITY separates PF from CP.*

Corollary 3.2. *Suppose $\mathsf{P} \not\subseteq \mathsf{NC}^1/\mathsf{poly}$. Then CP and PF are succinctly incomparable.*

4 Discussion and Conclusion

In this paper we show that the PARITY problem separates PF from CP, and the two formalisms are succinctly incomparable (assuming $\mathsf{P} \not\subseteq \mathsf{NC}^1/\mathsf{poly}$). Interestingly, our main result may at first appear counter-intuitive: the P-complete problem PATH has Poly-CP representations, while this does not hold for an "easy" problem PARITY. Actually, there is no contradiction. As noted in (Abiteboul, Hull, and Vianu 1995; Dantsin et al. 2001), a *complete* problem in a complexity class can be represented in a formalism $\mathcal{C}$, *does not* imply that *all* problems in that class can be represented in $\mathcal{C}$.

Generally speaking, the research of succinctness (Gogic et al. 1995; Coste-Marquis et al. 2004; Grohe and Schweikardt 2005; French et al. 2013) gives us a deeper understanding about KR formalisms, for it reveals their (in)abilities of concisely representing different problems under the condition that the encoded models are the *same*. This is particularly interesting if the formalisms are *equally expressive* and share the same reasoning complexity.

E.g., in addition to CP and NLP, programs with *cardinality constraints* and *choice rules* (CC, without classic negation $\neg$) (Simons, Niemelä, and Soininen 2002), *(simple) definite causal theories*[4] (S/DT) (Giunchiglia et al. 2004) and

[4] A theory is simple if each rule body is a conjunction of literals.

two-valued programs (TV) (Lifschitz 2012) are as expressive as PF and NP-complete for consistency checking. But they have a non-trivial succinctness picture, see Fig. 1.

Besides the theoretical interests, succinctness also tells us something like "which for what is the best" in choosing KR formalisms for a given application. E.g., one should choose ASP instead of SAT (or DT) if the application involves reasoning about PATH or Transitive Closure[5], because the former provides compact representations to avoid unnecessary overload. Recall that from the complexity viewpoint, even *one* extra variable may *double* the search space for intractable problems.

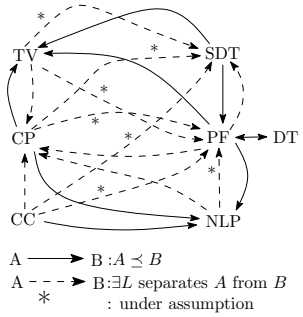

Figure 1: Succinctness Pic.

In future work we plan to establish the missing connections in Fig. 1, moreover, we will consider the succinctness of more expressive formalisms like programs with predicate symbols or higher-order atoms (Gebser, Schaub, and Thiele 2007), etc.

Heuristic Guided Optimization for Propositional Planning

Andreas Sideris and **Yannis Dimopoulos**
Department of Computer Science
University of Cyprus
Nicosia, Cyprus

Abstract

Planning as Satisfiability is an important approach to Propositional Planning. A serious drawback of the method is its limited scalability, as the instances that arise from large planning problems are often too hard for modern SAT solvers.

This work tackles this problem by combining two powerful techniques that aim at decomposing a planning problem into smaller subproblems, so that the satisfiability instances that need to be solved do not grow prohibitively large. The first technique, *incremental goal achievement*, turns planning into a series of boolean optimization problems, each seeking to maximize the number of goals that are achieved within a limited planning horizon. This is coupled with a second technique, called *heuristic guidance*, that directs search towards a state which satisfies all goals.

Introduction

Planning as Satisfiability (Kautz and Selman 1996; Kautz, Selman, and Hoffmann 2006) is an important method for optimal propositional planning. One of the advantages of the method is that it finds plans of optimal makespan. However, it often happens that the instances generated from planning problems, grow so large that they are unsolvable even by the most advanced SAT solvers.

This motivated a number of recent attempts to improve scalability at the cost of sacrificing the optimality of the generated solutions. One such example is `Madagascar` (Rintanen 2012), that enhanced a SAT solver with a planning specific variable selection heuristic, to generate suboptimal plans quickly. In a different spirit, the `PSP` system (Sideris and Dimopoulos 2012), introduced the idea of *planning as optimization*. `PSP` employs the increasing planning horizon technique, but unlike classic `SATPLAN`, it maximizes the goals that are achieved within each horizon, and adds them as intermediate goals in the problem model. However, as the plan length can grow arbitrarily long, at some point it is expected that both approaches will be confronted with performance difficulties.

In this work we take a different path. The basic idea is to split a planning problem into smaller subproblems, of a size that is not prohibitive for the underlying solver. `PSP-H`, the new planning system that is described here, shares with `PSP` the planning as optimization perspective, but it differs in a number of important ways. The first is the *incremental goal achievement* which, at a high level, works as follows. `PSP-H` first generates a sub-plan that, starting from the initial state, achieves a subset, of predefined size, of the problem goals. The state that results after the execution of the actions of this sub-plan, becomes the new initial state, and a new sub-plan that satisfies a larger subset of goals is computed. The procedure iterates and links together the subplans that are generated along the way. Therefore, instead of solving the original planning problem, `PSP-H` solves a series of smaller subproblems.

A downside of this greedy approach is that it focuses on maximizing the number of achieved goals in a limited planning horizon, and it ignores completely goals that cannot be achieved within this horizon. In order to overcome the limitations that this would place on the effectiveness of the system, `PSP-H` is enhanced by a second technique called *heuristic guidance*, which imposes an additional requirement on the intermediate states that are computed by the `PSP-H` algorithm. The property that these states need to satisfy is that there must be a *relaxed* plan from each such state to the final state. `PSP-H` employs three different relaxation methods that are all based on ignoring some of the problem constraints, but they differ in their strength.

The first relaxation method is the well-known delete lists relaxation, whereas the second method ignores all action mutexes. The last relaxation, which is stronger than the first but weaker than the second, ignores action mutexes and uses a subset of the fact mutexes that are heuristically selected.

`PSP-H` is a incomplete and suboptimal planner implemented on top of the `PSP` system. Our experimental evaluation on a number of domains taken from planning competitions, demonstrates that `PSP-H` can solve challenging problems, that require long plans. Moreover, a preliminary comparison with `Madagascar` shows that the new system can solve more problems in some domains, and generate better quality solutions both in term of plan length and number of actions.

Some of the techniques employed in `PSP-H` are similar to those used in other planning systems. For instance, the local optimization method of `PSP-H` bares some resemblance to the enforced hill-climbing approach of the

FF planner (Hoffmann and Nebel 2001). The CPT system (Vidal and Geffner 2006) combines heuristic estimators with constraint programming techniques in the context of optimal temporal planning. Finally, a study of the relation between the relaxation methods of PSP−H and the red-black heuristics of (Katz, Hoffmann, and Domshlak 2013a; 2013b) may lead to a tighter integration of heuristic and constrained optimization based planning.

Background

We assume familiarity with the planning as satisfiability framework. We discuss in brief pseudo-boolean optimization and the planning as optimization method of PSP.

A (STRIPS) planning problem is a triple $P =< I, G, \mathcal{A} >$, where I is the set of facts that hold in the initial state, G are the goals, and $\mathcal{A}$ is a set of actions. Each action has preconditions, add effects, and delete effects. In the SAT model of a planning problem, time-stamped propositional atoms (or variables) represent the action and facts of the problem. An atom $A(T)$, where A is an action, corresponds to the decision of whether action A is taken or not at time T, and analogously for variables of the form $f(T)$, where f is a fact.

PSP−H uses the SMP (Sideris and Dimopoulos 2010) encodings of a planning problem, that derives its clauses from the *planning graph* (Blum and Furst 1997) of the problem. Among the clauses of the SMP model there are those that correspond to fact and action *mutexes*, that are derived from the planning graph.

A *(Linear) Pseudo-boolean constraint* (PB-constraint) is an inequality of the form $\sum a_i x_i \geq b$, where x_i is a boolean variable, and a_i, b integers. A *Pseudo-boolean optimization* (PBO) problem on a set of variables X consists of a set of PB-constraints on X, together with a linear function on boolean variables from X. In PBO we seek a value assignment on the variables of X that maximizes the value of the boolean function, called objective function, and satisfies all the PB-constraints. The current implementation of PSP−H uses minisat+ (Eén and Sörensson 2006), to translate PB-constraints into CNF, and then invokes precosat (Biere 2009), that solves the SAT instance.

PSP−H is implemented as an extension of the PSP planning system (Sideris and Dimopoulos 2012). PSP follows a similar to the classic solve and expand approach, with the difference that it seeks to maximize the number of goals that can be achieved within a fixed planning horizon of, say, k steps. If this number is smaller than some user supplied value, the planning horizon is extended to $k + 1$ steps, and the procedure iterates. Moreover, the goals that are attained within the k steps are added to the problem as *intermediate goals*, that must be established in the $k + 1$ steps long plan that is generated in the next iteration. For a more detailed description of PSP the reader is referred to (Sideris and Dimopoulos 2012).

The PSP−H algorithm

PSP−H takes as input a (STRIPS) planning problem $(I, G, \mathcal{A})$, and a number of parameter values in the range [0..1]. The main technique implemented in PSP−H is the *incremental goal achievement*, that is embedded in its optimization phase. The core of the computation that is carried out in this phase is the solution of a series of PBO problems, where the maximization objective is $g_1(T)+\ldots+g_l(T)$, where $g_1, \ldots, g_l$ are the goal atoms and T the planning horizon. Obviously, the highest value that can be assumed by the objective function is l, which we denote by f_{max}.

