Sponsors / xxiv

Full Papers

Answer Set Programming and Logic Programming

Logic Programs with Ordered Disjunction: First-Order Semantics and Expressiveness / 2
Vernon Asuncion, Yan Zhang, Heng Zhang

Constructive Negation in Extensional Higher-Order Logic Programming / 12
Angelos Charalambidis, Panos Rondogiannis

The Well-Founded Semantics Is the Principle of Inductive Definition, Revisited / 22
Marc Denecker, Joost Vennekens

The Semantics of Gringo and Infinitary Propositional Formulas / 32
Amelia Harrison, Vladimir Lifschitz, Fangkai Yang

Argumentation

An SCC Recursive Meta-Algorithm for Computing Preferred Labellings in Abstract Argumentation / 42
Federico Cerutti, Massimiliano Giacomin, Mauro Vallati, Marina Zanella

On the Revision of Argumentation Systems: Minimal Change of Arguments Statuses / 52
Sylvie Coste-Marquis, Sébastien Konieczny, Jean-Guy Mailly, Pierre Marquis

A Dynamic Logic Framework for Abstract Argumentation / 62
Sylvie Doutre, Andreas Herzig, Laurent Perrussel

Characteristics of Multiple Viewpoints in Abstract Argumentation / 72
Paul E. Dunne, Wolfgang Dvorák, Thomas Linsbichler, Stefan Woltran

Automated Reasoning and Computation

The Parameterized Complexity of Reasoning Problems Beyond NP / 82
Ronald de Haan, Stefan Szeider

On OBDDs for CNFs of Bounded Treewidth / 92
Igor Razgon

Analyzing the Computational Complexity of Abstract Dialectical Frameworks via Approximation Fixpoint Theory / 101
Hannes Strass, Johannes Peter Wallner

Skolemization for Weighted First-Order Model Counting / 111
Guy Van den Broeck, Wannes Meert, Adnan Darwiche

Belief Revision and Nonmonotonicity

On Egalitarian Belief Merging / 121
Patricia Everaere, Sébastien Konieczny, Pierre Marquis

Justified Beliefs by Justified Arguments / 131
Davide Grossi, Wiebe Van Der Hoek

Belief Change Operations: A Short History of Nearly Everything, Told in Dynamic Logic of Propositional Assignments / 141
Andreas Herzig

Belief Change and Base Dependence / 151
Mehrdad Oveisi, James P. Delgrande, Francis Jeffry Pelletier, Fred Popowich

Belief Change and Semiorders / 160
Pavlos Peppas, Mary-Anne Williams

David Poole's Specificity Revised / 168
Claus-Peter Wirth, Frieder Stolzenburg

Causality and Rationality

Axiomatizing Rationality / 178
Adam Bjorndahl, Joseph Y. Halpern, Rafael Pass

Dynamic Causal Calculus / 188
Alexander Bochman

Appropriate Causal Models and Stability of Causation / 198
Joseph Y. Halpern

∃GuaranteeNash for Boolean Games Is NEXP-Hard / 208
Egor Ianovski, Luke Ong

Description Logics

Nested Regular Path Queries in Description Logics / 218
Meghyn Bienvenu, Diego Calvanese, Magdalena Ortiz, Mantas Simkus

Decidable Gödel Description Logics without the Finitely-Valued Model Property / 228
Stefan Borgwardt, Felix Distel, Rafael Peñaloza

Query Inseparability for Description Logic Knowledge Bases / 238
Elena Botoeva, Roman Kontchakov, Vladislav Ryzhikov, Frank Wolter, Michael Zakharyaschev

Answering Instance Queries Relaxed by Concept Similarity / 248
Andreas Ecke, Rafael Peñaloza, Anni-Yasmin Turhan

Stable Model Semantics for Guarded Existential Rules and Description Logics / 258
Georg Gottlob, André Hernich, Clemens Kupke, Thomas Lukasiewicz

Polynomial Combined Rewritings for Existential Rules / 268
Georg Gottlob, Marco Manna, Andreas Pieris

Lightweight Description Logics and Branching Time: A Troublesome Marriage / 278
Víctor Gutiérrez-Basulto, Jean Christoph Jung, Thomas Schneider

Finite Model Reasoning in Horn Description Logics / 288
Yazmín Ibañez-García, Carsten Lutz, Thomas Schneider

Exact Learning of Lightweight Description Logic Ontologies / 298
Boris Konev, Carsten Lutz, Ana Ozaki, Frank Wolter

Nominal Schemas in Description Logics: Complexities Clarified / 308
Markus Krötzsch, Sebastian Rudolph

Practical Uniform Interpolation and Forgetting for $\mathcal{ALC}$ TBoxes with Applications to Logical Difference / 318
Michel Ludwig, Boris Konev

Knowledge Representation and Reasoning

Certain Answers as Objects and Knowledge / 328
Leonid Libkin

A Formalization of Programs in First-Order Logic with a Discrete Linear Order / 338
Fangzhen Lin

Simultaneous Learning and Prediction / 348
Loizos Michael

Tackling Winograd Schemas by Formalizing Relevance Theory in Knowledge Graphs / 358
Peter Schüller

Generalized Multi-Context Systems / 368
Shahab Tasharrofi, Eugenia Ternovska

Qualitative Spatial Representation and Reasoning in Angry Birds: The Extended Rectangle Algebra / 378
Peng Zhang, Jochen Renz

Planning, Strategies, and Diagnosis

Diagnostic Problem Solving via Planning with Ontic and Epistemic Goals / 388
Jorge A. Baier, Brent Mombourquette, Sheila A. McIlraith

Satisfiability of Alternating-Time Temporal Epistemic Logic through Tableaux / 398
Francesco Belardinelli

Reasoning about Equilibria in Game-Like Concurrent Systems / 408
Julian Gutierrez, Paul Harrenstein, Michael Wooldridge

A Temporal Logic of Strategic Knowledge / 418
Xiaowei Huang, Ron van Der Meyden

An Abstraction Technique for the Verification of
Multi-Agent Systems against ATL Specifications / 428
Alessio Lomuscio, Jakub Michaliszyn

Reasoning about Actions and Processes

How to Progress Beliefs in Continuous Domains / 438
Vaishak Belle, Hector J. Levesque

Transforming Situation Calculus Action Theories for Optimised Reasoning / 448
Christopher Ewin, Adrian R. Pearce, Stavros Vassos

State-Boundedness in Data-Aware Dynamic Systems / 458
Babak Bagheri Hariri, Diego Calvanese, Marco Montali, Alin Deutsch

Decidable Reasoning in a Fragment of the Epistemic Situation Calculus / 468
Gerhard Lakemeyer, Hector J. Levesque

A First-Order Semantics for Golog and ConGolog under a
Second-Order Induction Axiom for Situations / 478
Fangzhen Lin

Model Checking Unbounded Artifact-Centric Systems / 488
Alessio Lomuscio, Jakub Michaliszyn

Forgetting in Action / 498
David Rajaratnam, Hector J. Levesque, Maurice Pagnucco, Michael Thielscher

Reports from the Field

Computing Narratives of Cognitive User Experience for Building Design Analysis: KR for Industry Scale
Computer-Aided Architecture Design / 508
Mehul Bhatt, Carl Schultz, Madhura Thosar

SmartPM: An Adaptive Process Management System through
Situation Calculus, IndiGolog, and Classical Planning / 518
Andrea Marrella, Massimo Mecella, Sebastian Sardina

Tweety: A Comprehensive Collection of Java Libraries for Logical Aspects of Artificial Intelligence and
Knowledge Representation / 528
Matthias Thimm

Uncertainty

Reasoning with Uncertain Inputs in Possibilistic Networks / 538
Salem Benferhat, Karim Tabia

Relational Logistic Regression / 548
Seyed Mehran Kazemi, David Buchman, Kristian Kersting, Sriraam Natarajan, David Poole

Probabilistic Sentential Decision Diagrams / 558
Doga Kisa, Guy Van den Broeck, Arthur Choi, Adnan Darwiche

Linear Programs for Measuring Inconsistency in Probabilistic Logics / 568
Nico Potyka

Short Papers

Axioms .2 and .4 as Interaction Axioms / 579
Guillaume Aucher

Stable Models of Multi-Valued Formulas: Partial versus Total Functions / 583
Michael Bartholomew, Joohyung Lee

Rough Set Semantics for Identity on the Web / 587
Wouter Beek, Stefan Schlobach, Frank van Harmelen

On the Progression of Knowledge in Multiagent Systems / 590
Vaishak Belle, Gerhard Lakemeyer

Interval Methods for Judgment Aggregation in Argumentation / 594
Richard Booth, Edmond Awad, Iyad Rahwan

Strong Equivalence of Non-Monotonic Temporal Theories / 598
Pedro Cabalar, Martín Diéguez

Using Answer Set Programming for Solving Boolean Games / 602
Sofie De Clercq, Martine De Cock, Kim Bauters, Steven Schockaert, Ann Nowé

Toward a Knowledge Level Analysis of Forgetting / 606
James P. Delgrande

A Psychology-Inspired Approach to Automated Narrative Text Comprehension / 610
Irene-Anna Diakidoy, Antonis Kakas, Loizos Michael, Rob Miller

Concept Dissimilarity with Triangle Inequality / 614
Felix Distel, Jamal Atif, Isabelle Bloch

On Redundant Topological Constraints (Extended Abstract) / 618
Matt Duckham, Sanjiang Li, Weiming Liu, Zhiguo Long

Belief Revision in the Propositional Closure of a Qualitative Algebra / 622
Valmi Dufour-Lussier, Alice Hermann, Florence Le Ber, Jean Lieber

How to Argue for Anything: Enforcing Arbitrary Sets of Labellings Using AFs / 626
Sjur Kristoffer Dyrkolbotn

Knowledge Maps of Web Graphs / 630
Valeria Fionda, Claudio Gutierrez, Giuseppe Pirró

ASP Encodings of Acyclicity Properties / 634
Martin Gebser, Tomi Janhunen, Jussi Rintanen

Tracking Beliefs and Intentions in the Werewolf Game / 638
Codruta Girlea, Eyal Amir, Roxana Girju

Representing and Reasoning about Time Travel Narratives: Foundational Concepts / 642
Leora Morgenstern

Aggregative Deontic Detachment for Normative Reasoning / 646
Xavier Parent, Leon van der Torre

Action Theories over Generalized Databases
with Equality Constraints (Extended Abstract) / 650
Fabio Patrizi, Stavros Vassos

An Abductive Reasoning Approach to the Belief-Bias Effect / 653
Luís Moniz Pereira, Emmanuelle-Anna Dietz, Steffen Hölldobler

Minimal Change in AGM Revision for Non-Classical Logics / 657
Marcio M. Ribeiro, Renata Wassermann

Predicting Performance of OWL Reasoners: Locally or Globally? / 661
Viachaslau Sazonau, Uli Sattler, Gavin Brown

Canonical Logic Programs Are Succinctly Incomparable with Propositional Formulas / 665
Yuping Shen, Xishun Zhao

Heuristic Guided Optimization for Propositional Planning / 669
Andreas Sideris, Yannis Dimopoulos

First-Order Default Logic Revisited / 673
Yi Zhou

Invited Talks

Ontology-Based Monitoring of Dynamic Systems / 678
Franz Baader

Datalog+/–: Questions and Answers / 682
Georg Gottlob, Thomas Lukasiewicz, Andreas Pieris

Index / 687

Preface

The KR conference series is a leading forum for timely in-depth presentation of progress in the theory and principles underlying the representation and computational management of knowledge.

The first Knowledge Representation & Reasoning (KR) conference was held 25 years ago in 1989. On this 25th year of the first KR conference, we have embarked on the 14th KR conference. While thoughts and discussions on KR go back to the early philosophers, the importance of KR in building intelligent systems was realized from the very beginning of the field of artificial intelligence (AI). This recognition and subsequent research on KR as an important aspect of AI was apt, as the two key aspects of "intelligence," modeling the available knowledge on the world and reasoning on the world by means of this model center around KR. Since then there has been significant progress in KR and now we have many well developed KR formalisms with supporting theories, building-block results, reasoning systems, and applications. There are many books that present these developments. We have reached a stage where various disciplines in AI and computer science are now using KR. Among them is the use of KR in agents, semantic web applications, video understanding, natural language understanding, and many others.