PSP−H is also supplied by the user with an objective function value threshold $thres$. It starts with an initial planning horizon o that is determined by information that is extracted from the underlying planning graph as in the classic SATPLAN system. PSP−H solves the PBO with horizon o and obtains an optimal value f for the objective function. If $f < thres * f_{max}$, the planning horizon is set to $o + 1$, and the procedure repeats. If for some horizon o_b a solution is found with a value f_b for the objective function such that $f_b \geq thres * f_{max}$, a $plan$ is extracted from the solution. At this point, the state I' that results after the execution of the actions in $plan$ becomes the new initial state, and PSP−H repeats the process with a new planning problem $P' =< I', G, \mathcal{A} >$, where $P =< I, G, \mathcal{A} >$ and I are the original problem and initial state respectively. Moreover, the objective value threshold $thres$ is increased and set to $thres+restart\_rate$, where $restart\_rate$ is a user supplied value, called *restart rate*. As the maximization objective is defined on the fact variables that correspond to goals, the increase in the threshold translates into an increase in the number of goals that are achieved. Hence the term *incremental goal achievement*.

The optimization phase of PSP−H terminates when the value $thres$ exceeds another user supplied value $finphase$. Its output is a plan that is formed by concatenating the partial plans that are generated during its iterations. The execution of the action in this plan defines a state I_{sat}. Then PSP−H, similarly to PSP, enters the satisfaction phase, where a new planning problem with initial state I_{sat}, is solved by SMP.

The periodic replacement of the initial state of the planning problem described above, is called *restart strategy*, where the value of the $restart\_rate$ parameter determines the frequency of the restarts. With the restart strategy PSP−H attempts to limit the length of the planning horizon, and hence the size of the satisfiability instances that are solved by the system. As it is often the case with greedy search methods, a difficulty with incremental goal achievement is that it tends to generate locally optimal plans, i.e. plans that maximize the number of attained goals in the limited planning horizon, and ignores goals that are not achievable within that horizon. This bias may lead to poor quality solutions, as well as insolvability when actions interact in complex ways, as in the case of the presence of non-renewable resources.

To tackle this problem, PSP−H combines incremental goal achievement with a heuristic method that is intended to

account for the effort that is needed to achieve the remaining goals. This is accomplished by a problem model that consists of the usual layers of action and fact propositions that correspond to different times/points, but it is divided in two parts: the *constrained* and the *relaxed* part.

The constrained part is the standard PB model of the problem, i.e. a straightforward translation of the SMP clauses into linear inequalities. The relaxed part is also obtained from the SMP encoding, but some of the constraints of the model are omitted. In fact, as depicted in Figure 1, the relaxed part is further divided into three segments that differ in the mutual exclusion information they contain.

The first segment of the relaxed part is the *action relaxation*, which is the SMP model without action mutex clauses, and it is similar to the "$\exists$ encoding" of (Rintanen, Heljanko, and Niemelä 2006). The last segment is the *full relaxation* that contains neither action nor fact mutexes. This segment corresponds to the well-known delete-lists relaxation heuristic that forms the basis of many heuristic search planners. All goals are added as unit clauses in a final layer $q + 1$ (layer numbering is taken from figure 1).

Between the above two segments lies the *intermediate relaxation* segment. It is less constrained (more relaxed) than the action relaxation, but more constrained (less relaxed) than the full relaxation. It contains no action mutexes, and only a subset of the fact mutexes that is heuristically selected by PSP−H. This selection process is based on the analysis of the multi-valued variable representation of the problem that is carried out with the help of the preprocessor of LAMA (Richter and Westphal 2010). For some problem variables all corresponding mutexes are omitted, for others all mutexes are added, whereas for some variables x with domain values $x_1, \ldots, x_n$, instead of the constraint $\sum_{i=1}^{n} x_i <= 1$, PSP−H adds the weaker inequality $\sum_{i=1}^{n} x_i <= k$, for heuristically selected values of k. Due to space limitation, a more complete description of the intermediate relaxation falls outside the scope of this paper.

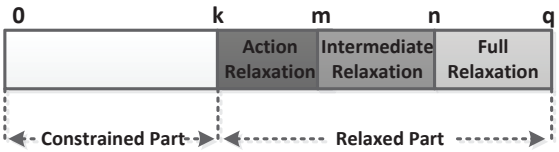

Figure 1: The different part of the encoding in PSP−H.

From the above discussion it must have become apparent that the problem model becomes less constrained as we move from left to right in figure 1. All the constraints of the different parts must be satisfied during the optimization phase of PSP−H, while the objective function that is maximized is $g_1(k) + \ldots + g_l(k)$, i.e. the goals refer to the last layer of the constraint part. The action variables of the first k layers (ie. the constrained part) that are assigned true in a solution generated by PSP−H in an iteration of the optimization phase, form a valid plan that achieves some of the goals at time k. The execution of the actions of this plan defines a valid state s_k at time k. As noted in the beginning of this section, this state s_k may become the initial state of the new problem that is solved in the next iteration of the optimization phase. The PSP−H encoding ensures that a state that satisfies all goals is reachable from s_k within $q + 1 - k$ *relaxed* steps. Therefore, PSP−H searches for a state s_k for which there is not only a valid plan from the current initial state, but there is also a relaxed, heuristically specified, plan from s_k to a final state. Hence the term *heuristic guided optimization*.

The computation of the length of the full relaxation segment takes into account a user supplied value for parameter h_init_perc, and is carried out as follows. PSP−H first removes all delete-lists from all problem actions, and then builds a planning graph until all goals are reachable. If the number of layers of this graph is len, the length of the relaxation part (corresponding to value $q - n$ in figure 1) is set to $len * h\_init\_perc$.

The length of the other segments of the relaxed part are computed in a similar way. First, PSP−H builds a planning graph of the original problem, and extends it until all goals are reachable. If the graph has len layers, the length of the action relation part is set to $len * r\_init\_perc1$ and the intermediate relaxation part to $len * r\_init\_perc2$, where again r_init_perc1 and r_init_perc2 are input parameter values.

In order to enhance the effects of heuristic guided optimization, PSP−H shortens the relaxed part periodically as the planner approaches a final state. The reduction always starts with the full relaxation segment, while its rate is determined by an input parameter h_red_rate. Roughly speaking, each time that the value of the objective function that is maximized in the optimization phase improves by h_red_rate, the full relaxation segment is reduced by one step. When its length reaches the value 1, the intermediate relaxation segment is reduced in a similar way. Action relaxation is never reduced.

Experimental evaluation

PSP−H is a prototype system that has been implemented to test the ideas that are presented in this work. It has been built on top of SATPLAN, from which it inherits the very slow and memory demanding planning graph construction phase. This imposes serious limitations on the size of the problem that can be solved by PSP−H. In fact, in many domains the current version of PSP−H spends more time in manipulating data structures than in constraint solving and optimization.

PSP−H has been evaluated on a number of domains from various planning competitions and compared with LAMA and Madagascar. All experiments were run on a server with 24 X5690 cores at 3.47GHz running under CentOS. Both LAMA and Madagascar were run with their default parameter values, and a CPU cutoff limit of 3600 seconds. In all experiments with PSP−H, the optimization phase terminated after 300 CPU seconds, in which case the planning horizon was extended by one step. PSP−H was also run with a CPU limit of 3600 seconds.

Table 1 summarizes the number of problems solved by each system. The first column lists the domains of the ex-

Domain	Num. of Probl.	LAMA	Madag	PSP-H
Pipesworld	25	25	22	25
Satellite	22	22	22	22
Storage	29	20	29	29
Openstacks	30	30	18	18
Elevators	30	30	30	30
Transport	19	19	19	18
Visitall	28	28	19	21
Barman	40	40	28	40
Total	223	214	187	202

Table 1: Number of problems solved by the planners within a 3600 seconds CPU limit. The second column lists the number of problems tried in each domain.

perimental evaluation, with the name with which they are known in the literature. The second column lists the number of problems included from each domain, as it was determined by PSP-H's memory consumption. Problems which exceed the memory capabilities of PSP-H are excluded from the study. The third and fourth column present the problems solved within the CPU cutoff limit by LAMA and Madagascar respectively. The last column refers to a characteristic run of PSP-H (the specific parameter values of this run are not of particular interest) that feature frequent restarts, thus making the satisfiability problems easier for the underlying boolean optimizer.

A comparison of PSP-H's column with that of LAMA, clearly shows that the heuristic planner outperforms PSP-H. In fact, the only domain where PSP-H (and Madagascar) solves more problems is Storage. On the other hand, PSP-H can solve more problems than Madagascar in Pipesworld, but its advantage shows more clearly in the Visitall and Barman domains, and this is not accidental. The plans in these domains are long, and it seems that the techniques employed by PSP-H address successfully this problem, at least in certain cases. We note that the longest plan that PSP-H was able to synthesize comes from Visitall and was 248 steps long.

Table 2 presents results about the quality of the plans that were generated by the systems for the largest 5 problems in each domain that were solved by all planners. The numbers in parentheses are the sums of the number of actions in all the 5 problems, whereas the numbers outside parentheses sum the parallel plan lengths, and hence they are not meaningful for LAMA which generates sequential plans. Clearly, PSP-H generates better quality plans in all domains except Satellite. On the other hand, in some domains with low or no action parallelism, such as Openstacks, Visitall and Barman, PSP-H generates plans that have less actions than those of LAMA. However, in domains with high parallelism, LAMA's plans contain considerably fewer actions.

Domain	LAMA	Madag	PSP-H
Pipesworld	(167)	193 (432)	152 (281)
Satellite	(366)	99 (457)	109 (527)
Storage	-	450 (1339)	194 (725)
Openstacks	(662)	448 (606)	396 (572)
Elevators	(839)	428 (2056)	382 (1629)
Transport	(341)	432 (1161)	220 (666)
Visitall	(448)	535 (535)	447 (447)
Barman	(814)	896 (1184)	561 (780)
Total	(3637)	3031 (6431)	2267 (4902)

Table 2: Sums of the solution length (number of parallel steps) and in parentheses the sums of the number of actions for the largest five problems in each domain. In the last line the total counts for all domains except Storage.

First-Order Default Logic Revisited

Yi Zhou
Artificial Intelligence Research Group
School of Computing, Engineering and Mathematics
University of Western Sydney, Australia

Abstract

Reiter's original proposal for default logic is unsatisfactory for open default theories because of Skolemization and grounding. In this paper, we reconsider this long-standing problem and propose a new world view semantics for first-order default logic. Roughly speaking, a world view of a first-order default theory is a maximal collection of structures satisfying the default theory where the default part is fixed by the world view itself. We show how this semantics generalizes classical first-order logic and first-order answer set programming, and we discuss its connections to Reiter's semantics and other related semantics. We also argue that first-order default logic under the world view semantics provides a rich framework for integrating classical logic based and rule based formalisms in the first-order case.

Introduction

As a predominant approach for nonmonotonic reasoning, default logic has attracted many researchers since Reiter's seminal work (Reiter 1980). Reiter's semantics targets on general first-order default theories in two steps. First, an extension semantics is defined for closed default theories in which no free variable occurs in any default rules. Then, general default theories with free variables (also called open default theories) are converted into closed ones by Skolemization and grounding so that the above extension semantics can be applied.

However, as pointed out by Poole (1987) and many other researchers (Lifschitz 1990; Baader and Hollunder 1995; Kaminski 1995; 1999), Reiter's semantics may lead to counterintuitive phenomena for open default theories. For instance, Lifschitz (1990) proposed an example with a single default rule $\frac{:M\neg P(x)}{\neg P(x)}$ and a single first-order assertion $P(a)$. One should expect that we have the following information hidden in the default theory

$$\forall x\,(P(x) \leftrightarrow (x = a)).$$

However, in Reiter's extension semantics, the default rule will only be grounded on a and another Skolem constant c different than a. Therefore, one can only conclude $P(a) \wedge \exists x\,\neg P(x)$.

The unsatisfactory performance of Reiter's original semantics for open first-order default theories is indeed a serious semantic issue. As pointed out by Reiter himself (1980),

"the genuinely interesting cases involve open defaults."

In this paper, we reconsider this long standing problem and propose a new world view semantics. Instead of first-order theories, we use collections of structures sharing the same domain and function interpretations (called *views*) as the candidate solution concept. Roughly speaking, a world view of a first-order default theory is a maximal view (collection of structures) satisfying the default theory where the default part is fixed by the world view itself. Although related, this semantics is essentially different from Reiter's extension semantics, even for closed default theories. However, they coincide on some restricted classes.

Our work is also strongly motivated from the attempt to combine classical logic based formalisms and rule based formalisms, particularly the recent development in ontology engineering for adding rules onto the description logics layer (Baader and Hollunder 1995; Motik et al. 2006; Eiter et al. 2008; Motik and Rosati 2010; Lukasiewicz 2010; Zhou and Zhang 2012). We argue that default logic provides a rich framework for this task. First, we show that it generalizes both classical logic and first-order answer set programming. Then, we show how default logic can handle both monotonic reasoning and nonmonotonic reasoning and flexibly switch between open world reasoning and closed world reasoning.

The main contribution of this paper is to provide a new world view semantics for first-order default logic. Although this is a long standing problem, we believe that research in this direction will further deepen our understandings and shed new insights in

- default logic and nonmonotonic reasoning,
- dealing with free variables in complex knowledge representation formalisms, and
- integration of classical logic based and rule based formalisms in the first-order case.

Syntax

We assume that the readers are familiar with the basic notions and notations in classical first-order logic. A (first-

order) *default rule* (*rule* for short if clear from the context) is of the following form

$$\alpha_1 \mid \ldots \mid \alpha_n \leftarrow \beta_1, \ldots, \beta_m, \texttt{Not}\ \gamma_1, \ldots, \texttt{Not}\ \gamma_l, \quad (1)$$

where $\alpha_i, 1 \leq i \leq n$, $\beta_j, 1 \leq j \leq m$ and $\gamma_k, 1 \leq k \leq l$ are first-order formulas. A *default theory* is a set of rules of the form (1).

Intuitively, rule (1) means that if an agent believes that every $\beta_j, 1 \leq j \leq m$ is true, and the agent does not believe that any of $\gamma_k, 1 \leq k \leq l$ is true, then the agent must believe that at least one of $\alpha_i, 1 \leq i \leq n$ is true.

Given a rule r of the form (1), the set $\{\alpha_1, \ldots, \alpha_n\}$ is called the *head* of r, denoted by $Head(r)$; the set $\{\beta_1, \ldots, \beta_m\}$ is called the *positive body* of r, denoted by $Pos(r)$; the set $\{\texttt{Not}\ \gamma_1, \ldots, \texttt{Not}\ \gamma_l\}$ is called the *negative body* of r, denoted by $Neg(r)$;[1] also the set $\{\beta_1, \ldots, \beta_m, \texttt{Not}\ \gamma_1, \ldots, \texttt{Not}\ \gamma_l\}$ is called the *body* of r, denoted by $Body(r)$. Clearly, $Body(r) = Pos(r) \cup Neg(r)$.

Notice that the form (1) follows the well adopted syntactic form of rules in logic programming (in particular answer set programming), which actually differs from Reiter's original syntax of default rules as follows

$$\frac{\alpha(\overrightarrow{x}) : M\beta_1(\overrightarrow{x}), \ldots, M\beta_m(\overrightarrow{x})}{\omega(\overrightarrow{x})}, \quad (2)$$

where $\alpha(\overrightarrow{x})$, $\beta_i(\overrightarrow{x}), 1 \leq i \leq m$ and $\omega(\overrightarrow{x})$ are formulas and $\overrightarrow{x}$ is the set of free variables occurred in all these formulas. Intuitively, a rule of form (2) means that if an agent believes that $\alpha(\overrightarrow{x})$ is true and her/his beliefs are consistent with any of $\beta_j, 1 \leq j \leq m$, then the agent must believe that $\omega(\overrightarrow{x})$ is true. In addition, in Reiter's original syntax, a default theory is a pair (D, W), where D is a set of rules of the form (2) and $W = \{S_1, \ldots, S_k, \ldots\}$ is a set of sentences.

Our syntax is actually a generalization of Reiter's syntactic form in the sense that a rule of the Reiter's form

$$\frac{\alpha(\overrightarrow{x}) : M\beta_1(\overrightarrow{x}), \ldots, M\beta_m(\overrightarrow{x})}{\omega(\overrightarrow{x})}, \quad (3)$$

can be rewritten as

$$\omega(\overrightarrow{x}) \leftarrow \alpha(\overrightarrow{x}), \texttt{Not}\ \neg\beta_1(\overrightarrow{x}), \ldots, \texttt{Not}\ \neg\beta_m(\overrightarrow{x}) \quad (4)$$

in form (1), and a sentence $S \in W$ in a default theory (D, W) can be simply rewritten as

$$S \leftarrow$$

in form (1). Notice that the component $M\beta_j(\overrightarrow{x})$ in form (2) is actually corresponding to $\texttt{Not}\ \neg\beta_j(\overrightarrow{x})$ but not $\texttt{Not}\ \beta_j(\overrightarrow{x})$ in (4). Here, $\neg$ is the classical negation operator.

We say that a rule r of the form (1) is a *fact* if $Pos(r) = Neg(r) = \emptyset$, a *constraint* if $Head(r) = \emptyset$, *positive* if $Neg(r) = \emptyset$, a *logic programming rule* if all formulas occurred in r (i.e. $\alpha_i, 1 \leq i \leq n$, $\beta_j, 1 \leq j \leq m$, $\gamma_k, 1 \leq k \leq l$) are atoms, *closed* if all formulas occurred in r are closed.

We say that a default theory is a *classical theory* if every rule in it is a fact, a *logic program* if every rule in it is a logic programming rule, *normal* if every rule in it is normal, *closed* if every rule in it is closed.

[1]The head, the positive body and the negative body of a default rule are also called consequent/conclusion, prerequisite and justification respectively in the literature.

Defining the World View Semantics

We start to define the world view semantics for first-order default logic.

Definition 1 (Configuration). Let τ be a vocabulary. A *configuration* of τ is a tuple $\Delta = (A, c_1^{\mathcal{A}}, \cdots, c_m^{\mathcal{A}}, f_1^{\mathcal{A}}, \cdots, f_l^{\mathcal{A}})$, where A is the domain, $c_1^{\mathcal{A}}, \cdots, c_m^{\mathcal{A}}$ are the constant mappings and $f_1^{\mathcal{A}}, \cdots, f_l^{\mathcal{A}}$ are the function interpretations.

A configuration Δ can be extended into a structure $\mathcal{M}$ by interpreting the predicates. In this case, we say that Δ is the configuration of $\mathcal{M}$, and conversely, $\mathcal{M}$ is a structure on Δ. We use $\Delta^{\mathcal{M}}$ to denote the configuration of $\mathcal{M}$. Then notion of configuration is analogous to the notion of pre-interpretation introduced by Kaminski (1995).