The 2014 edition of KR is held as part of the Vienna Summer of Logic together with the Federated Conference on Logic, Logic Colloquium, and other related events, making it a very special edition.

We received 220 submissions to the conference of which 58 (26.4 percent) were accepted as regular papers. In addition to regular papers, the conference hosts 25 short technical papers, following a tradition introduced at KR 2010. Accepted papers can be broadly divided into the following areas: description logics (11), reasoning about actions and processes (7), belief revision and nonmonotonicity (6), general knowledge representation and reasoning (6), planning, strategies, and diagnosis (5), answer set programming and logic programming (4), argumentation (4), automated reasoning and computation (4), causality and rationality (4), uncertainty (4), and reports from the field (3).

The conference program has been enriched with several tutorials and invited talks on traditional KR topics as well as on emerging application areas.

With respect to applications, Tony Cohn contributes an invited talk, Knowledge Representation Meets Computer Vision: From Pixels to Symbolic Activity Descriptions, which discusses the role of KR in video understanding; and Ekaterina Ovchinnikova holds a tutorial on Natural Language Understanding with World Knowledge and Inference, which discusses the role of KR in natural language understanding (NLU), as well as various available knowledge bases that can be and are being used in developing NLU systems.

Research in dynamic systems and multi-agent systems has been strongly influenced by advances in KR; this is underlined by Franz Baader in his invited VSL/KR Keynote talk, supported by ECCAI, Ontology-Based Monitoring of Dynamic Systems. In addition, Alessio Lomuscio presents the tutorial Verification of Multi-Agent Systems against Epistemic Specifications, and Lawrence S. Moss presents another tutorial Dynamic Epistemic Logic and its Interaction with Knowledge Representation.

The close connection between databases, ontologies and KR is emphasized by Georg Gottlob, who gives an invited talk Datalog+/–: Questions and An-

swers and by Riccardo Rosati in his tutorial Query Answering and Rewriting in Ontology-Based Data Access.

The invited talks are rounded out by the traditional Great Moments in KR talk, which Sheila McIlraith delivers on Situation Calculus: The Last 15 Years. This talk will honor Ray Reiter and address the impact of his ground-breaking work on situation calculus.

We would like to thank several people who helped in the many aspects that are needed to make KR 2014 a successful event. The Senior Program Committee and Program Committee members were extremely helpful and supportive in their thorough and timely review of the submissions. Birte Glimm and Adrian Pearce took over the important charge of organizing the doctoral consortium and Marco Maratea was chasing sponsorships and liaisoning with organizations full of verve. We gratefully acknowledge the support of our sponsors. A special thanks goes to Michael Fink and Stefan Woltran and their team for the local organization, including Eva Nedoma, Markus Pichlmair, Johannes Wallner, Thomas Linsbichler, Sylwia Polberg, Friedrich Slivovsky, and all volunteers. We are also very grateful to the VSL Organization Chair Vesna Sabljakovic-Fritz. And if you have been attracted by the amazing KR 2014 poster or webpage design: contact Paolo Felli!

In closing, we thank our KR colleagues for their contributions which appear in the following pages and welcome our readers to this record of KR 2014.

Summer of Logic
July, 2013

Vienna Summer of Logic

In the summer of 2014, Vienna hosted the largest scientific conference in the history of logic. The Vienna Summer of Logic consisted of twelve large conferences and 82 workshops, attracting more than 2,000 researchers from all over the world. This unique event was organized by the Kurt Gödel Society at Vienna University of Technology and held from July 9 to 24, 2014, under the auspices of the Federal President of the Republic of Austria, Dr. Heinz Fischer.

The conferences and workshops dealt with the main theme — logic — from three important angles: logic in computer science, mathematical logic, and logic in artificial intelligence. They naturally gave rise to respective streams gathering the following meetings:

Logic in Computer Science / Federated Logic Conference (FLoC)

- 26th International Conference on Computer Aided Verification (CAV)
- 27th IEEE Computer Security Foundations Symposium (CSF)
- 30th International Conference on Logic Programming (ICLP)
- 7th International Joint Conference on Automated Reasoning (IJCAR)
- 5th Conference on Interactive Theorem Proving (ITP)
- Joint meeting of the 23rd EACSL Annual Conference on Computer Science Logic (CSL) and the 29th ACM/IEEE Symposium on Logic in Computer Science (LICS)
- 25th International Conference on Rewriting Techniques and Applications (RTA) joint with the 12th International Conference on Typed Lambda Calculi and Applications (TLCA)
- 17th International Conference on Theory and Applications of Satisfiability Testing (SAT)
- 76 FLoC Workshops
- FLoC Olympic Games (System Competitions)

Mathematical Logic

- Logic Colloquium 2014 (LC)
- Logic, Algebra and Truth Degrees 2014 (LATD)
- Compositional Meaning in Logic (GeTFun 2.0)
- The Infinity Workshop (INFINITY)
- Workshop on Logic and Games (LG)
- Kurt Gödel Fellowship Competition

Logic in Artificial Intelligence

- 14th International Conference on Principles of Knowledge Representation and Reasoning (KR)
- 27th International Workshop on Description Logics (DL)
- 15th International Workshop on Non-Monotonic Reasoning (NMR)
- 6th International Workshop on Knowledge Representation for Health Care 2014 (KR4HC)

The VSL keynote talks, which were directed to all participants, were given by Franz Baader (Technische Universität Dresden), Edmund Clarke (Carnegie Mellon University), Christos Papadimitriou (University of California, Berkeley) and Alex Wilkie (University of Manchester); Dana Scott (Carnegie Mellon University) spoke in the opening session. Since the Vienna Summer of Logic contained more than a hundred invited talks, it is infeasible to list them here.

The program of the Vienna Summer of Logic was very rich, including not only scientific talks, poster sessions and panels, but also two distinctive events. One was the award ceremony of the Kurt Gödel Research Prize Fellowship Competition, in which the Kurt Gödel Society awarded three research fellowship prizes endowed with 100.000 Euro each to the winners. This was the third edition of the competition, themed Logical Mind: Connecting Foundations and Technology this year.

The other distinctive event were the 1st FLoC Olympic Games hosted by the Federated Logic Con-

ference (FLoC) 2014. Intended as a new FLoC element, the games brought together 12 established logic solver competitions by different research communities. In addition to the competitions, the Olympic Games facilitated the exchange of expertise between communities, and increased the visibility and impact of state-of-the-art solver technology. The winners in the competition categories were honored with Kurt Gödel medals at the FLoC Olympic Games award ceremonies.

Organizing an event like the Vienna Summer of Logic has been a challenge. We are indebted to numerous people whose enormous efforts were essential in making this vision become reality. With so many colleagues and friends working with us, we are unable to list them individually here. Nevertheless, as representatives of the three streams of VSL, we would like to particularly express our gratitude to all people who have helped to make this event a success: the sponsors and the honorary committee; the organization committee and the local organizers; the conference and workshop chairs and program committee members; the reviewers and authors; and of course all speakers and participants of the many conferences, workshops and competitions.

The Vienna Summer of Logic continues a great legacy of scientific thought that started in Ancient Greece and flourished in the city of Gödel, Wittgenstein and the Vienna Circle. The heroes of our intellectual past shaped the scientific world-view and changed our understanding of science. Owing to their achievements, logic has permeated a wide range of disciplines, including computer science, mathematics, artificial intelligence, philosophy, linguistics, and many more. Logic is everywhere – or in the language of Aristotle, πάντα πλήρη λογικῆς τέχνης.

– *Matthias Baaz, Thomas Eiter, Helmut Veith*
Vienna, July 2014

Invited Talks

VSL/KR Keynote Talk, Supported by ECCAI

Ontology-Based Monitoring of Dynamic Systems

Franz Baader, TU Dresden

Our understanding of the notion "dynamic system" is a rather broad one: such a system has states, which can change over time. Ontologies are used to describe the states of the system, possibly in an incomplete way. Monitoring is then concerned with deciding whether some run of the system or all of its runs satisfy a certain property, which can be expressed by a formula of an appropriate temporal logic. I consider different instances of this broad framework, which can roughly be classified into two cases. In one instance, the system is assumed to be a black box, whose inner working is not known, but whose states can be (partially) observed during a run of the system. In the second instance, one has (partial) knowledge about the inner working of the system, which provides information on which runs of the system are possible.

In this talk, I will review some of our recent research that investigates different instances of this general framework of ontology-based monitoring of dynamic systems. I will also sketch possible extensions towards probabilistic reasoning and the integration of mathematical modeling of dynamical systems.

Franz Baader has been a full professor of theoretical computer science at TU Dresden since 2002, and dean of the Faculty of Computer Science of TU Dresden since 2012. He obtained his PhD in computer science at the University of Erlangen in 1989. He was a senior researcher at the German Research Centre for Artificial Intelligence (DFKI) in Kaiserslautern and Saarbrücken for four years, and associate professor of theoretical computer science at RWTH Aachen for eight years. His main research area is logic in computer science and artificial intelligence, in particular knowledge representation (description logics, modal logics, ontologies) and automated deduction (term rewriting, unification theory, combination of decision procedures). He was program chair of the KI'01, CADE'03, LPAR'04, and RTA'07 conferences, is an editorial board member of several journals in AI and logic in computer Sscience, and has published more than 200 refereed articles in major journals and conferences. He is a member of the Academia Europaea and an ECCAI fellow, and was for twelve years president of CADE Inc., the organization that runs the International Conference on Automated Deduction.

Knowledge Representation Meets Computer Vision: From Pixels to Symbolic Activity Descriptions

Tony Cohn, University of Leeds

While the fields of KR and computer vision have diverged since the early days of AI, there have been recent moves to re-integrate these fields. I will talk about some of this work, focusing on research from Leeds on building models of video activity from video input. I will present techniques, both supervised and unsupervised, for learning the spatio-temporal structure of tasks and events from video or other sensor data, particularly in the case of scenarios with concurrent activities. The representations exploit qualitative spatio-temporal relations which have been an active area of research in KR for a number of years. I will also talk about the problem of robustly computing symbolic descriptions from noisy video data. Finally, I will show how objects can be functionally categorised according to their spatiotemporal behaviours.

Tony Cohn holds a personal chair at the University of Leeds, where he is professor of automated reasoning and director of the Institute for Artificial Intelligence and Biological Systems. His work on knowledge representation and reasoning has a par-

ticular focus on qualitative spatial/spatio-temporal reasoning, the best known being the well cited region connection calculus (RCC). His current research interests range from theoretical work on spatial calculi and spatial ontologies, to cognitive vision, modeling spatial information in the hippocampus, and detecting buried underground assets (e.g. utilities and archaeological residues) using a variety of geolocated sensors. He has been chairman or president of SSAISB, ECCAI, KR inc, the IJCAI Board of Trustees and is presently editor-in-chief of the AAAI Press, *Spatial Cognition and Computation,* and the *Artificial Intelligence* journal. He was elected a founding Fellow of ECCAI, and is also a Fellow of AAAI, AISB, the BCS, and the IET. Work from the Cogvis project won the British Computer Society Machine Intelligence prize in 2004, and the VAULT system from his Mapping the Underworld project won a 2012 IET Innovation Award.

Datalog+/–: Questions and Answers

Georg Gottlob, University of Oxford

Datalog$^{+/?}$ is a family of languages for knowledge representation and reasoning. These languages extend Datalog with features such as existential quantifiers, equalities, and the falsum in rule heads, and, at the same time, applies restrictions to achieve decidability and tractability. After a general overview of the Datalog$^{+/?}$ family, this talk will focus on more recent issues. Among other things, I will report on the combination of the two main decidability paradigms guardedness and stickiness, yielding the Tame Fragment, and on incorporating non-monotonic negation and disjunction into Datalog+/–:. I will also report about a special version of Datalog$^{+/?}$ suitable for reasoning with reverse-engineered UML class diagrams, and about the TriQ language that expresses SPARQL with entailment regimes.