Definition 2 (View). A *view* of a vocabulary τ is a collection of τ-structures with the same configuration, i.e., sharing the same domain, constant mappings and function interpretations. More precisely, let Δ be a configuration, a view $\mathcal{W}$ on Δ is a collection $\mathcal{M}_1, \ldots, \mathcal{M}_t, \ldots$ of structures such that for all t, $\Delta^{\mathcal{M}_t} = \Delta$.

Here, we say that Δ is the configuration of $\mathcal{W}$. Sometimes we use $\Delta^{\mathcal{W}}$ to denote the configuration of $\mathcal{W}$ for better readability. Intuitively, a view represents an agent's belief in the sense that each structure in the view is corresponding to a possible world.

We now define the satisfaction relation between views associated with assignments and default rules. Let r be a rule of the form (1), $\mathcal{W} = \{\mathcal{M}_1, \ldots, \mathcal{M}_t, \ldots\}$ a view and η an assignment. We say that $\mathcal{W}$ *satisfies* r on η, denoted by $\mathcal{W} \models r[\eta]$, if

(†) $\mathcal{W} \models Pos(r)[\eta]$ and $\mathcal{W} \not\models Neg(r)[\eta]$ implies that $\mathcal{W} \models Head(r)[\eta]$.

As the default part (i.e. the negative body) of a default rule plays a role of assumption, we also need a different notion to define the satisfaction relation by fixing this part. Let r be a rule of the form (1), $\mathcal{W} = \{\mathcal{M}_1, \ldots, \mathcal{M}_t, \ldots\}$ and $\mathcal{W}' = \{\mathcal{M}'_1, \ldots, \mathcal{M}'_t, \ldots\}$ two views, and η an assignment. We say that $\mathcal{W}'$ *satisfies* r on η by fixing the default part with $\mathcal{W}$, denoted by $(\mathcal{W}', \mathcal{W}) \models r[\eta]$, if

(‡) $\mathcal{W}' \models Pos(r)[\eta]$ and $\mathcal{W} \not\models Neg(r)[\eta]$ implies that $\mathcal{W}' \models Head(r)[\eta]$.

Let Π be a default theory, η an assignment and $\mathcal{W}$ and $\mathcal{W}'$ two views. We say that $\mathcal{W}$ *satisfies* Π on η, denoted by $\mathcal{W} \models\!\!\models \Pi[\ \eta]$, if for all $r \in \Pi$, $\mathcal{W} \models r[\eta]$. We say that $\mathcal{W}$ *satisfies* Π, denoted by $\mathcal{W} \models\!\!\models \Pi$, if for all assignments η, $\mathcal{W} \models\!\!\models \Pi[\ \eta]$. We say that $\mathcal{W}'$ *satisfies* Π on η by fixing the default part with $\mathcal{W}$, denoted by $(\mathcal{W}', \mathcal{W}) \models\!\!\models \Pi[\ \eta]$, if for all $r \in \Pi$, $(\mathcal{W}', \mathcal{W}) \models r[\eta]$. We say that $\mathcal{W}'$ *satisfies* Π by fixing the default part with $\mathcal{W}$, denoted by $(\mathcal{W}', \mathcal{W}) \models \Pi$, if for all assignments η, $(\mathcal{W}', \mathcal{W}) \models\!\!\models \Pi[\ \eta]$.

The following property holds straightforwardly from the definitions.

Proposition 1. *Let Π be a default theory and $\mathcal{W}$ a view. Then, $(\mathcal{W}, \mathcal{W}) \models \Pi$ iff $\mathcal{W} \models \Pi$.*

Definition 3 (World View). Let Π be a default theory and $\mathcal{W}$ a view. We say that $\mathcal{W}$ is a *world view* of Π if $\mathcal{W} \models \Pi$

and there does not exist another view $\mathcal{W}'$ such that $\mathcal{W} \subset \mathcal{W}'$ and $(\mathcal{W}', \mathcal{W}) \models \Pi$.

Intuitively, a world view of a default theory is a maximal collection of structures satisfying the default theory, where the default part is fixed by the world view itself. Definition 3 can be presented in an alternative way closer to Reiter's original fixed-point definition. Let Π be a default theory and $\mathcal{W}$ a view such that $\mathcal{W} \models \Pi$, by $\Gamma(\mathcal{W})$, we denote the maximal view (in terms of set inclusion) satisfying the following conditions:

- $\mathcal{W} \subseteq \Gamma(\mathcal{W})$.
- $(\Gamma(\mathcal{W}), \mathcal{W}) \models \Pi$.

Notice that a drawback of this definition is that one needs to assure that such a $\Gamma(\mathcal{W})$ always exists (although this is indeed the case under our context). Clearly, $\mathcal{W}$ is a world view of Π iff $\mathcal{W}$ is the fixed point of the operator Γ, i.e., $\mathcal{W} = \Gamma(\mathcal{W})$.

The world view semantics has many origins from the literature. The term world view is borrowed from (Gelfond 1994), although the semantics is defined in a very different manner. Definition 3 actually follows the well known Gelfond-Lifschitz reduct semantics for propositional answer set programming, that is, an answer set of a propositional logic program is a maximal set of propositional atoms satisfying the reduct of the program relative to this set. Here, $(\mathcal{W}', \mathcal{W}) \models \Pi$ is analogous to $\mathcal{W}' \models \Pi^{\mathcal{W}}$, where $\Pi^{\mathcal{W}}$ is the reduct of Π relative to $\mathcal{W}$. However, we cannot use the notation of reduct $\Pi^{\mathcal{W}}$ here in our world view semantics as it is not a real program or default theory.

Of course, Definition 3 shares some basic ideas of Reiter's original semantics. On one side, the default part plays a role of assumptions, which is fixed by a candidate. On the other side, the world view semantics can also be defined in a fixed point style as shown before. However, the main difference between the world view semantics and Reiter's original semantics is that the solution concept for the former is defined upon views (i.e. collections of structures), while the one for the latter is defined upon first-order theories (i.e. collections of sentences). Note that collections of structures and first-order theories correspond to each other in the sense that all the models of a first-order theory form a collection of structures. We shall discuss later in the paper why we need to define upon collections of structures rather than collections of sentences for first-order open default theories, and the detailed relationships between the world view semantics and Reiter's original one.

Relationships to Reiter's Semantics

In this section, we study the relationships between the world view semantics and Reiter's extension semantics (Reiter 1980). Clearly, for open default theories, the world view semantics is very different from Reiter's extension semantics. In fact, this is indeed the case even for closed default theories as well. The key reason why these two semantics behave quite differently, even for closed default theories, is that all views are forced to have the same configuration. This is because a configuration itself includes some information, for instance, the domain size and the mapping of terms.

Nevertheless, these two semantics coincide if we only consider the first-order sentences whose satisfiability is independent of a configuration. We say that a first-order sentence ϕ is *configuration independent* if that ϕ is consistent implies that ϕ has a model on every configuration. We say that a closed default theory is *configuration independent* if all formulas occurring in every rule in the default theory are configuration independent.

Theorem 1. *Let Π be a configuration independent closed default theory. If a first-order theory E is an extension of Π, then for any configuration Δ, the set of models of E on Δ is a world view of Π. Conversely, if a view $\mathcal{W}$ on a configuration Δ is a world view of Π, then there exists an extension E of Π such that $\mathcal{W}$ is the set of models of E on Δ.*

Corollary 2. *Let Π be a propositional default theory. Then, a formula F is equivalent to an extension of Π iff the set of models of F is a world view of Π.*

Classical First-Order Logic + First-Order Answer Set Programming

In this section, we show how the world view semantics generalizes both classical first-order logic and first-order answer set programming. We also argue that first-order default logic provides a rich framework for integrating them.

Theorem 3. *Let S be a set of first-order sentences and Δ a configuration such that S has models on Δ. Then, S has a unique world view on Δ, which is the class of all models of S on Δ.*

Next, we show that the stable model semantics for first-order answer set programming is a special case of the world view semantics for first-order default theories as well. A first-order logic program is a special case of first-order default rules except that the formulas occurring in rules are atoms. The semantics for first-order logic programs can be defined through by a transformation into second-order logic (Ferraris, Lee, and Lifschitz 2011; Zhou and Zhang 2011).

Theorem 4. *Let Π be a logic program. If a structure $\mathcal{M}$ is a stable model of Π, then $\mathcal{M}^+$ is a world view of Π, where $\mathcal{M}^+$ contains all structures on the same configuration bigger than $\mathcal{M}$.[2] Conversely, if a view $\mathcal{W}$ is a world view of Π, then the structure on the same configuration that interprets each predicate P as $\bigcap_{\mathcal{M} \in \mathcal{W}} P^{\mathcal{M}}$ is a stable model of Π.*

Theorems 3 and 4 show that both classical first-order logic and first-order answer set programming can be considered as special cases of first-order default logic. Moreover, we argue that default logic not only generalizes classical logic and answer set programming but also integrates them in a natural way. In the propositional case, propositional default logic provides an ideal framework for integrating classical propositional logic and propositional answer set programming. Lifted into the first-order case, first, the syntax of first-order default theory combines the syntax of both classical logic and logic programming. For semantics, Theorem 3 and

[2] We say that a structure $\mathcal{M}'$ is bigger than another structure $\mathcal{M}$ if for all predicates P, $P^{\mathcal{M}} \subseteq P^{\mathcal{M}'}$.