Georg Gottlob is a professor of informatics at Oxford University, a Fellow of St John's College, Oxford, and an adjunct professor at TU Wien. His interests include knowledge representation and reasoning including ontological reasoning, logic and complexity, database theory, graph decomposition techniques, and web data extraction. Gottlob has received the Wittgenstein Award from the Austrian National Science Fund, is an ACM Fellow, an ECCAI Fellow, a Fellow of the Royal Society, and a member of the Austrian Academy of Sciences, the German National Academy of Sciences, and the Academia Europaea. He chaired the Program Committees of IJCAI 2003 and ACM PODS 2000. He is currently a member of the editorial boards of *CACM* and *JCSS.* He was the main founder of Lixto (www.lixto.com), a company that provides tools and services for web data extraction which was recently acquired by McKinsey & Company. Gottlob was awarded an ERC Advanced Investigator's Grant for the project DIADEM: Domain-centric Intelligent Automated Data Extraction Methodology project. Great Moments in KR Talk

Situation Calculus: The Last 15 Years

Sheila McIlraith, University of Toronto

In 2001 Ray Reiter published his seminal book, *Knowledge in Action: Logical Foundations for Specifying and Implementing Dynamical Systems*. The book represented the culmination of 10 years of work by Reiter and his many collaborators investigating, formalizing, and extending the situation calculus, first introduced by John McCarthy in 1963 as a way of logically specifying dynamical systems. While researchers continue to extend the situation calculus, it has also seen significant scientific deployment to aid in the specification and implementation of a diversity of automated reasoning endeavors including diagnosis, web services composition and customization, and nonclassical automated planning. In this talk I will examine the important role the situation calculus has more recently been playing in explicating nuances in the logical specification and realization of some of these diverse automated reasoning tasks.

Sheila McIlraith is a professor in the Department of Computer Science, University of Toronto. Prior to joining the University of Toronto, she spent six years as a research scientist at Stanford University, and one year at Xerox PARC. McIlraith's research is in the area of knowledge representation and automated reasoning, with specific interest in reasoning

about dynamical systems and decision making in its many guises. She has 10 years of industrial research and development experience developing artificial intelligence applications. McIlraith is a fellow of AAAI and a past associate editor of the journal *Artificial Intelligence.* She is past program cochair of the 13th International Conference on Principles of Knowledge Representation and Reasoning (KR2012), and the International Semantic Web Conference (ISWC2004). In 2011 she and her coauthors were honored with the SWSA 10-year Award, recognizing the highest impact paper from the International Semantic Web Conference, 10 years prior. Her research has also made practical contributions to the development of next-generation space systems and to emerging web standards.

Tutorials

Verification of Multi-Agent Systems against Epistemic Specifications

Alessio Lomuscio, Imperial College London

Autonomous multiagent systems are typically specified by using expressive properties representing, among others, the knowledge of the agents and what they can bring about collectively or on their own in a system. This tutorial will survey some of the current techniques addressing the model checking of multi-agent systems against agent-based specifications. Specifically, the tutorial will cover syntax and semantics for the temporal-epistemic logic CTLK and ATLK, the epistemic variant of alternating time temporal logic. It will also cover ordered-binary decision diagrams and symbolic labeling, parameter synthesis and strategy synthesis in ATLK specifications, verification of systems with an unbounded number of agents, and MCMAS: a model checker for multiagent systems implementing these techniques, as well as the application of the techniques to a range of scenarios including in service-oriented computing.

Alessio Lomuscio is a professor in logic for multiagent systems in the Department of Computing, Imperial College London, where he leads the Verification of Autonomous Systems research group. He currently holds an EPSRC leadership fellowship. He received a PhD in computer science from the University of Birmingham in 1999 and a Laurea in electronic engineering from Politecnico di Milano in 1995. Before joining Imperial he was a lecturer at King's College London and a senior lecturer at University College London. His research interests concern the specification and verification of multiagent systems by means of techniques based on computational logic. In particular he has made theoretical contributions in the area of logic for multiagent systems (including studying the completeness, decidability and complexity of several temporal-epistemic formalisms) and has put forward several symbolic model checking techniques for the verification of agent-based systems. He has applied these techniques to the verification of a range of applications including autonomous underwater vehicles, webservices and security protocols including e-voting.

Dynamic Epistemic Logic and Its Interaction with Knowledge Representation

Lawrence S. Moss, Indiana University

Dynamic epistemic logic (DEL) takes the classical topic epistemic logic and adds features from propositional dynamic logic (PDL). DEL comes to life in the multiagent setting. It allows one to represent epistemic actions in addition to epistemic situations. DEL has been around for about 20 years, and so it has seen a lot of progress. By now, the original topics have been applied, generalized, and adapted in various ways. My primary goal in this tutorial is to present an overview of the area to people at KR 2014. The talk will discuss recent work in KR that uses DEL. After this, I would like to ask why it is that tools from DEL are not more used in the KR community. Turning things around, I also ask what influence issues from KR and other fields will have on the future of DEL and related frameworks.

Lawrence S. Moss is director of Indiana University's program in pure and applied logic. He is a professor of mathematics, and an adjunct professor of computer science, informatics, linguistics, and philosophy. For a number of years he was the steering committee chair of the North American Summer School in Logic, Language, and Information (NASSLLI).

Natural Language Understanding with World Knowledge and Inference

Ekaterina Ovchinnikova, University of Southern California

In order to understand natural language expressions it is usually not enough to know the literal (dictionary) meaning of words used in these expressions and compositional rules of the corresponding language. Much more knowledge is involved here; knowledge, which may have nothing to do with the linguistic competence but is rather related to our general conception of the world. In this tutorial, I will present an overview of the approaches to modeling knowledge-intensive natural language understanding (NLU) in a computational framework, with the main focus on inference-based NLU. I will discuss the types of knowledge required for NLU and the techniques to obtain this knowledge in a machine-readable form. The tutorial will cover lexical-semantic knowledge bases, ontologies (general and domain-specific), and corpora-based resources. Then I will focus on reasoning procedures applicable to NLU and compare two main forms of logical inference: deduction and abduction. In the last part of the tutorial, I will present applications of some of the recent large-scale inference-based NLU systems to such knowledge-intensive tasks as recognizing textual entailment, metaphor interpretation, and narrativization of videos.

*Ekaterina Ovchinnikova i*s a computer scientist (faculty) at the Institute of Information Sciences, University of Southern California. Her research interests include computational natural language understanding, human and automated reasoning, knowledge representation and extraction, scene recognition, and ontologies. Applications she is currently working on include metaphor interpretation, narrativization of videos, textual entailment recognition, and other knowledge intensive natural language understanding tasks. In 2011, Ekaterina earned her PhD degree in cognitive science from the Institute of Cognitive Science, University of Osnabrück (Germany). In her dissertation project, Ekaterina was focusing on inference-based natural language understanding. The main results of this work were published in *Integration of World Knowledge for Natural Language Understanding.*

Query Answering and Rewriting in Ontology-Based Data Access

Riccardo Rosati, Sapienza University of Rome

Ontology-based data access (OBDA) has recently become a hot research topic in knowledge representation and data management. The basic idea underlying OBDA is to superimpose an ontology (conceptual layer) to a set of data sources (data layer), and use the ontology as a virtual schema for querying the data sources. The ontology and the data sources are connected through declarative mappings that provide the semantic relationship between the two layers. This tutorial will introduce ontology-based data access and will deal with the problem of query answering in OBDA, focusing in particular on the query rewriting approach to query answering. After a brief history of ontology-based data access, the tutorial will overview the most important results obtained in this area. Then, the main query rewriting techniques for OBDA will be presented and compared. The relationship between OBDA and other research topics will also be addressed. The main focus of the tutorial is on ontologies expressed using Description Logics: however, other ontology specification languages, like Datalog+/–:, will be considered.

Riccardo Rosati is an associate professor in the Department of Computer, Control, and Management Engineering, Sapienza University of Rome, Italy. His main research interests are in the fields of databases and artificial intelligence, and include knowledge representation, description logics, ontologies, semantic web, databases, and nonmonotonic reasoning. He is the author of more than 150 publications in international journals and conferences. He is a member of the steering committees of the Description Logics workshop, the Nonmonotonic Reasoning workshop, and the International Conference on Web Reasoning and Rule Systems.

Logic Programs with Ordered Disjunction: First-Order Semantics and Expressiveness

Vernon Asuncion[1,2], **Yan Zhang**[1], **Heng Zhang**[1]
[1] School of Computing, Engineering and Mathematics, University of Western Sydney, Australia
[2] Department of Computer Science and Engineering, Qatar University, Qatar

Abstract

Logic programs with ordered disjunction (LPODs) (Brewka 2002) generalize normal logic programs by combining alternative and ranked options in the heads of rules. It has been showed that LPODs are useful in a number of areas including game theory, policy languages, planning and argumentations. In this paper, we extend propositional LPODs to the first-order case, where a classical second-order formula is defined to capture the stable model semantics of the underlying first-order LPODs. We then develop a progression semantics that is equivalent to the stable model semantics but naturally represents the reasoning procedure of LPODs. We show that on finite structures, every LPOD can be translated to a first-order sentence, which provides a basis for computing stable models of LPODs. We further study the complexity and expressiveness of LPODs and prove that almost positive LPODs precisely capture first-order normal logic programs, which indicates that ordered disjunction itself and constraints are sufficient to represent negation as failure.

Introduction

Logic programs with ordered disjunction (LPODs) generalize normal logic programs by combining features of qualitative choice logic so that alternative and ranked options may be explicitly expressed in the heads of rules (Brewka 2002; Brewka, Benferhat, and Berre 2002). A LPOD contains a finite set of rules of the form

$$\alpha_1 \times \cdots \times \alpha_k \leftarrow \beta_1, \cdots, \beta_l, \mathsf{not}\,\gamma_1, \cdots, \mathsf{not}\,\gamma_m, \quad (1)$$

where $\alpha_i, \beta_j, \gamma_h$ ($1 \leq i \leq k, 1 \leq j \leq l, 1 \leq h \leq m$) are propositional atoms. Intuitively, rule (1) says that when the body is satisfied, then whenever it is possible, derive α_1, otherwise if possible, derive α_2, and so on. The semantics of an LPOD is defined in terms of the stable models of so-called *split programs* of the underlying LPOD.

Let us consider a simple program Π_1 from (Brewka 2002):

$$A \times B \leftarrow \mathsf{not}\, C,$$
$$B \times C \leftarrow \mathsf{not}\, D.$$

Copyright © 2014, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

Π_1 has the following four split programs:

$$A \leftarrow \mathsf{not}\, C \qquad A \leftarrow \mathsf{not}\, C$$
$$B \leftarrow \mathsf{not}\, D \qquad C \leftarrow \mathsf{not}\, D, \mathsf{not}\, B$$

$$B \leftarrow \mathsf{not}\, C, \mathsf{not}\, A \qquad B \leftarrow \mathsf{not}\, C, \mathsf{not}\, A$$
$$B \leftarrow \mathsf{not}\, D \qquad C \leftarrow \mathsf{not}\, D, \mathsf{not}\, B.$$

Then the class of stable models of Π consists of all stable models of these four split programs, which is $\{\{A, B\}, \{B\}, \{C\}\}$. Then by integrating proper preference relation among these stable models, the preferred stable models can be obtained for an LPOD.

There have been several extensions of LPODs in recent years: Karger *et al* (2008) extended LPODs by allowing both ordered and unordered disjunction in the heads of rules; Confalonieri *et al* (2010) recently defined a possibilistic semantics for LPODs in order to handle uncertainty; and Cabalar (2011) also proposed a direct translation from LPODs to normal logic programs via the logic of Here-and-There. It has been argued that LPODs provide a natural way to deal with preference in reasoning that are useful in various applications such as game theory, policy languages, planning and argumentations (Brewka 2002; Cabalar 2011; Confalonieri et al. 2010).

On the other hand, in recent years, Answer Set Programming (ASP) has been generalized to arbitrary first-order sentences (Ferraris, Lee, and Lifschitz 2011). One challenging research along this direction is to establish proper logical and computational foundations for promoting useful functionalities in existing ASP paradigm to the first-order level. A number of topics in this aspect have been investigated and relevant properties revealed, e.g., (Asuncion et al. 2012; Asuncion, Zhang, and Zhou 2013; Lee and Meng 2011; Babb and Lee 2012). One major advantage of first-order ASP is that it provides a succinct declarative language, in which the underlying problem constraints (rules) may be completely separated from concrete problem instances, and hence more flexible for problem representation and modeling (Lin and Zhou 2011).

In this paper, we study the semantics and expressiveness of LPODs on the first-order level. We make the following main contributions towards this topic:

1. Following the style of general stable model semantics

(Ferraris, Lee, and Lifschitz 2011), we define the stable model semantics for first-order LPODs via a classical second-order sentence, and show that this semantics is a correct lifting of Brewka's original LPODs semantics to the first-order level. We then develop a progression semantics that is equivalent to the second-order based semantics but naturally represents the reasoning procedure of LPODs.

2. We propose a translation from LPODs to first-order sentences on finite structures. We argue that this translation actually may be used as a computational basis for developing an LPOD solver.
3. We address the complexity and expressiveness issues of LPODs. We show that LPODs data complexity is NP-complete, that remains true even for positive LPODs. We also prove that almost positive LPODs precisely capture the full class of first-order normal logic programs, which indicates that ordered disjunction itself and constraints are sufficient to represent negation as failure.
4. We further consider preferred LPODs, and provide a logic characterization of such preference semantics, which again, generalizes the corresponding preferred propositional LPODs.

The rest of this paper is organized as follows. In section 2 we focus on the syntax and semantics of first-order LPODs. In section 3 we then present a progression semantics for first-order LPODs, which we believe is more intuitive to reflect the underlying derivation process embedded in LPODs. Considering to compute stable models of an LPOD, in section 4 we propose a translation from LPODs to first-order sentences on finite structures, so that the problem of computing stable models of an LPOD can be viewed as a SAT solving problem. We study the complexity and expressiveness issues in section 5. In section 6 we define the preferred stable models for LPODs and provide a logic formulation for that. Finally, we conclude the paper with some remarks in section 7.

First-order LPODs: Syntax and Semantics

We consider a second-order logic but without function symbols (i.e., functions of arities not greater than 0). A *signature* τ is a set of symbols of the form $\{c_1, \ldots, c_m, P_1, \ldots, P_n\}$ such that c_i (for $1 \leq i \leq m$) are *constant* symbols and P_j (for $1 \leq j \leq n$) are *predicate* symbols. A *structure* $\mathcal{M}$ of signature τ (or a τ-structure) is a tuple of the form

$$(M, c_1^{\mathcal{M}}, \ldots, c_m^{\mathcal{M}}, P_1^{\mathcal{M}}, \ldots, P_n^{\mathcal{M}}), \tag{2}$$

where M is the *domain* of $\mathcal{M}$, which we will mostly refer to as $Dom(\mathcal{M})$; $c_i^{\mathcal{M}}$ and $P_j^{\mathcal{M}}$ are the respective interpretations of the constant and predicate symbols.

Let $\mathcal{M}$ be a τ-structure and $\mathcal{M}'$ a τ'-structure such that $\tau' \subseteq \tau$ and where (1) $Dom(\mathcal{M}') = Dom(\mathcal{M})$; (2) $c^{\mathcal{M}'} = c^{\mathcal{M}}$ for each constant symbol c of τ'; and (3) $P^{\mathcal{M}'} = P^{\mathcal{M}}$ for each predicate symbol P of τ'. We refer $\mathcal{M}'$ as the *restriction* of $\mathcal{M}$ to the signature of τ', which we denote by $\mathcal{M}\restriction_{\tau'}$, i.e., $\mathcal{M}' = \mathcal{M}\restriction_{\tau'}$. Symmetrically, $\mathcal{M}$ would be called an *expansion* of $\mathcal{M}'$ to the signature τ.

The Syntax

An *ordered disjunction rule* is a construct of the form:

$$\alpha_1 \times \ldots \times \alpha_k \leftarrow \beta_1, \ldots, \beta_l, \mathsf{not}\, \gamma_1, \ldots, \mathsf{not}\, \gamma_m, \tag{3}$$

where:

- Each α_i (for $1 \leq i \leq k$) is a standard atom $P(\mathbf{x})$ for some predicate P and tuple of terms (variables or constants) $\mathbf{x}$. If $k = 0$, then (3) is called a *constraint*.
- Each β_i ($1 \leq i \leq l$) and γ_i ($1 \leq i \leq m$) are either a standard or an equality atom.
- By $Head(r)$, we denote the ordered expression $\alpha_1 \times \ldots \times \alpha_k$, that corresponds to the head of r. We also denote $Head(r)_i = \alpha_i$.
- As usual, by $Body(r)$, we denote the set of literals $\{\beta_1, \ldots, \beta_l, \mathsf{not}\, \gamma_1, \ldots, \mathsf{not}\, \gamma_m\}$.
- Similarly, by $Pos(r)$ and $Neg(r)$, we denote the sets of atoms $\{\beta_1, \ldots, \beta_l\}$ and $\{\gamma_1, \ldots, \gamma_m\}$, respectively.

A *first-order logic program with ordered disjunction*, or simply called (first-order) LPOD, Π, is a finite set of ordered disjunction rules of the form (3). If for all rules $r \in \Pi$ we have that $k \leq 1$ in $Head(r) = \alpha_1 \times \ldots \times \alpha_k$, then Π becomes a normal logic program. It is obvious that this first-order LPOD syntax naturally extends Brewka's original propositional logic programs with ordered disjunction (Brewka 2002) to the first-order case.

For a given LPOD Π, a predicate is called *intensional* if it occurs at least once in the head of some rule in Π. All other predicates are called *extensional*. For convenience, we denote by $\tau(\Pi)$, $\mathcal{P}_{ext}(\Pi)$ and $\mathcal{P}_{int}(\Pi)$, the signature of Π, the set of extensional predicates and the set of intensional predicates, respectively. Furthermore, we also use $\tau_{ext}(\Pi)$ and $\tau_{int}(\Pi)$ to denote the sub-signatures of $\tau(\Pi)$ which only contain extensional and intensional predicates respectively, together with all constant symbols of $\tau(\Pi)$. When there is no confusion in the context, we often omit the parameter Π in these notions.

The Stable Model Semantics

For a rule of the form (3), we denote by $\widehat{Body(r)}$, the formula $\beta_1 \wedge \cdots \wedge \beta_l \wedge \neg\gamma_1 \wedge \cdots \wedge \neg\gamma_m$, and $Head(r)^{FO}$, the following formula

$$\alpha_1 \vee (\neg\alpha_1 \wedge \alpha_2) \vee (\neg\alpha_1 \wedge \neg\alpha_2 \wedge \alpha_3) \vee \ldots \vee (\neg\alpha_1 \wedge \neg\alpha_2 \wedge \ldots \wedge \neg\alpha_{k-1} \wedge \alpha_k).$$

Note that Cabalar (2011) has showed the strong equivalence of $\alpha_1 \times \cdots \times \alpha_k$ and $Head(r)^{FO}$ for the propositional case, that can be easily extended to our first-order case. Then for an LPOD Π, by $\widehat{\Pi}$, we denote the conjunction

$$\bigwedge_{r \in \Pi} (\widehat{Body(r)} \rightarrow Head(r)^{FO}). \tag{4}$$

Definition 1 *Let Π be an LPOD with tuple of distinct (intensional) predicates $\mathbf{P} = P_1 P_2 \ldots P_n$ and $\mathcal{M}$ a $\tau(\Pi)$-structure. Then we say that $\mathcal{M}$ is a* stable model *of Π iff it is a model of the following second-order sentence:*

$$\mathrm{SM}_{\mathbf{P}}(\Pi) = \widehat{\Pi} \wedge \neg\exists \mathbf{U}(\mathbf{U} < \mathbf{P} \wedge \widehat{\Pi}(\mathbf{U})^*), \tag{5}$$

where:

- $\mathbf{U} = U_1 U_2 \ldots U_n$ *is a fresh tuple of distinct predicates matching* $\mathbf{P}$*;*
- $\mathbf{U} < \mathbf{P}$ *denotes the formula*

$$\bigwedge_{1 \le i \le n} \forall \mathbf{x}(U_i(\mathbf{x}) \rightarrow P_i(\mathbf{x})) \wedge \neg \bigwedge_{1 \le i \le n} \forall \mathbf{x}(P_i(\mathbf{x}) \rightarrow U_i(\mathbf{x}));$$

- $\widehat{\Pi}(\mathbf{U})^*$ *denotes the formula*

$$\bigwedge_{r \in \Pi, \atop r \text{ of form the (3)}} \forall \mathbf{x}_r(\, \beta_1^* \wedge \ldots \wedge \beta_l^* \wedge \neg\gamma_1 \wedge \ldots \wedge \neg\gamma_m \rightarrow (\alpha_1 \times \ldots \times \alpha_k)^*\,),$$

where $(\alpha_1 \times \ldots \times \alpha_k)^*$ *denotes the formula:*

$$\alpha_1^* \vee (\neg\alpha_1 \wedge \alpha_2^*) \vee (\neg\alpha_1 \wedge \neg\alpha_2 \wedge \alpha_3^*) \vee \ldots \vee (\neg\alpha_1 \wedge \neg\alpha_2 \wedge \ldots \wedge \neg\alpha_{k-1} \wedge \alpha_k^*), \quad (6)$$

and such that $P_i(\mathbf{x})^* = U_i(\mathbf{x})$ *for any atomic formula* $P_i(\mathbf{x})$ *with* $1 \le i \le n$*, and* $Q(\mathbf{y})^* = Q(\mathbf{y})$ *otherwise.*

It is not difficult to see that Definition 1 is a counterpart of the second-order definition for the general stable model semantics (Ferraris, Lee, and Lifschitz 2011), with the additional operation (6). In the following, we will show that Definition 1 is also a generalization of the semantics for the original propositional LPODs, and hence, our first-order LPOD stable model semantics is a proper uplifting from the propositional level.

Let τ be a signature of Π with the sets $\mathcal{P}_{ext}$ and $\mathcal{P}_{int}$ of extensional and intensional predicates respectively, and let $\mathcal{M}$ be a τ-structure. Then we define $I_{\mathcal{M}}$ as follows:

$$I_{\mathcal{M}} := \{P(\mathbf{a}) \mid P \in (\mathcal{P}_{ext} \cup \mathcal{P}_{int}) \text{ and } \mathbf{a} \in P^{\mathcal{M}}\},$$

i.e., the set of propositional atoms corresponding to the extents of the predicates of τ under $\mathcal{M}$. In addition, by $Ext_{\mathcal{M}}$, define the set of rules (which are facts) as follows:

$$Ext_{\mathcal{M}} := \{Q(\mathbf{a}) \;\leftarrow \mid Q \in \mathcal{P}_{ext} \text{ and } \mathbf{a} \in Q^{\mathcal{M}}\},$$

i.e., the set of "facts" corresponding to the extensional database under $\mathcal{M}$.

In addition to the two previous notions, we now introduce the notion of a grounded program. Let Π be an LPOD and $\mathcal{M}$ a $\tau(\Pi)$-structure with domain denoted by $Dom(\mathcal{M})$. Then by $\Pi\,|_{Dom(\mathcal{M})}$, let us denote the propositional program obtained from Π by (1) simultaneously replacing the variables by domain elements from $Dom(\mathcal{M})$ in all possible ways, and the constant symbols by their corresponding interpretation in $Dom(\mathcal{M})$ under $\mathcal{M}$; and (2) removing all rules that contain false instantiations of equality predicates and deleting those true instantiations of equalities from the remaining rules.

Before we present the following result, we also need a formal definition of split programs for a given propositional LPOD. Let Π be a propositional LPOD consisting of rules of the form of (3), but all those α's, β's and γ's are propositional atoms. Then a *split program* of Π is a normal logic program Π' obtained from Π by replacing each rule of (3) in Π, for some $i \le k$, by

$$\alpha_i \leftarrow \beta_1, \ldots, \beta_l, \mathsf{not}\ \gamma_1, \ldots, \mathsf{not}\ \gamma_m, \mathsf{not}\ \alpha_1, \cdots, \mathsf{not}\ \alpha_{i-1}. \quad (7)$$

Theorem 1 *Let* Π *be an LPOD and* $\mathcal{M}$ *a* $\tau(\Pi)$*-structure. Then* $\mathcal{M}$ *is a stable model of* Π *iff* $I_{\mathcal{M}}$ *is a stable model of some split program of* $\Pi|_{Dom(\mathcal{M})} \cup Ext_{\mathcal{M}}$*.*

Progression Semantics: An Alternative

According to Definition 1, the semantics of first-order LPODs is defined via a second-order sentence, which hardly reveals the rule based reasoning feature of the underlying LPOD. In this section, we provide an alternative semantics for FO LPODs - the progression semantics, which is an extension of Zhang and Zhou's progression semantics for first-order normal logic program (Zhang and Zhou 2010). As we will see, the important feature of such semantics is that it naturally represents the reasoning procedure through the progression stages.