Theorem 4 show respectively that classical first-order logic and first-order disjunctive logic programming under the stable model semantics can be viewed as special cases of first-order default logic. Moreover, classical logic and logic programming actually form two different dimensions of first-order default logic, where the classical logic dimension is corresponding to the interrelationships among structures in a world view and the logic programming dimension is corresponding to the interrelationships among different world views.

Related Work

A number of alternative semantics have been proposed to address the unsatisfactory semantics for open defaults (Poole 1987; Lifschitz 1990; Baader and Hollunder 1995; Kaminski 1995; 1999). As far as we know, this problem was firstly reported by Poole (1987), who also provided an alternative solution by using Hilbert's ε-symbol. However, Baader and Hollunder (1995) pointed out that, although improved, this semantics is still not that satisfactory as it cannot escape from Skolemization. Instead, Baader and Hollunder considered a weak semantics, in which default rules only apply to known individuals.

The idea of using collections of structures as the solution concept for default logic is not new. This was presented by Guerreiro and Casanova for closed default theories (Guerreiro and Casanova 1990), and later extended by Lifschitz for open default theories restricted to a fixed universe (Lifschitz 1990). Lifschitz fixed a pre-given universe and extended the language by introducing a new constant for each element in the universe. An extension of a default theory is then defined as the set of sentences satisfied by a class of structures, which is a fixed point of an operator similar to Reiter's Γ operator but defined on classes of structures. Kaminski pointed out some problems with Lifschitz's approach, for instance, a default theory is not equivalent to its grounded version under the domain closure assumption (Kaminski 1995). Instead, Kaminski modified Lifschitz's semantics by fixing a pre-given infinite Herbrand universe as well as the interpretations of functions (Kaminski 1995).

In fact, the world view semantics can be regarded as a modification of Lifschitz's and Kaminski's approaches. However, there are three major differences. First, we do not introduce any new universe and we do not need to extend the language by introducing a new constant for each domain element in the new universe. Second, we do not ground on Herbrand universe nor on any other domains. Finally, we do not use the notion $Th(W)$ to denote the set of sentences satisfied by a structure or a class of structures. Although this notion is well defined, one has to be very careful as not every class of structures is corresponding to a set of first-order sentences. We regard the world view semantics as a purely model theoretical approach. Similar to the classical first-order semantics, the notions and notations used in the world view semantics are merely restricted in the language of the default theory.

Conclusion

The main contribution of this paper is the world view semantics for first-order default logic. Roughly speaking, a world view of a default theory is a maximal class of structures sharing the same configuration and satisfying the default theory, where the default part is fixed by the world view itself. A major rationale for using collections of structures as the solution concept is that first-order theories, such as extensions, are not powerful enough to capture all information hidden in a first-order default theory. The world view semantics is essentially different from Reiter's original proposal, even for closed default theories. Nevertheless, they coincide on configuration independent closed default theories. First-order default logic under the world view semantics provides a rich framework for knowledge representation and reasoning as it not only generalizes but also integrates classical first-order logic and first-order answer set programming.

Ontology-Based Monitoring of Dynamic Systems*

Franz Baader
Theoretical Computer Science, TU Dresden
Nöthnitzer Str. 46, 01062 Dresden, Germany
baader@tcs.inf.tu-dresden.de

Abstract

Our understanding of the notion "dynamic system" is a rather broad one: such a system has states, which can change over time. Ontologies are used to describe the states of the system, possibly in an incomplete way. Monitoring is then concerned with deciding whether some run of the system or all of its runs satisfy a certain property, which can be expressed by a formula of an appropriate temporal logic. We consider different instances of this broad framework, which can roughly be classified into two cases. In one instance, the system is assumed to be a black box, whose inner working is not known, but whose states can be (partially) observed during a run of the system. In the second instance, one has (partial) knowledge about the inner working of the system, which provides information on which runs of the system are possible.

In this paper, we will review some of our recent work that can be seen as instances of this general framework of ontology-based monitoring of dynamic systems. We will also mention possible extensions towards probabilistic reasoning and the integration of mathematical modeling of dynamical systems.

Introduction

In this paper we use the term "dynamic system" to denote a system that shows dynamic behavior in that it changes its states over time. Here "system" is seen in a broad sense, encompassing both man-made systems and natural systems: it may be a computer system, air traffic observed by radar, a patient in an intensive care unit, or a biological cell. We make no general assumptions about the form of the system's states, except that the states can be described using an appropriate ontology language. These descriptions may be incomplete (partial) in the sense that they do not uniquely determine a single state, but only restrict the possible states to a subset of all states.

In the case of a *black box* system, we have no information on how the system works internally, i.e., we do not know which state is transformed into which other state. In this setting, we assume that the system is observed by certain "sensors" (e.g., heart-rate and blood pressure monitors for a patient), and the results of sensing are stored in a fact base expressed using the given ontology language. Based on the information stored in the fact base, the monitor is supposed to detect certain predefined situations (e.g., heart-rate very high and blood pressure low), which require a reaction (e.g., fetch a doctor or give medication). More precisely, sensor readings are available for different points in time, and thus we obtain a time-stamped sequence of fact bases, each describing (possibly in an incomplete way) the state of the system at the respective time point. The situations to be described may be concerned with not just one state of the system, but a sequence of states (e.g., blood pressure decreasing and heart-rate increasing for a certain time). To describe such situations, the ontology language needs to be combined with an appropriate temporal logic.

In the case of a *white box* system, we have some knowledge about the inner working of the system, i.e., we have a specification of how states of the system are transformed into each other. This description may, however, be nondeterministic in the sense that a given state may not have a uniquely determined successor state, but a set of possible successor states. Given a (possibly incomplete) description of an initial state, the specification then determines a set of possible runs of the system, and we may ask whether some or all of these runs satisfy a certain property, formulated in an appropriate temporal logic.

Of course, we may also have a *combination* of both settings, where a (partial) specification of the system is available, and in addition one can observe the system during one of its runs.

In the following, we will review some of our recent work that can be seen as instances of the general framework of ontology-based monitoring of dynamic systems outlined above. Because of space limitations, we cannot introduce the technical definitions and results in detail. For these and also for detailed descriptions of related work we refer the reader to the cited papers. The ontology languages used in these papers are based on description logics. Again, we do not introduce them in detail, but refer the reader to "The Description Logic Handbook" (Baader et al. 2003) for a comprehensive introduction. We will finish this short paper with mentioning possible extensions of the described approaches towards probabilistic reasoning and the integration of mathematical modeling of dynamical system.

Monitoring Black Box Systems

As mentioned in the introduction, an important ingredient of such a monitoring approach is an appropriate temporal logic, which enables the specification of situations whose definition depends on several of the observed states of the system.

The temporal logic $\mathcal{ALC}$-LTL

Motivated by a situation awareness application (Baader et al. 2009), in which the system was air and marine traffic observed by radar, we have introduced the temporalized description logic $\mathcal{ALC}$-LTL (Baader, Ghilardi, and Lutz 2008; 2012) as such a logic. It combines the ontology language $\mathcal{ALC}$ with the propositional linear temporal logic LTL. Since the temporal structure underlying LTL are the natural numbers, this means that we consider a discrete flow of time. In contrast to propositional LTL, the states are not propositional valuations, but $\mathcal{ALC}$ interpretations, i.e., relational structures with unary predicates (concepts) and binary predicates (roles).

An important design decision for $\mathcal{ALC}$-LTL was, on the one hand, to restrict the application of temporal operators to $\mathcal{ALC}$ axioms, i.e., terminological axioms of the form $C \sqsubseteq D$ and assertional axioms of the form $C(a)$ and $r(a, b)$, where C, D are concepts, r a role, and a, b individuals. From a syntactic point of view, $\mathcal{ALC}$-LTL is obtained from propositional LTL by allowing the use of $\mathcal{ALC}$ axioms in place of propositional variables. For example, the $\mathcal{ALC}$-LTL formula

$$\Diamond\Box(\mathsf{UScitizen} \sqsubseteq \exists \mathsf{insured\_by}.\mathsf{HealthInsurer})$$

says that there is a future time point from which on US citizens will always have health insurance, and the formula

$$\Diamond\big((\exists \mathsf{finding}.\mathsf{Concussion})(\mathsf{BOB}) \wedge \mathsf{Conscious}(\mathsf{BOB})\,\mathsf{U}\,(\exists \mathsf{procedure}.\mathsf{Examination})(\mathsf{BOB})\big)$$

says that, sometime in the future, Bob will have a concussion with no loss of consciousness between the concussion and the examination. However, what cannot be expressed in $\mathcal{ALC}$-LTL is the general concept of a concussion with no loss of consciousness since expressing this concept would require the application of temporal operators within the concept:

$$\exists \mathsf{finding}.\mathsf{Concussion} \sqcap \mathsf{Conscious}\,\mathsf{U}\,\exists \mathsf{procedure}.\mathsf{Examination}.$$

On the other hand, the second important design decision was to allow for rigid concepts and roles, i.e., concepts/roles whose interpretation does not vary over time. For example, the concept Human and the role has_father should probably be rigid since a human being will stay a human being and have the same father over his/her lifetime, whereas Conscious should be a flexible concept (i.e., not rigid) since someone that is conscious at the moment need not always by conscious. Similarly, insured_by should be modeled as a flexible role. Using a logic that cannot enforce rigidity of concepts/roles may result in unintended models, and thus prevent certain useful inferences to be drawn. For example, the concept description $\exists \mathsf{has\_father}.\mathsf{Human} \sqcap \Diamond\,(\forall \mathsf{has\_father}.\neg\mathsf{Human})$ is only unsatisfiable if both has_father and Human are rigid. It should be noted that rigid concepts and roles provide some information about the inner working of the system since they tell us that their interpretation cannot be changed by state transitions.