Definition 2 *Let* Π *be a FO LPOD and* $\mathcal{M}$ *a* $\tau(\Pi)$*-structure*

$$(Dom(\mathcal{M}), c_1^{\mathcal{M}}, \ldots, c_r^{\mathcal{M}}, Q_1^{\mathcal{M}}, \ldots, Q_s^{\mathcal{M}}, P_1^{\mathcal{M}}, \ldots, P_n^{\mathcal{M}})$$

such that c_i *(for* $1 \le i \le r$*),* Q_i *(for* $1 \le i \le s$*), and* P_i *(for* $1 \le i \le n$*) are its constant symbols, extensional and intensional predicate symbols, respectively. We define the* $\tau(\Pi)$*-structure* $\mathcal{M}^{t+1}(\Pi)$ *inductively as follows:*

$$\mathcal{M}^0(\Pi) = (Dom(\mathcal{M}), c_1^{\mathcal{M}^0(\Pi)}, \ldots, c_r^{\mathcal{M}^0(\Pi)}, Q_1^{\mathcal{M}^0(\Pi)}, \ldots, Q_s^{\mathcal{M}^0(\Pi)}, P_1^{\mathcal{M}^0(\Pi)}, \ldots, P_n^{\mathcal{M}^0(\Pi)}), \quad (8)$$

where $c_i^{\mathcal{M}^0(\Pi)} = c_1^{\mathcal{M}}$ *(for* $1 \le i \le r$*),* $Q_i^{\mathcal{M}^0(\Pi)} = Q_i^{\mathcal{M}}$ *(for* $1 \le i \le s$*), and* $P_i^{\mathcal{M}^0(\Pi)} = \emptyset$ *(for* $1 \le i \le n$*);*

$$\mathcal{M}^{t+1}(\Pi) = \mathcal{M}^t(\Pi) \cup \{\alpha_i\eta \mid \exists r \in \Pi \textit{ with } Head(r) = \alpha_1 \times \ldots \times \alpha_i \times \ldots \times \alpha_k \textit{ and } \eta \textit{ an assignment such that:}$$

1. $Pos(r)\eta \subseteq \mathcal{M}^t(\Pi)$ *and* $Neg(r)\eta \cap \mathcal{M} = \emptyset$*;*

2. i *(for* $1 \le i \le k$*) is the largest* i *such that* $\{\alpha_1\eta, \ldots, \alpha_{i-1}\eta\} \cap \mathcal{M} = \emptyset\}$. (9)

Then let $\mathcal{M}^{\infty}(\Pi) = \bigcup_{0 \le t \le \infty} \mathcal{M}^t(\Pi)$.

Since $\mathcal{M}^t(\Pi) \subseteq \mathcal{M}^{t+1}(\Pi)$, we know that the sequence $\mathcal{M}^0, \mathcal{M}^1, \cdots$ is monotonic and $\mathcal{M}^t(\Pi)$ always converges to its fixpoint. Also note that when $Head(r) = \alpha_1$ (i.e., r is a normal rule), then we will have in Item 2 in (9) that $i = 1$ will automatically be the largest i such that $\{\alpha_1\eta, \ldots, \alpha_{i-1}\eta\} \cap \mathcal{M} = \emptyset$. From this fact, the following proposition shows that the progression characterization captures the stable models when Π is a normal logic program.

Proposition 1 *Let* Π *be a normal logic program and* $\mathcal{M}$ *a* $\tau(\Pi)$*-structure. Then* $\mathcal{M}$ *is a stable model of* Π *iff* $\mathcal{M}^{\infty}(\Pi) = \mathcal{M}$*.*

Proof: If Π is a normal program, then we will have by default in Item 2 in (9) of Definition 2 that $i = 1$ will be the largest i such that $\{\alpha_1\eta, \ldots, \alpha_{i-1}\eta\} \cap \mathcal{M} = \emptyset$, since $\{\alpha_1, \ldots, \alpha_{i-1}\} = \emptyset$ in this case. Therefore, we can omit Item 2 in (9) so that $\mathcal{M}^{t+1}(\Pi)$ will be as originally defined in (Zhang and Zhou 2010) for normal programs. □

Theorem 2 shows that the progression semantics coincides with the second-order stable model semantics of LPODs as defined in Definition 1. We first present the following lemma which is needed in the proof of Theorem 2.

Lemma 1 *If $\mathcal{M}^\infty(\Pi) = \mathcal{M}$ then $\mathcal{M} \models \widehat{\Pi}$.*

Theorem 2 *Let Π be an LPOD and $\mathcal{M}$ a $\tau(\Pi)$-structure. Then $\mathcal{M}$ is a stable model of Π iff $\mathcal{M}^\infty(\Pi) = \mathcal{M}$.*

Proof: ($\Rightarrow$) First we show that $\mathcal{M}^\infty \subseteq \mathcal{M}$ by showing $\mathcal{M}^t \subseteq \mathcal{M}$ holds for all $t \geq 0$ by induction. Clearly, $\mathcal{M}^0(\Pi) \subseteq \mathcal{M}$ holds by the definition of $\mathcal{M}^0(\Pi)$ since all the intensional relations are set to empty. Now assume that $\mathcal{M}^{t'}(\Pi) \subseteq \mathcal{M}$ holds for all $0 \leq t' \leq t$ and let $P(\mathbf{a}) \in \mathcal{M}^{t+1}(\Pi)$ such that $P(\mathbf{a}) \notin \mathcal{M}^t(\Pi)$. Then by the definition of $\mathcal{M}^{t+1}(\Pi)$, we have that there exists a rule $r \in \Pi$ with $Head(r) = \alpha_1 \times \ldots \times \alpha_i \times \ldots \times \alpha_k$ and assignment η such that:

1. $P(\mathbf{a}) = \alpha_i\eta$;
2. $Pos(r)\eta \subseteq \mathcal{M}^t(\Pi)$ and $Neg(r) \cap \mathcal{M} = \emptyset$;
3. i (for $1 \leq i \leq k$) is the largest i such that $\{\alpha_1\eta, \ldots, \alpha_{i-1}\eta\} \cap \mathcal{M} = \emptyset$.

Then since $Pos(r)\eta \subseteq \mathcal{M}^t(\Pi)$ and $Neg(r) \cap \mathcal{M} = \emptyset$, and where $\mathcal{M}^t(\Pi) \subseteq \mathcal{M}$, it follows that $\mathcal{M} \models \widehat{Body(r)}\eta$. Thus, since $\mathcal{M} \models \widehat{\Pi}$ (because $\mathcal{M} \models \mathrm{SM}_{\mathbf{P}}[\Pi]$), then it follows that $\mathcal{M} \models Head(r)^{FO}\eta \equiv (\neg\alpha_1 \wedge \ldots \wedge \neg\alpha_{i-1} \wedge \alpha_i)\eta$, which implies that $\alpha_i\eta = P(\mathbf{a}) \in \mathcal{M}$. Therefore, we had shown that $\mathcal{M}^\infty(\Pi) \subseteq \mathcal{M}$. Now let us assume on the contrary that it is also the case that $\mathcal{M}^\infty(\Pi) \subset \mathcal{M}$ and we show we derive a contradiction. Then define a $\tau(\Pi) \cup \{U_1, \ldots, U_n\}$-structure $\mathcal{U}$ as follows:

- $c^{\mathcal{U}} = c^{\mathcal{M}}$ for every constant c of $\tau(\Pi)$;
- $Q^{\mathcal{U}} = Q^{\mathcal{M}}$ for every extensional predicate of $\tau(\Pi)$;
- $P_i^{\mathcal{U}} = P_i^{\mathcal{M}}$ for every intensional predicate P_i of $\tau(\Pi)$, such that $1 \leq i \leq n$.
- $U_i^{\mathcal{U}} = P_i^{\mathcal{M}^\infty(\Pi)}$ for every predicate U_i in $\{U_1, \ldots, U_n\}$, with $1 \leq i \leq n$.

Now we will show that $\mathcal{U} \models \mathbf{U} < \mathbf{P}$ and $\mathcal{U} \models \widehat{\Pi}(\mathbf{U})^*$. The first part $\mathcal{U} \models \mathbf{U} < \mathbf{P}$ follows from the fact that $\mathcal{M}^\infty(\Pi) \subset \mathcal{M}$ and by the way the $\tau(\Pi) \cup \{U_n, \ldots, U_n\}$-structure $\mathcal{U}$ is constructed from $\mathcal{M}$ and $\mathcal{M}^\infty(\Pi)$ above. Now we show the second part. So assume for some rule r in Π of the form (3) and some assignment η that $\mathcal{U} \models \widehat{Body(r)}^*\eta$. Then since $\mathcal{U} \models \mathbf{U} < \mathbf{P}$ and by the definition of $\mathcal{U}$, it follows that $Pos(r)\eta \subseteq \mathcal{M}^\infty(\Pi)$, which implies that $Pos(r)\eta \subseteq \mathcal{M}^t(\Pi) \subseteq \mathcal{M}^\infty(\Pi) \subset \mathcal{M}$ for some $t \geq 0$. Then since $Pos(r)\eta \subset \mathcal{M}$, then $\mathcal{M} \models \widehat{Body(r)}\eta$ as well. Then since $\mathcal{M} \models \widehat{\Pi}$, we have that $\mathcal{M} \models Head(r)^{FO}\eta$, which further implies that $\mathcal{M} \models \neg\alpha_1 \wedge \ldots \wedge \neg\alpha_{i-1} \wedge \alpha_i$ for some $1 \leq i \leq k$. Then by Item 2 of (9), this implies that $\alpha_i\eta \in \mathcal{M}^{t+1}(\Pi) \subseteq \mathcal{M}^\infty(\Pi)$ since i will be the largest i such that $\{\alpha_1\eta, \ldots, \alpha_{i-1}\eta\} \cap \mathcal{M} = \emptyset$, which further implies that $\mathcal{U} \models Head(r)^*\eta$ by the way $\mathcal{U}$ was constructed from $\mathcal{M}^\infty(\Pi)$ and since $\mathcal{M}^{t+1}(\Pi) \subseteq \mathcal{M}^\infty(\Pi)$. Therefore, because we have shown that $\mathcal{U} \models \widehat{\Pi}(\mathbf{U})^*$, then we now have a contradiction since we initially assumed that $\mathcal{M} \models \mathrm{SM}_{\mathbf{P}}(\Pi)$, and where this implies that $\mathcal{M} \models \neg\exists\mathbf{U}(\mathbf{U} < \mathbf{P} \wedge \widehat{\Pi}(\mathbf{U})^*)$ (which is contradicted by the existence of the structure $\mathcal{U}$).

($\Leftarrow$) Now let us assume $\mathcal{M}^\infty(\Pi) = \mathcal{M}$ but, on the contrary that $\mathcal{M} \not\models \mathrm{SM}_{\mathbf{P}}[\Pi]$. Since by Lemma 1 we have that $\mathcal{M} \models \widehat{\Pi}$, then this implies that $\mathcal{M} \not\models \neg\exists\mathbf{U}(\mathbf{U} < \mathbf{P} \wedge \widehat{\Pi}(\mathbf{U})^*)$. Thus, assume that $\mathcal{U}$ is a $\tau(\Pi) \cup \{U_n, \ldots, U_n\}$-structure such that that $\mathcal{U} \models \mathbf{U} < \mathbf{P} \wedge \widehat{\Pi}(\mathbf{U})^*$. Then we will show by induction on t that $P_i^{\mathcal{M}^t(\Pi)} \subseteq U_i^{\mathcal{U}}$, for $1 \leq i \leq n$. Therefore, since $\mathcal{U} \models \mathbf{U} < \mathbf{P}$ (i.e., $\mathbf{U}$ is "strictly smaller" than $\mathbf{P}$), then this contradicts the assumption that $\mathcal{M}^\infty(\Pi) = \mathcal{M}$ (because $\mathcal{M}^\infty(\Pi)$ would be "strictly less" than $\mathcal{M}$ in this case). The base case for $\mathcal{M}^0(\Pi)$ clearly holds since $P_i^{\mathcal{M}^0(\Pi)} = \emptyset$, for $1 \leq i \leq n$. So let us assume that $P_i^{\mathcal{M}^t(\Pi)} \subseteq U_i^{\mathcal{U}}$, for $1 \leq i \leq n$, and consider $\mathcal{M}^{t+1}(\Pi)$. Indeed, let $P(\mathbf{a}) \in \mathcal{M}^{t+1}(\Pi) \setminus \mathcal{M}^t(\Pi)$. Then by the definition of $\mathcal{M}^{t+1}(\Pi)$ as we find in (9) of Definition (2), there exists a rule $r \in \Pi$ with $Head(r) = \alpha_1 \times \ldots \times \alpha_i \times \ldots \times \alpha_k$ such that:

1. $Pos(r)\eta \subseteq \mathcal{M}^t(\Pi)$ and $Neg(r)\eta \cap \mathcal{M} = \emptyset$;
2. i (for $1 \leq i \leq k$) is the largest i such that $\{\alpha_1\eta, \ldots, \alpha_{i-1}\eta\} \cap \mathcal{M} = \emptyset$,

and where $P_i(\mathbf{a}) = \alpha_i\eta$. Then it is not difficult to see that $\mathcal{U} \models \widehat{Body(r)}^*\eta$ as well since $P_i^{\mathcal{M}^t(\Pi)} \subseteq U_i^{\mathcal{U}}$, for $1 \leq i \leq n$. Then since $\mathcal{U} \models \widehat{\Pi}(\mathbf{U})^*$, we have that $\mathcal{U} \models Head(r)^*$, and where in particular, $\mathcal{U} \models (\neg\alpha_1 \wedge \ldots \wedge \neg\alpha_{i-1} \wedge \alpha_i^*)\eta$, so that $\alpha_i^*\eta = P(\mathbf{a}) \in \mathcal{U}$. This completes the proof of Theorem 2. □

Example 1 *Let Π be the following LPOD with the two rules:*

$$r_1 : P(x) \times Q(x) \times R(x) \leftarrow S(x), \tag{10}$$
$$r_2 : T(x) \times U(x) \leftarrow Q(x), \tag{11}$$

such that S is the only extensional predicate. Now let $\mathcal{M}$ be a $\tau(\Pi)$-structure such that:

$$\mathcal{M} = (\{a, b\}, S^{\mathcal{M}} = \{a, b\}, P^{\mathcal{M}} = \{a\}, Q^{\mathcal{M}} = \{b\}, R^{\mathcal{M}} = \emptyset, T^{\mathcal{M}} = \emptyset, U^{\mathcal{M}} = \{b\}).$$

Now based on (8) of Definition 2, we have that

$$\mathcal{M}^0(\Pi) = (\{a, b\}, S^{\mathcal{M}} = \{a, b\}, P^{\mathcal{M}} = \emptyset, Q^{\mathcal{M}} = \emptyset, R^{\mathcal{M}} = \emptyset, T^{\mathcal{M}} = \emptyset, U^{\mathcal{M}} = \emptyset),$$

i.e., all the intensional relations are initially set to empty. Now let us compute $\mathcal{M}^1(\Pi)$. From (9) of Definition 2, we have that $P(a) \in \mathcal{M}^1(\Pi)$ since $\alpha_{i=1}\eta = P(a)$ (with $\eta : x \longrightarrow a$) is the largest i such that $\{\alpha_1\eta, \ldots, \alpha_{i-1}\eta\} = \emptyset \cap \mathcal{M} = \emptyset$. Similarly, we also have that $Q(b) \in \mathcal{M}^1(\Pi)$ since in this case, with $\eta : x \longrightarrow b$, we have that $\alpha_{i=2}\eta = Q(b)$ is the largest i such that $\{\alpha_1\eta, \ldots, \alpha_{i-1}\eta\} = \{P(b)\} \cap \mathcal{M} = \emptyset$ (i.e., since $P(b) \notin \mathcal{M}$), so that we now have

$$\mathcal{M}^1(\Pi) = (\{a, b\}, S^{\mathcal{M}} = \{a, b\}, P^{\mathcal{M}} = \{a\}, Q^{\mathcal{M}} = \{b\}, R^{\mathcal{M}} = \emptyset, T^{\mathcal{M}} = \emptyset, U^{\mathcal{M}} = \emptyset).$$

Similarly, we will have $\mathcal{M}^2(\Pi)$ as follows:

$$(\{a, b\}, S^{\mathcal{M}} = \{a, b\}, P^{\mathcal{M}} = \{a\}, Q^{\mathcal{M}} = \{b\}, R^{\mathcal{M}} = \emptyset, T^{\mathcal{M}} = \emptyset, U^{\mathcal{M}} = \{b\}),$$

and further, we can obtain $\mathcal{M}^2(\Pi) = \mathcal{M}^t(\Pi)$ *for all* $t \geq 3$*, that is* $\mathcal{M}^\infty(\Pi) = \mathcal{M}^2(\Pi)$*. Therefore, since* $\mathcal{M}^\infty(\Pi) = \mathcal{M}$*, we have by Theorem 2 that* $\mathcal{M}$ *is a stable model of* Π*.* □

From LPODs to First-order Formulas

While Definition 2 provides an alternative semantics for FO LPODs, which represents the program reasoning feature through progression process, it, however, still does not reveal much information about how a stable model of a given LPOD may be computed. In this section, we show how a variant of the ordered completion (Asuncion et al. 2012) for normal logic programs can capture the stable models of first-order LPODs, which, like demonstrated in (Asuncion et al. 2012), may be viewed as a computational basis for an FO LPOD solver development.

For this purpose, for a given pair of predicates (P, Q) (where P and Q can be the same), by $\leq_{PQ}$, we denote a new predicate such that its arity is the sum of the arities of P and Q. We refer to such predicates as the *comparison predicates*. The intuitive meaning of atom $\leq_{PQ}(\mathbf{x}, \mathbf{y})$ is that: $Q(\mathbf{y})$ is true only if $P(\mathbf{x})$ is true.

Definition 3 *Let* Π *be an LPOD with tuple of distinct (intensional) predicates* $\mathbf{P}$*. Then by* $\text{MCOMP}_{\mathbf{P}}(\Pi)$*, we denote the following first-order sentence:*

$$\bigwedge_{r \in \Pi} \forall \mathbf{x}_r (\, \widehat{Body(r)} \rightarrow Head(r)^{FO}\,) \tag{12}$$

$$\wedge \bigwedge_{P \in \mathbf{P}} \forall \mathbf{x} (\, P(\mathbf{x}) \rightarrow \bigvee_{\substack{r \in \Pi, \\ Head(r)_i = P(\mathbf{y}), \\ 1 \leq i \leq k}} \exists \mathbf{x}_r (\mathbf{x} = \mathbf{y} \wedge \widehat{Body(r)} \wedge \widehat{Pos(r) < P}(\mathbf{x}) \wedge \bigwedge_{1 \leq j \leq i-1} \neg Head(r)_j)\,), \tag{13}$$

where:

- *For a rule* $r \in \Pi$*,* $\mathbf{x}_r$ *in (12) and (13) is the tuple of distinct variables of* r*;*
- *We assume that* $\mathbf{x}$ *in (13) is a tuple of fresh distinct variables not mentioning those from* $\mathbf{x}_r$*;*
- *For two tuples* $\mathbf{x} = x_1 x_2 \ldots x_s$ *and* $\mathbf{y} = y_1 y_2 \ldots y_s$*,* $\mathbf{x} = \mathbf{y}$ *in (13) denotes the formula* $(x_1 = y_1) \wedge (x_2 = y_2) \wedge \ldots \wedge (x_s = y_s)$*;*
- $\widehat{Pos(r) < P}(\mathbf{x})$ *in (13) denotes the formula*

$$\bigwedge_{\substack{Q(\mathbf{z}) \in Pos(r), \\ Q \in \mathbf{P}}} (\leq_{QP}(\mathbf{z}, \mathbf{x}) \wedge \neg \leq_{PQ}(\mathbf{x}, \mathbf{z})),$$

where the "$\leq_{QP}$*" and "*$\leq_{PQ}$*" here are comparison predicates.*

Then finally, we define

$$\text{OC}_{\mathbf{P}}(\Pi) = \text{MCOMP}_{\mathbf{P}}(\Pi) \wedge \text{TRANS}_{\mathbf{P}}(\Pi),$$

where $\text{TRANS}_{\mathbf{P}}(\Pi)$ *denotes the following formula:*

$$\bigwedge_{P,Q,R \in \mathbf{P}} \forall \mathbf{xyz} (\leq_{PQ}(\mathbf{x}, \mathbf{y}) \wedge \leq_{QR}(\mathbf{y}, \mathbf{z}) \rightarrow \leq_{PR}(\mathbf{x}, \mathbf{z})), \tag{14}$$

and each of $\mathbf{x}$*,* $\mathbf{y}$*, and* $\mathbf{z}$ *are tuples of distinct variables.*

Now we present the main result of this section as follows.

Theorem 3 *Let* Π *be an LPOD with tuple of distinct intensional predicates* $\mathbf{P}$ *and* $\mathcal{M}$ *a finite* $\tau(\Pi)$*-structure. Then* $\mathcal{M}$ *is a stable model of* Π *iff it can be expanded to a model of* $\text{OC}_{\mathbf{P}}(\Pi)$*.*

Proof: ($\Rightarrow$) Then $\mathcal{M} \models \widehat{\Pi}$, so that $\mathcal{M}$ is also a model of (12). Therefore, it is now sufficient to show that $\mathcal{M}$ can be expanded to a model of (13) and (14). Indeed, by Theorem 2, we have that $\mathcal{M}^\infty(\Pi) = \mathcal{M}$ as well since $\mathcal{M}$ is a stable model of Π (by assumption). Then based on the progression stages $\mathcal{M}^1(\Pi)$, $\mathcal{M}^2(\Pi)$, …, $\mathcal{M}^k(\Pi)$, $\mathcal{M}^{k+1}(\Pi)$, …, we now construct an expansion $\mathcal{M}'$ of $\mathcal{M}$ to the signature $\tau(\Pi) \cup \{\leq_{PQ} |\ P, Q \in \mathbf{P}\}$. Thus, for $t \geq 0$, set $\Delta^t(\Pi)$ as the $\tau(\Pi)$-structure defined inductively as follows: $\Delta^0(\Pi) = \mathcal{M}^0(\Pi)$ and where for $t \geq 1$, $\Delta^t(\Pi) = \mathcal{M}^t(\Pi) \setminus \mathcal{M}^{t-1}(\Pi)$. Then intuitively speaking, for $t \geq 1$, $\Delta^t(\Pi)$ represents the difference of the intensional relations between the stages t and $t-1$. Then we can prove the following Claim 1.