While rigid concepts and roles increase the expressive power of the formalism, they are problematic from a computational point of view. In fact, in a logic that allows the application of temporal operators within concepts, rigid roles can even cause undecidability (Gabbay et al. 2003). In $\mathcal{ALC}$-LTL, rigid concepts and roles are less harmful, but they still increase the complexity of reasoning: the satisfiability problem in $\mathcal{ALC}$-LTL is 2-ExpTime-complete if both rigid concepts and roles are allowed; NExpTime-complete if only rigid concepts, but no rigid roles are allowed; and ExpTime-complete if neither concepts nor roles may be rigid.

These results are relevant for the monitoring of dynamic systems since it is easy to see that the monitoring problem can indeed be expressed as a satisfiability problem in $\mathcal{ALC}$-LTL: assume that ψ is an $\mathcal{ALC}$-LTL formula expressing a critical situation (e.g., the formula talking about Bob from above); that ϕ_t is an $\mathcal{ALC}$-LTL formula describing the observations made until time point t (e.g., observations made at certain time points by nurses or heart-rate sensors, and compiled into an $\mathcal{ALC}$-LTL formula using the next-operator); and ϕ is a conjunction of terminological axioms expressing (atemporal) background information (e.g., a medical ontology). Then the critical situation can be detected by testing whether the $\mathcal{ALC}$-LTL formula $\Box\phi \wedge \phi_t \wedge \neg\psi$ is satisfiable.

Runtime verification

A potential problem with the monitoring approach sketched above is that the size of the formula ϕ_t increases with every additional time point at which an observation is made, and thus one needs to solve ever larger satisfiability problems. For propositional LTL, this problem has been addressed in the runtime verification community: for a given LTL formula ψ a monitor M_ψ (i.e., a deterministic finite automaton with state output) is constructed whose size depends only on the formula describing the critical situation, and not on the number of time points (Bauer, Leucker, and Schallhart 2011). At each time point, the observations lead to a transition of the monitor, and the output of the state reached through this transition says whether ψ has been violated or not.

Building on results from (Baader, Ghilardi, and Lutz 2008; 2012), we have shown in (Baader, Bauer, and Lippmann 2009) that this approach can be extended from propositional LTL to $\mathcal{ALC}$-LTL. The main advantage of this extension over the propositional case is, on the one hand, that one can employ ontologies defining the important concepts of the application domain (e.g., concepts defined in a medical ontology) to describe critical situations. On the other hand, in contrast to runtime verification for propositional LTL, where for every time point one assumes to have complete information about the values of the propositional variables, the approach developed in (Baader, Bauer, and Lippmann 2009) can also deal with incomplete information. Improving on the results in (Baader, Bauer, and Lippmann

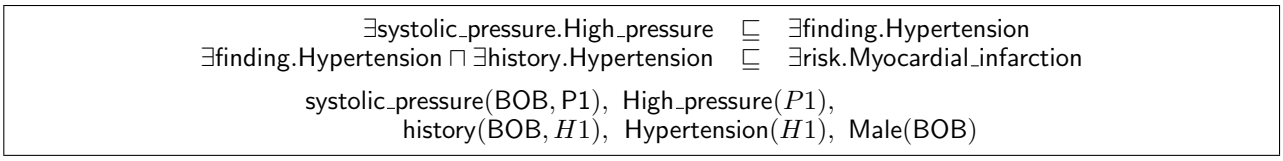

Figure 1: An ontology and a fact base

2009), where some of the monitor constructions were triple-exponential, we show in (Baader and Lippmann 2014) that, for a given $\mathcal{ALC}$-LTL formula ψ, a monitor M_ψ of double-exponential size can be constructed in double-exponential time. In general, this double-exponential blow-up cannot be avoided, even in the propositional case.

Temporalizing ontology-based data access

In (Baader, Borgwardt, and Lippmann 2013), we introduce an extension of $\mathcal{ALC}$-LTL where conjunctive queries using concepts and roles as predicates can be used in place of $\mathcal{ALC}$ axioms. For example, the conjunctive query

$$\exists y.\mathsf{risk}(x, y) \wedge \mathsf{Myocardial\_infarction}(y) \wedge \mathsf{Male}(x)$$

asks for male patients that are at risk to have a heart attack. The obvious difference to $\mathcal{ALC}$ axioms is the use of variables in conjunctive queries. On the one hand, there are the free variables (called answer variables): for these (x in the example) one wants to find named individuals such that replacing the variable by the individual name makes the query true. On the other hand, there are existentially quantified variables, which may refer to unnamed individuals. In our example, the myocardial infarction y need not have an explicit name in the fact base. Answering such queries w.r.t. an ontology is called *ontology-based data access*. Here one assume that one has a fact base, consisting of assertions, and an ontology, consisting of terminological axioms. As an example, assume that the fact base contains the assertions about the patient Bob shown in the lower part of Figure 1, which say that Bob has high blood pressure (obtained from sensor data), and is male and has a history of hypertension (obtained from the patient record). In addition, we have an ontology that says that patients with high blood pressure have hypertension and that patients that currently have hypertension and also have a history of hypertension are at risk for a heart attack, as shown in the upper part of Figure 1. The situation we want to recognize for a given patient x is whether this patient is a male person that is at risk for a heart attack, which is described by the conjunctive query from above. Given the information in the fact base and the axioms in the ontology, we can derive that Bob satisfies this query. Obviously, without the ontology this answer could not be derived.

The complexity of OBDA, i.e., the complexity of checking whether a given tuple of individuals is an answer of a conjunctive query in a fact base w.r.t. an ontology, has been investigated in detail for cases where the ontology is expressed in an appropriate description logic. One can either consider the *combined complexity*, which is measured in the size of the whole input (consisting of the query, the ontology, and the fact base), or the *data complexity*, which is measured in the size of the fact base only (i.e., the query and the ontology are assumed to be of constant size). The underlying assumption is that query and ontology are usually relatively small, whereas the size of the data may be huge. In the database setting (where there is no ontology and closed world assumption is used), answering conjunctive queries is NP-complete w.r.t. combined complexity and in AC^0 w.r.t. data complexity. For OBDA w.r.t. $\mathcal{ALC}$ ontologies, the complexity is considerably higher: ExpTime-complete w.r.t. combined complexity and coNP-complete w.r.t. data complexity (Calvanese, De Giacomo, and Lenzerini 1998; Lutz 2008; Calvanese et al. 2006).

In (Baader, Borgwardt, and Lippmann 2013), we have extended these results to temporal conjunctive queries, which are obtained from LTL by replacing propositional variables with conjunctive queries. The complexity again depends on whether rigid concepts/roles are allowed or not. For the combined complexity, the obtained complexity results are identical to the ones for $\mathcal{ALC}$-LTL, though the upper bounds are considerably harder to show. For data complexity, we obtain the same complexity as for atemporal OBDA (coNP-complete) if no rigid roles are allowed. With rigid roles, we have an ExpTime upper bound (in contrast to 2-ExpTime for combined complexity), but can only show a coNP lower bound.

Monitoring White Box Systems

In this setting, one assumes that one has some knowledge about the inner working of the system, i.e., a (possibly incomplete) specification of how states of the system are transformed into each other. In principle, such a specification could be provided by an appropriate temporal logic. However, there are some problems with this approach. First, such a specification may require a temporalized description logic in which temporal operators can be applied within concepts, which may cause computational problems. Second, in addition to saying what changes during a state transition, one also needs to specify what does not change. This so-called *frame problem* has been investigated in detail in the *reasoning about actions* community. In (Baader et al. 2005; Baader, Lippmann, and Liu 2010) we have introduced action formalisms based on description logics, which inherit Reiter's solution to the frame problem from situation calculus (Reiter 2001).

Based on an action theory defined in such a formalism, one can specify the inner working of a system (e.g., an autonomous robot) using the action programming language Golog (de Giacomo, Lespérance, and Levesque 2000). In this setting, rather than monitoring a single run of the system, we are interested in the *verification problem*: show that certain (temporal) properties are satisfied by any run of the

program. The first attempt to solve the verification problem for action theories based on description logics can be found in (Baader, Liu, and ul Mehdi 2010). However, instead of examining the actual execution sequences of a given Golog program, this approach considers infinite sequences of actions that are accepted by a given Büchi automaton $\mathcal{B}$. If this automaton over-approximates the program, i.e. all possible execution sequences of the program are accepted by $\mathcal{B}$, then any property that holds in all the sequences accepted by $\mathcal{B}$ is also a property that is satisfied by any execution of the program. As logic for specifying properties of infinite sequences of actions, the approach again uses $\mathcal{ALC}$-LTL. In (Baader and Zarrieß 2013), we improve on the results in (Baader, Liu, and ul Mehdi 2010) by directly considering all (finite and infinite) sequences of actions that are runs of a given Golog program.

Future Research

One important topic for future research are extensions towards probabilistic reasoning. Probabilities may come into our framework of ontology-based monitoring of dynamic systems for a variety of reasons: sensors used to populate the fact base may be erroneous with some probability; based on the observed run of the system, one may compute projections into the future, which are again equipped with a probability; the application of an action may have probabilistic outcomes (the action may, e.g., succeed only with some probability).