Claim 1. *If* $P(\mathbf{a}) \in \Delta^t(\Pi)$ *then for all* $t' \neq t$*, we have that* $P(\mathbf{a}) \notin \Delta^{t'}(\Pi)$*.*

Now the expansion $\mathcal{M}'$ of $\mathcal{M}$ is constructed by setting:

$$\leq_{PQ}^{\mathcal{M}'} = \{\mathbf{ab} \mid P(\mathbf{a}) \in \Delta^{t_1}(\Pi), Q(\mathbf{b}) \in \Delta^{t_2}(\Pi), \text{ and } t_1 < t_2\},$$

for each pair of predicates P and Q (can be the same) of $\mathbf{P}$. Now we show that $\mathcal{M}'$ satisfies both (13) and (14). Indeed, let $\mathbf{ab} \in \leq_{PQ}^{\mathcal{M}'}$ and $\mathbf{bc} \in \leq_{QR}^{\mathcal{M}'}$ for some predicates P, Q, and R of $\mathbf{P}$. Then by the definitions of the interpretations $\leq_{PQ}^{\mathcal{M}'}$ and $\leq_{QR}^{\mathcal{M}'}$, we have that: $P(\mathbf{a}) \in \Delta^{t_1}(\Pi)$ and $Q(\mathbf{b}) \in \Delta^{t_2}(\Pi)$ with $t_1 < t_2$; and $Q(\mathbf{b}) \in \Delta^{t_1'}(\Pi)$ and $R(\mathbf{c}) \in \Delta^{t_2'}(\Pi)$ with $t_1' < t_2'$. Then since by Claim 1, $Q(\mathbf{b})$ can only be in one particular t such that it is in $\Delta^t(\Pi)$, then we have that $t_2 = t_1'$, so that by transitivity, we have $t_1 < t_2'$. Then by the definition of the interpretation $\leq_{PR}^{\mathcal{M}'}$, we have that $\mathbf{ac} \in \leq_{PR}^{\mathcal{M}'}$, so that $\mathcal{M}'$ satisfies (14). Now to show $\mathcal{M}'$ satisfies (13), let $P(\mathbf{a}) \in \mathcal{M}'$ such that $P \in \mathbf{P}$. Then $P(\mathbf{a}) \in \mathcal{M}^\infty(\Pi)$ since $\mathcal{M}$ is a stable model of Π and $\mathcal{M}^\infty(\Pi) = \mathcal{M}$ by Theorem 2. Then for some t, we have that $P(\mathbf{a}) \in \mathcal{M}^t(\Pi)$. Let us assume without loss of generality that $P(\mathbf{a}) \notin \mathcal{M}^{t'}(\Pi)$ for all $0 \leq t' < t$, i.e., t is the first stage that derives $P(\mathbf{a})$. Then by the definition of $\mathcal{M}^t(\Pi)$, there exists some rule $r \in \Pi$ with $Head(r) = \alpha_1 \times \ldots \times \alpha_i \times \ldots \times \alpha_k$ and assignment η such that:

1. $Pos(r)\eta \subseteq \mathcal{M}^{t-1}(\Pi) \subseteq \mathcal{M}$ (and where $\mathcal{M}^{t-1}(\Pi) \subseteq \mathcal{M}$ since $\mathcal{M}^{t-1}(\Pi) \subseteq \mathcal{M}^\infty(\Pi) = \mathcal{M}$) and $Neg(r)\eta \cap \mathcal{M} = \emptyset$;
2. i (for $1 \leq i \leq k$) is the largest i such that $\{\alpha_1\eta, \ldots, \alpha_{i-1}\eta\} \cap \mathcal{M} = \emptyset$.

Then since $\mathcal{M}'$ is simply the expansion of $\mathcal{M}$ to include the interpretation of the comparison symbols in $\{\leq_{PQ} |\ P, Q \in \mathbf{P}\}$, we have that

$$\mathcal{M}' \models (\mathbf{a} = \mathbf{y} \wedge \widehat{Body(r)} \wedge \bigwedge_{1 \leq j \leq i-1} \neg \alpha_j)\eta.$$

Therefore, it is only left to show that $\mathcal{M}' \models (\widehat{Pos(r) < P}(\mathbf{a}))\eta$ so that

$$\mathcal{M}' \models (\mathbf{a} = \mathbf{y} \wedge \widehat{Body(r)} \wedge Pos(\widehat{r) < P}(\mathbf{a}) \wedge \bigwedge_{1 \leq j \leq i-1} \neg\alpha_j)\eta \tag{15}$$

as well. Indeed, since $\mathcal{M}^t(\Pi)$ is the first stage that derives $P(\mathbf{a})$, then by the definition of $\Delta^t(\Pi)$, we have that $P(\mathbf{a}) \in \Delta^t(\Pi)$. Now let $Q(\mathbf{b}) \in Pos(r)\eta$ such that $Q \in \mathbf{P}$. Then since $Q(\mathbf{b}) \in \mathcal{M}^{t-1}(\Pi)$, there exists the least stage $t' \leq t-1$ such that $Q(\mathbf{b}) \in \mathcal{M}^{t'}(\Pi)$. Then this implies that $Q(\mathbf{b}) \in \Delta^{t'}(\Pi)$, and since $t' \leq t-1 < t$, we further have by the definition of the interpretation $\leq_{QP}^{\mathcal{M}'}$ that $\mathbf{ba} \in \leq_{QP}^{\mathcal{M}'}$. Now we show that $\mathbf{ab} \notin \leq_{PQ}^{\mathcal{M}'}$. Otherwise, assume that $\mathbf{ab} \in \leq_{PQ}^{\mathcal{M}'}$. Then by the definition of $\leq_{PQ}^{\mathcal{M}'}$, there exists t_1 and t_2, where $t_1 < t_2$, such that $P(\mathbf{a}) \in \Delta^{t_1}(\Pi)$ and $Q(\mathbf{b}) \in \Delta^{t_2}(\Pi)$. Then by Claim 1, we have that $t_2 = t'$ since $Q(\mathbf{b})$ is both in $\Delta^{t_2}(\Pi)$ and $\Delta^{t'}(\Pi)$. Then because we already have that $t' < t$ and where $t_1 < t_2 = t' < t$, then we have that $t_1 < t$. Thus, since $P(\mathbf{a})$ is both in $\Delta^{t_1}(\Pi)$ and $\Delta^t(\Pi)$ where $t_1 \neq t$ (since $t_1 < t$), this is a contradiction by Claim 1. Therefore, it follows that $\mathcal{M}' \models \widehat{Pos(r) < P}(\mathbf{a})$ so that (15) holds as well.

($\Leftarrow$) Assume that $\mathcal{M}'$ is the expansion of $\mathcal{M}$ such that $\mathcal{M}' \models \mathrm{OC}_{\mathbf{P}}(\Pi)$. Then there exists a *strict-partial* order $\mathcal{P} = (Dom(\mathcal{P}), <^{\mathcal{P}})$, where

$$Dom(\mathcal{P}) = \{P(\mathbf{a}) \mid \mathbf{a} \in P^{\mathcal{M}} \text{ and } P \in \mathbf{P}\},$$

such that $\mathcal{P}$ is induced by the interpretations of the comparison predicates $\leq_{PQ}$ (for $P, Q \in \mathbf{P}$). Then by the *Order-extension Theorem* (Kaye and Macpherson 1994), there exists a *strict-total* order $\mathcal{T} = (Dom(\mathcal{T}), <^{\mathcal{T}})$, where $Dom(\mathcal{T}) = Dom(\mathcal{P})$, such that for all distinct elements $P(\mathbf{a})$ and $Q(\mathbf{b})$ in $Dom(\mathcal{T})$, either $P(\mathbf{a}) <^{\mathcal{T}} Q(\mathbf{b})$ or $Q(\mathbf{b}) <^{\mathcal{T}} P(\mathbf{a})$ holds. Now, since $\mathcal{M}$ is finite, then $Dom(\mathcal{T})$ will be finite as well, so that a bottom element, denoted $bot(\mathcal{T})$, exists. Then for a $P(\mathbf{a}) \in Dom(\mathcal{T})$, define $\mathcal{T}^{P(\mathbf{a})}$ inductively by:

1. $\mathcal{T}^{bot(\mathcal{T})} = \{bot(\mathcal{T})\}$;
2. $\mathcal{T}^{succ(P(\mathbf{a}))} = \mathcal{T}^{P(\mathbf{a})} \cup \{succ(P(\mathbf{a}))\}$,

where $succ(P(\mathbf{a}))$ denotes the *successor* of $P(\mathbf{a})$ under the ordering $<^{\mathcal{T}}$. Then $\mathcal{T}^{top(\mathcal{T})}$, where $top(\mathcal{T})$ is the greatest element under $<^{\mathcal{T}}$, is simply the collection of all the elements of $Dom(\mathcal{T})$, since $\mathcal{T}$ is a strict-total ordering of $Dom(\mathcal{T})$. We will now show by induction on $P(\mathbf{a})$ that $\mathcal{T}^{P(\mathbf{a})} \subseteq \mathcal{M}^\infty(\Pi)$ for all $P(\mathbf{a}) \in Dom(\mathcal{T})$. For the base case, assume $bot(\mathcal{T}) = P(\mathbf{a})$. Then since $\mathcal{M}'$ satisfies (13), there exists a rule $r \in \Pi$ with $Head(r) = \alpha_1 \times \ldots \times \alpha_k$ such that for some $1 \leq i \leq k$ and some assignment η, we have that

$$\mathcal{M}' \models (\mathbf{a} = \mathbf{y} \wedge \widehat{Body(r)} \wedge Pos(\widehat{r) < P}(\mathbf{a}) \wedge \bigwedge_{1 \leq j \leq i-1} \neg\alpha_j)\eta,$$

and where $\alpha_i = P(\mathbf{y})$. Moreover, since $P(\mathbf{a})$ is the bottom element under the ordering $<^{\mathcal{T}}$, then $Pos(r)$ does not mention atoms of intensional predicates (since the strict-total order $\mathcal{T}$ is induced by the interpretation of the comparison atoms). Therefore, since $P(\mathbf{a}) = \alpha_i\eta \in \mathcal{M}$ (because $Dom(\mathcal{T}) = \{P(\mathbf{a}) \mid \mathbf{a} \in P^{\mathcal{M}} \text{ and } P \in \mathbf{P}\}$), then it is not difficult to verify by Item 2 in (9) that $P(\mathbf{a}) \in \mathcal{M}^1(\Pi) \subseteq \mathcal{M}^\infty(\Pi)$. Now assume $\mathcal{T}^{Q(\mathbf{b})} \subseteq \mathcal{M}^\infty(\Pi)$ and we will show that $\mathcal{T}^{succ(Q(\mathbf{b}))} \subseteq \mathcal{M}^\infty(\Pi)$ as well. Thus, for convenience, assume that $succ(Q(\mathbf{b})) = P(\mathbf{a})$. Now, since $\mathcal{M}'$ satisfies (13), then there exists some rule $r \in \Pi$ with $Head(r) = \alpha_1 \times \ldots \times \alpha_k$ and assignment η such that

$$\mathcal{M}' \models (\mathbf{a} = \mathbf{y} \wedge \widehat{Body(r)} \wedge Pos(\widehat{r) < P}(\mathbf{a}) \wedge \bigwedge_{1 \leq j \leq i-1} \neg\alpha_j)\eta,$$

where $\alpha_i = P(\mathbf{y})$ (the "ordered support" for $P(\mathbf{a})$). Then since $\mathcal{M}' \models (\widehat{Pos(r) < P}(\mathbf{a}))\eta$ and $\mathcal{T}$ is the total-order extension of the strict-partial order induced by the interpretation of the comparison atoms, we have that $Pos(r)\eta \subseteq \mathcal{T}^{Q(\mathbf{b})}$ since $Q(\mathbf{b}) <^{\mathcal{T}} P(\mathbf{a})$. Moreover, since $\mathcal{M}' \models \widehat{Body(r)}\eta$, then $Neg(r)\eta \cap \mathcal{M} = \emptyset$ as well. Therefore, since $\mathcal{T}^{Q(\mathbf{b})} \subseteq \mathcal{M}^t(\Pi)$ for some t (since $\mathcal{T}^{Q(\mathbf{b})} \subseteq \mathcal{M}^\infty(\Pi)$ by the inductive hypothesis), then we have that both $Pos(r)\eta \subseteq \mathcal{M}^t(\Pi)$ and $Neg(r)\eta \cap \mathcal{M} = \emptyset$ holds. In addition, since we also have from (13) that $\mathcal{M} \models (\neg\alpha_1 \times \ldots \times \neg\alpha_{i-1})\eta$ and where $\alpha_i\eta = P(\mathbf{a}) \in \mathcal{M}$, then it follows from (9) that $P(\mathbf{a}) \in \mathcal{M}^{t+1}(\Pi)$. Hence, since we have shown that $\mathcal{T}^{top(\mathcal{T})} \subseteq \mathcal{M}^\infty(\Pi)$, then since $\mathcal{M}^0(\Pi) \subseteq \mathcal{M}^\infty(\Pi)$, it follows that $(\mathcal{T}^{top(\mathcal{T})} \cup \mathcal{M}^0(\Pi)) = \mathcal{M} \subseteq \mathcal{M}^\infty(\Pi)$. Therefore, to show that $\mathcal{M} = \mathcal{M}^\infty(\Pi)$, it is left for us to show that $\mathcal{M}^\infty(\Pi) \subseteq \mathcal{M}$. We now show this fact by induction on t. For the base case, we clearly have that $\mathcal{M}^0(\Pi) \subseteq \mathcal{M}$ since for $\mathcal{M}^0(\Pi)$, all the interpretation of the comparison predicates are set to empty. Now let us assume that for $0 \leq t' \leq t$, we have that $\mathcal{M}^{t'}(\Pi) \subseteq \mathcal{M}$ holds and we will now show that $\mathcal{M}^{t+1}(\Pi) \subseteq \mathcal{M}$ holds as well. Indeed, let $P(\mathbf{a}) \in \mathcal{M}^{t+1}(\Pi) \setminus \mathcal{M}^t(\Pi)$. Then by the definition of $\mathcal{M}^{t+1}(\Pi) \setminus \mathcal{M}^t(\Pi)$, there exists a rules $r \in \Pi$ with $Head(r) = \alpha_1 \times \ldots \times \alpha_i \times \ldots \times \alpha_k$ and assignment η such that

1. $P(\mathbf{a}) = \alpha_i\eta$;
2. $Pos(r)\eta \subseteq \mathcal{M}^t(\Pi)$ and $Neg(r)\eta \cap \mathcal{M} = \emptyset$;
3. i (for $1 \leq i \leq k$) is the largest i such that $\{\alpha_1\eta, \ldots, \alpha_{i-1}\eta\} \cap \mathcal{M} = \emptyset$.