Another interesting topic is the integration of numerical sensor values. In the black box setting, these values can be represented using description logics with concrete domains (Lutz 2003), which may, however, cause computational problems. In the white box setting, one needs approaches for describing how the numerical values change of time. One possibility for expressing this is to use systems of differential equations, as done in mathematical modeling of dynamical systems (Scheinerman 2012).

Datalog+/–: Questions and Answers

Georg Gottlob and **Thomas Lukasiewicz** and **Andreas Pieris**

Department of Computer Science, University of Oxford, UK
firstname.lastname@cs.ox.ac.uk

• *What is Datalog$^\pm$ and what are its advantages?*

Datalog$^\pm$ is a rule-based formalism that combines the advantages of logic programming in Datalog with features for expressing ontological knowledge and advanced data modeling constraints. Datalog$^\pm$ provides a uniform framework for query answering and reasoning with incomplete data. It generalizes disparate other KR formalisms such as plain Datalog, description logics (DLs), in particular, DL-Lite and $\mathcal{EL}$, F-Logic Lite, highly relevant fragments of UML class diagrams, data-exchange formalisms, graph query languages such as SPARQL, and so on. Datalog$^\pm$ is a conceptually very simple and clear cut formalism that extends plain Datalog with features such as existential quantifiers, equalities, and the falsum ($\bot$) in rule heads and, at the same time, restricts the rule syntax so as to achieve decidability and, when required, tractability. Its closeness to logic programming allowed us to enrich it by non-monotonic negation under the stratified, well-founded, and stable model semantics.

• *How do Datalog$^\pm$ rules look like?*

A self-explanatory set of Datalog$^\pm$ rules follows:

$$\begin{array}{ll}\sigma_1 & : \ emp(X) \ \rightarrow \ \exists Y \ hasMgr(X,Y), emp(Y), \\ \sigma_2 & : \ hasMgr(X,Y), emp(X) \ \rightarrow \ emp(Y), \\ \sigma_3 & : \ emp(X), emp(Y) \ \rightarrow \ colleagueOf(X,Y), \\ \sigma_4 & : \ emp(X) \ \rightarrow \ \exists Y \ worksIn(X,Y), dept(Y).\end{array}$$

Such rules are also known as *tuple-generating dependencies (tgds)*. All variables that are not existentially quantified are assumed to be universally quantified. We just omit the universal quantifiers in front of such rules. As will be pointed out later, Datalog$^\pm$ rules may also contain equalities and the falsum symbol ($\bot$) in their heads.

• *Which reasoning tasks are considered with Datalog$^\pm$?*

The main reasoning task is query answering under the so-called *certain-answers semantics*. If $Q(\mathbf{X})$ is a conjunctive query (CQ) or a union of conjunctive queries (UCQ) with free variables $\mathbf{X}$, D a database over a domain (universe) Δ whose tuples are interpreted in the usual way as ground facts, and Σ a Datalog$^\pm$ program (a.k.a. Datalog$^\pm$ ontology), then the answer to Q consists of all those tuples $\mathbf{a}$ of Δ-elements such that $D \cup \Sigma \models Q(\mathbf{a})$. For Boolean queries, the answer is, accordingly, *true* or *false*. Other relevant reasoning tasks are instance checking, query containment and consistency (or satisfiability) checking. These latter tasks are, however, easily reduced to Boolean query answering.

• *Which are the main decidable Datalog$^\pm$ languages?*

There are so far three main paradigms which extend plain Datalog with existential quantifiers in rule heads, and also guarantee the decidability of query answering:

Weakly-acyclic Datalog$^\pm$, based on weakly acyclic tgds introduced in the context of data exchange (Fagin et al. 2005), guarantees the existence of a finite universal model, which in turn implies the decidability of query answering. The rules $\{\sigma_2, \sigma_3, \sigma_4\}$ given above form a weakly-acyclic set of Datalog$^\pm$ rules. Extensions of weak-acyclicity have been studied, e.g., in (Marnette 2009; Grau et al. 2013).

Guarded Datalog$^\pm$ ensures the existence of treelike universal models, which in turn implies the decidability of query answering (Calì, Gottlob, and Kifer 2013). A rule is guarded if it has an atom which contains all the body-variables; e.g., the rules $\{\sigma_1, \sigma_2, \sigma_4\}$. An important subclass of guarded Datalog$^\pm$ is linear Datalog$^\pm$, where rules have only one body-atom, e.g., the rules $\{\sigma_1, \sigma_4\}$. Extensions of guardedness have been studied in (Baget et al. 2011).

Sticky Datalog$^\pm$ guarantees the termination of backward resolution, and thus the decidability of query answering (Calì, Gottlob, and Pieris 2012). The key idea underlying stickiness is that the body-variables which are in a join always are propagated (or "stick") to the inferred atoms; e.g., the set of rules $\{\sigma_1, \sigma_3, \sigma_4\}$. The main goal of stickiness was the definition of a language that allows for joins in rule-bodies, which are not always expressible via guarded rules.

Interestingly, the consolidation of the above paradigms leads to more expressive decidable formalisms. Notable examples are *glut-guardedness* (Krötzsch and Rudolph 2011), obtained by combining weak-acyclicity and guardedness, *weak-stickiness* (Calì, Gottlob, and Pieris 2012), obtained by joining weak-acyclicity and stickiness, and *tameness*, obtained by combining guardedness and stickiness (Gottlob, Manna, and Pieris 2013). Another important language is *shy* Datalog$^\pm$ (Leone et al. 2012).

• *What about equalities and the falsum ($\bot$) in rule heads?*

Weakly-acyclic Datalog$^\pm$ can be safely combined with arbitrary equality rules, a.k.a. *equality-generating dependen-*

Language	Data Complexity	Combined Complexity
Weakly-acyclic Datalog$^{\pm}$	PTIME-complete UB: (Fagin et al. 2005, Cor. 4.3) LB: (Dantsin et al. 2001, Thm. 4.4)	2EXPTIME-complete UB: implicit in (Fagin et al. 2005) LB: (Calì, Gottlob, and Pieris 2012, Thm. 5.1)
Guarded Datalog$^{\pm}$	PTIME-complete UB: (Calì, Gottlob, and Lukasiewicz 2012, Thm. 6) LB: (Calì, Gottlob, and Lukasiewicz 2012, Thm. 6)	2EXPTIME-complete UB: (Calì, Gottlob, and Kifer 2013, Thm.6.1) LB: (Calì, Gottlob, and Kifer 2013, Thm.6.1)
Sticky Datalog$^{\pm}$	in AC_0 UB: (Calì, Gottlob, and Pieris 2012, Thm. 3.5)	EXPTIME-complete UB: (Calì, Gottlob, and Pieris 2012, Thm. 3.3) LB: (Calì, Gottlob, and Pieris 2012, Thm. 3.4)

Table 1: Complexity of query answering; UB and LB stands for upper and lower bound, respectively.

cies (egds), without destroying decidability of query answering (Fagin et al. 2005). However, this is not true for the other languages mentioned above. For those languages, to guarantee decidability, one has to somewhat restrict the interaction between egds and existential rules, for instance, by admitting *non-conflicting* egds only, see (Calì, Gottlob, and Lukasiewicz 2012; Calì, Gottlob, and Pieris 2012). The falsum ($\bot$) in rule heads can be easily treated since such rules (a.k.a. negative constraints) can be conceived as queries. Thus, a language which guarantees the decidability of query answering can be safely extended with this feature.

• *What is the complexity of query answering under the main Datalog$^{\pm}$ languages?*

The data complexity (the query and the set of rules are considered fixed) and combined complexity of query answering under the main Datalog$^{\pm}$ languages (enriched with equality and the falsum) are summarized in Table 1. In each cell, we have indicated where to find the results.

• *What are typical applications of Datalog$^{\pm}$?*

As already said, Datalog$^{\pm}$ is a framework for knowledge representation and reasoning, and for a variety of other applications. Three of its basic applications are (1) reasoning over conceptual models; (2) ontology querying; and (3) querying the semantic web. Let us give some more details for each of the above applications:

1. UML class diagrams (UCDs) are a widely adopted formalism for modeling the intensional structure of a software system. A fundamental property of UCDs is consistency, showing that the system is realizable in practice. Guarded Datalog$^{\pm}$ is powerful enough to capture a core fragment of UCDs, and in particular each diagram which is the result of a reverse engineering process. Thus, consistency of re-engineered UCDs, a key problem in software engineering, can be reduced to reasoning under guarded Datalog$^{\pm}$. This fact allows us to exploit mature and efficient database technology for solving the consistency problem of re-engineered UCDs, which sensibly improves the performance of existing approaches (Gottlob, Orsi, and Pieris 2014).

2. Description Logics (DLs) are a family of knowledge representation formalisms. It is well-known that reasoning under expressive DLs is very hard or even undecidable. For this reason, several lightweight DLs have been proposed in the literature. Two of the most prominent lightweight DLs are DL-Lite$_{\mathcal{R}}$ (Calvanese et al. 2007) and $\mathcal{EL}$ (Baader, Brandt, and Lutz 2005), which provide the logical underpinning for the OWL 2 QL and OWL 2 EL profiles of OWL 2, respectively. Interestingly, guarded Datalog$^{\pm}$ provides a unifying framework for the above DLs without losing tractability of query answering. More precisely, query answering under DL-Lite$_{\mathcal{R}}$ or $\mathcal{EL}$ can be reduced to query answering under guarded Datalog$^{\pm}$ (Calì, Gottlob, and Lukasiewicz 2012). Notice that guarded Datalog$^{\pm}$ is strictly more expressive than the above DLs. Sticky Datalog$^{\pm}$ is also more expressive than DL-Lite$_{\mathcal{R}}$ (Calì, Gottlob, and Pieris 2012).

Another example of a knowledge representation formalism which is captured by a slightly more expressive version of guarded Datalog$^{\pm}$, namely weakly-guarded Datalog$^{\pm}$, is F-Logic Lite (Calì, Gottlob, and Kifer 2013). F-Logic Lite (Calì and Kifer 2006) is an expressive restricted version of F-Logic, a well-known formalism, originally introduced for object-oriented deductive databases, but is now most frequently used for expressing Semantic Web ontologies.

3. The problem of querying RDF data is a central issue for the development of the Semantic Web. The query language SPARQL 1.1 was recently released, which includes entailment regimes for RDFS and OWL vocabularies, and a mechanism to express navigation patterns through regular expressions. However, there are still some useful navigation patterns that cannot be expressed in SPARQL 1.1, and the language lacks of a general mechanism to express recursive queries. With the aim of filling this gap, a query language called TriQ, based on weakly-guarded Datalog$^{\pm}$, has been recently proposed (Arenas, Gottlob, and Pieris 2014). In particular, if we focus on the OWL 2 QL profile of OWL 2, then every SPARQL query enriched with the above features can be naturally translated into a query expressed in TriQ, and also in a lightweight version of TriQ, called TriQ-Lite, which ensures tractability of query evaluation. Notice that TriQ captures EXPTIME; the upper bound has been established in (Arenas, Gottlob, and Pieris 2014), while the lower bound in (Gottlob, Rudolph, and Simkus 2014).

• *Apart from the modeling features mentioned above, what else is allowed in the existing Datalog$^{\pm}$ languages? For example, do you allow for negation in rule bodies?*

The most common semantics for nonmonotonic normal (logic) programs have been extended to Datalog$^{\pm}$ with negation in rule bodies. More precisely, we have studied guarded Datalog$^{\pm}$ with negation under the perfect model semantics (PMS) for the stratified case (Calì, Gottlob, and Lukasiewicz 2012), the well-founded semantics (WFS) (Gottlob et al. 2012a; Hernich et al. 2013), and the stable model semantics

(SMS) (Gottlob et al. 2014b). Actually, it is not difficult to define a negation semantics for Datalog$^{\pm}$, as is this inherited from its standard counterpart in normal logic programs with function symbols. In fact, existentially quantified variables can be replaced by Skolem terms in rule heads. The tricky part, however, is to show that Datalog$^{\pm}$ with negation under the new semantics remains decidable, and pinpoint the exact complexity of query answering.

The WFS comes in two flavors depending on whether the unique name assumption (UNA) is applied to Skolem terms or not. The first approach leads to the "equality-friendly" WFS (Gottlob et al. 2012a), while the second one leads to the standard WFS (Hernich et al. 2013). The SMS (Gelfond and Lifschitz 1988) is another predominating semantics for nonmonotonic normal programs. In (Gottlob et al. 2014b), we have defined and studied the SMS for guarded Datalog$^{\pm}$ under the UNA (note that an equality-friendly SMS with UNA also exists). There are cases in which the SMS leads to better query answers than the WFS. For example, given the fact $FiveStar(ritz)$ and the set of rules

$$FiveStar(X) \rightarrow Hotel(X),$$
$$FiveStar(X), \mathrm{not}\, Pool(X,Y) \rightarrow \exists Z\ Beach(X,Z),$$
$$FiveStar(X), \mathrm{not}\, Beach(X,Y) \rightarrow \exists Z\ Pool(X,Z),$$
$$Beach(X,Y) \rightarrow \exists Z\ SwimOpp(X,Z),$$
$$Pool(X,Y) \rightarrow \exists Z\ SwimOpp(X,Z),$$

only the atoms $FiveStar(ritz)$ and $Hotel(ritz)$ are entailed under the WFS, while the atom $SwimOpp(ritz)$ is additionally entailed under the SMS (as desired).

As several DLs can be embedded into Datalog$^{\pm}$, the decidability results for Datalog$^{\pm}$ with negation can also be applied to define decidable extensions of DLs with nonmonotonic negation. We have done this in particular for DL-Lite$_{\mathcal{R}}$ and DL-Lite$_{\mathcal{R},\sqcap}$ (Calvanese et al. 2007), as well as $\mathcal{ELHI}$ (Baader, Brandt, and Lutz 2005). The above example corresponds to the following set of DL axioms, expressed in an extension of $\mathcal{ELHI}$ by nonmonotonic negation:

$$\begin{aligned} FiveStar &\sqsubseteq \mathrm{Hotel}, \\ FiveStar \sqcap \mathrm{not}\exists Pool &\sqsubseteq \exists Beach, \\ FiveStar \sqcap \mathrm{not}\exists Beach &\sqsubseteq \exists Pool, \\ \exists Beach &\sqsubseteq \exists SwimOpp, \\ \exists Pool &\sqsubseteq \exists SwimOpp, \end{aligned}$$

• *Is Datalog$^{\pm}$ powerful enough for nondeterministic reasoning? In other words, can the existing languages enriched with disjunction in rule heads?*

Weakly-acyclic and guarded Datalog$^{\pm}$ (and their extensions) can be extended with disjunction, without sacrificing the decidability of query answering. In fact, the impact of disjunction on the complexity of query answering under guarded-based Datalog$^{\pm}$ languages has been recently investigated in (Gottlob et al. 2012b; Bourhis, Morak, and Pieris 2013). Unfortunately, the above decidability result does not hold for sticky Datalog$^{\pm}$. A recent (still unpublished) result shows that the combination of stickiness with disjunction leads to undecidability. This result gives rise to the question whether a restricted, yet meaningful fragment of sticky Datalog$^{\pm}$ can be isolated, which can be safely extended with disjunction. This will be the subject of future research.

• *What other developments have been made related to Datalog$^{\pm}$?*

1. Query rewriting has been extensively studied. Several algorithms have been designed with the aim of reducing the problem of query answering under Datalog$^{\pm}$ languages into evaluation of database queries (Gottlob, Orsi, and Pieris 2011; Orsi and Pieris 2011; Gottlob and Schwentick 2012; Gottlob et al. 2014a; Gottlob, Manna, and Pieris 2014a).

2. In (Gottlob et al. 2013), a probabilistic extension of Datalog$^{\pm}$ that is based on Markov logic networks as underlying probabilistic semantics is presented. It may, e.g., be used in data extraction from the Web.

3. In (Lukasiewicz, Martinez, and Simari 2012), a general framework for inconsistency management in Datalog$^{\pm}$ ontologies based on incision functions from belief revision is developed. It may, e.g., be used for handling inconsistencies in the Semantic Web.

4. Towards personalized semantic search (e.g., in social networks), in (Lukasiewicz, Martinez, and Simari 2013) an approach to preference-based query answering in ontologies, combining Datalog$^{\pm}$ with preference management as in relational databases, is presented.

5. Query answering under *finite* models has been also investigated. More precisely, query answering for most of the languages, without egds, mentioned above is *finitely controllable*. This means that the answers to a query remain exactly the same when, instead of considering arbitrary models, we restrict our attention to finite models. Finite controllability of query answering under (weakly-)guarded Datalog$^{\pm}$ was shown in (Bárány, Gottlob, and Otto 2010) (extending the work by (Rosati 2011)), under sticky Datalog$^{\pm}$ in (Gogacz and Marcinkowski 2013), and under tame Datalog$^{\pm}$ in (Gottlob, Manna, and Pieris 2014b).

• *Are there any other modeling features that will be added to Datalog$^{\pm}$?*

We are planning to investigate more expressive equality assertions and transitivity. Let us give some more details:

1. Though existing languages are powerful enough to express equality assertions, as said, this can only be done as long as the non-conflicting condition is satisfied. However, in real-life examples, new intensional knowledge may be inferred from the equality rules, which implies that the non-conflicting condition is violated. Hence, more general conditions, beyond the non-conflicting one, are needed.

2. Transitivity is partially captured by some Datalog$^{\pm}$ languages, e.g., weakly-sticky Datalog$^{\pm}$, as long as the necessary join operations are performed on finitely many values. However, this is not powerful enough for expressing some natural transitivity axioms. We only know that guarded-based Datalog$^{\pm}$ languages cannot be safely extended with transitivity since this leads to undecidability (Gottlob, Pieris, and Tendera 2013). Thus, the enrichment of Datalog$^{\pm}$ with this feature will be the subject of future substantial research.

• *Are there any implemented systems for reasoning over Datalog$^{\pm}$ languages?*

We know of three such systems: (1) Nyaya (Virgilio et al. 2012) is a system able to treat the first-order rewritable fragments of Datalog$^{\pm}$, that is, linear and sticky Datalog$^{\pm}$.

In fact, the given set of rules and query are compiled into an SQL query, which is then evaluated over the extensional database; (2) DLV$^{\exists}$ (Leone et al. 2012) implements a bottom-up evaluation strategy for shy Datalog$^{\pm}$ inside the well-known Answer Set Programming (ASP) system DLV (Leone et al. 2006); and (3) Alaska (König et al. 2012), similarly to Nyaya, is able to treat the first-order rewritable fragments of Datalog$^{\pm}$, and it is based on SQL-rewritings. The above are interesting prototypes which show that a complete system, which is able to effectively answer queries over Datalog$^{\pm}$ ontologies, is realistic. The implementation of such a system will be the subject of future research.