Then since $\mathcal{M}^t(\Pi) \subseteq \mathcal{M}$ and $\mathcal{M} \models \widehat{\Pi}$ (since $\mathcal{M}$ satisfies (12)), then it follows that $P(\mathbf{a}) \in \mathcal{M}$. Therefore, since we had shown that $\mathcal{M}^\infty(\Pi) = \mathcal{M}$, then we have by Theorem 2 that $\mathcal{M}$ is a stable model of Π. □

Theorem 3 has an important practical value towards an LPOD solver development. Basically, for a given LPOD, to compute its stable models, we can firstly translate this program into its corresponding ordered completion $\mathrm{OC}_{\mathbf{P}}(\Pi)$, then by taking extensional databases as input to ground $\mathrm{OC}_{\mathbf{P}}(\Pi)$ to a propositional formula, and finally compute its classical models by calling an SAT solver (e.g., SMT). Some advantages of this approach over other ASP solvers for normal logic programs have been demonstrated in (Asuncion et al. 2012).

Proposition 2 *Let Π be an LPOD. Then $\mathrm{OC}_{\mathbf{P}}(\Pi)$ can be computed in time $O(|\Pi| \cdot N \cdot H \cdot |\mathbf{P}| + |\mathbf{P}|^3)$, where N and H are the maximum length of the rules and the maximum length of the ordered disjunctive heads in the rules of Π, respectively.*

Complexity and Expressiveness

Now we investigate the complexity and expressiveness issues of LPODs. For the propositional case, we can prove that the stable model existence problem for LPODs is NP-complete[1]. In the following, we focus on the first-order case. Let Π_1 and Π_2 be two programs and $\tau(\Pi_1) \subseteq \tau(\Pi_2)$. We say that Π_1 and Π_2 are *equivalent under* $\tau(\Pi_1)$ if Π_1 and Π_2 have exactly the same stable models by restricting each Π_2's stable model $\mathcal{M}$ to $\mathcal{M}\restriction_{\tau(\Pi_1)}$.

We say that a program is *positive* if negation only occurs on atoms of extensional predicates. A normal logic program is *local variable free* if all the variables in the bodies of rules are also mentioned in their corresponding heads.

Proposition 3 *Under finite structures, every local variable free normal logic program Π can be translated to a positive LPOD with auxiliary predicates such that these two programs are equivalent under $\tau(\Pi)$.*

Proof: Let Π^{NORM} be a local variable free FO normal program with intensional predicate symbols $\mathcal{P}_{int}(\Pi^{\mathrm{NORM}})$. Then for each predicate $P \in \mathcal{P}_{int}(\Pi^{\mathrm{NORM}})$, let us introduce a new predicate $\overline{P}$ of the same arity as P. Roughly speaking, $\overline{P}$ will encode the negative extents of P. Now we are ready to define the positive LPOD Π^{LPOD}.

Denote by $(\Pi^{\mathrm{NORM}})^{pos}$ the following set of rules:

$$\{\alpha \leftarrow \beta_1, \ldots, \beta_l, \overline{\gamma_1}, \ldots, \overline{\gamma_m} \mid \alpha \leftarrow \beta_1, \ldots, \beta_l, \mathsf{not}\ \gamma_1, \ldots, \mathsf{not}\ \gamma_m \in \Pi^{\mathrm{NORM}}, \text{ for } 1 \leq i \leq m, \text{if } \gamma_i = P(\mathbf{t}) \text{ and } P \in \mathcal{P}_{int}(\Pi^{\mathrm{NORM}}) \text{ then } \overline{\gamma_i} = \overline{P}(\mathbf{t}), \text{ otherwise } \overline{\gamma_i} = \gamma_i\}. \quad (16)$$

Then clearly, $(\Pi^{\mathrm{NORM}})^{pos}$ is a positive LPOD of signature $\tau(\Pi) \cup \{\overline{P} \mid P \in \mathcal{P}_{int}(\Pi^{\mathrm{NORM}})\}$.

Let S be a set of atoms occurring in Π, we denote by $\mathcal{A}_{ext}(S)$ and $\mathcal{A}_{int}(S)$ the sets of extensional and intensional atoms in S, respectively. Now let us define another program Π' as follows:

$$\{Bd_{r_1}(\mathbf{x}) \times \ldots \times Bd_{r_k}(\mathbf{x}) \leftarrow P(\mathbf{x}) \mid P \in \mathcal{P}_{int}(\Pi^{\mathrm{NORM}}), P \text{ has defining rules } r_1, \ldots, r_k \in \Pi^{\mathrm{NORM}}\} \quad (17)$$

$$\cup \{\beta \leftarrow Bd_r(\mathbf{x}), \bot \leftarrow \mathsf{not}\ \beta', Bd_r(\mathbf{x}), \overline{\gamma} \leftarrow Bd_r(\mathbf{x}), \bot \leftarrow \gamma', Bd_r(\mathbf{x}) \mid r \in \Pi^{\mathrm{NORM}}, \beta \in \mathcal{A}_{int}(Pos(r)), \beta' \in \mathcal{A}_{ext}(Pos(r)), \gamma \in \mathcal{A}_{int}(Neg(r)), \gamma' \in \mathcal{A}_{ext}(Neg(r))\} \quad (18)$$

$$\cup \{<_{QP}(\mathbf{z}, \mathbf{x}) \leftarrow Bd_r(\mathbf{x}) \mid r \in \Pi^{\mathrm{NORM}}, Head(r) = P(\mathbf{x}), Q(\mathbf{z}) \in \mathcal{A}_{int}(Pos(r))\} \quad (19)$$

$$\cup \{<_{PR}(\mathbf{x}, \mathbf{z}) \leftarrow <_{PQ}(\mathbf{x}, \mathbf{y}), <_{QR}(\mathbf{y}, \mathbf{z}) \mid P, Q, R \in \mathcal{P}_{int}(\Pi^{\mathrm{NORM}})\} \quad (20)$$

$$\cup \{\bot \leftarrow <_{PQ}(\mathbf{x}, \mathbf{y}), <_{QP}(\mathbf{y}, \mathbf{x}) \mid P, Q \in \mathcal{P}_{int}(\Pi^{\mathrm{NORM}})\}. \quad (21)$$

Lastly, further define one more program Π'' as follows:

$$\{\bot \leftarrow P(\mathbf{x}), \overline{P}(\mathbf{x}), \quad (22)$$

$$P(\mathbf{x}) \times \overline{P}(\mathbf{x}) \leftarrow \mid P \in \mathcal{P}_{int}(\Pi^{\mathrm{NORM}})\}. \quad (23)$$

Then we can now set Π^{LPOD} as the union $(\Pi^{\mathrm{NORM}})^{pos} \cup \Pi' \cup \Pi''$. Clearly, Π^{LPOD} is a positive LPOD.

Intuitively, we have that (16)-(21) encode the ordered completion of Π^{NORM} within the LPOD Π^{LPOD} itself. In particular, we note (18), which encodes the "supporting" atoms for the "body atoms" $Bd_r(\mathbf{x})$ (which corresponds to the body of the rule r), but in such a way that we avoid defining the extensional predicates in a head of a rule. On the other hand, (22) enforces that $(P(\mathbf{x}) \rightarrow \neg\overline{P}(\mathbf{x})) \wedge (\overline{P}(\mathbf{x}) \rightarrow \neg P(\mathbf{x}))$ while (23) enforces that $(\neg P(\mathbf{x}) \rightarrow \overline{P}(\mathbf{x})) \wedge (\neg\overline{P}(\mathbf{x}) \rightarrow P(\mathbf{x}))$, i.e., the "necessary" counterpart of (22) with respect to the extents of $\overline{P}$ being the symmetric negation of those in P. □

Theorem 4 *Let Π be an LPOD and $\mathcal{M}$ a finite $\tau_{ext}(\Pi)$-structure, i.e., an extensional or input database structure. Then the problem of determining if $\mathcal{M}$ can be expanded to a stable model of Π is NP-complete. This result remains true even for positive LPODs.*

Proof: (*Membership*) Given our reduction of Π to the FO formula $\mathrm{OC}_{\mathbf{P}}[\Pi]$ via Theorem 3 (i.e., the reduction of Π to its ordered completion), we have that determining if $\mathcal{M}$ can be expanded to a model of $\mathrm{OC}_{\mathbf{P}}[\Pi]$ is the model expansion problem, which is in NP (model expansion is in fact NP-complete).

(*Hardness*) Consider the 3-color program Π_{3color} as fol-

[1] In our full version, we provide a polynomial translation from normal logic programs to LPODs. This result can be also obtained using a different translation proposed in (Nieuwenborgh and Vermeir 2003).

lows:

$$C_1(x) \leftarrow \mathsf{not}\, C_2(x), \mathsf{not}\, C_3(x), \quad (24)$$
$$C_2(x) \leftarrow \mathsf{not}\, C_1(x), \mathsf{not}\, C_3(x), \quad (25)$$
$$C_3(x) \leftarrow \mathsf{not}\, C_1(x), \mathsf{not}\, C_2(x), \quad (26)$$
$$\leftarrow E(x,y), C_1(x), C_1(y), \quad (27)$$
$$\leftarrow E(x,y), C_2(x), C_2(y), \quad (28)$$
$$\leftarrow E(x,y), C_3(x), C_3(y). \quad (29)$$
$$(30)$$

Given a graph structure $\mathcal{G} = (Dom(\mathcal{G}), V^{\mathcal{G}}, E^{\mathcal{G}})$ such that $V^{\mathcal{G}} = Dom(\mathcal{G})$ (i.e., the vertices of $\mathcal{G}$), $\mathcal{G}$ has a corresponding 3-coloring iff Π_{3color} has a stable model. It is well known that the problem of 3-coloring is NP-complete. On the other hand, we have by Proposition 3 that Π_{3color} can be reduced to a positive LPOD since Π_{3color} is a local variable free normal program. □

A LPOD is called *almost positive* if each negated intensional atoms in the program only occurs in the bodies of some constraints. The following theorem states that almost positive LPODs precisely capture the full class of normal logic programs. That is, ordered disjunction and constraints are sufficient enough to represent negation as failure.

Theorem 5 *Every normal logic program* Π *can be translated to an almost positive LPODs with auxiliary predicates such that these two programs are equivalent under* $\tau(\Pi)$.

Proof: Let Π^{NORM} be an arbitrary normal logic program. We define a reduction from Π^{NORM} to an almost positive LPOD Π^{LPOD} by defining Π^{LPOD} as the following set of rules:

$$\{\alpha \leftarrow \beta_1, \ldots, \beta_l, \overline{\gamma_1}, \ldots, \overline{\gamma_m} \mid \alpha \leftarrow \beta_1, \ldots, \beta_l, \mathsf{not}\, \gamma_1, \ldots, \mathsf{not}\, \gamma_m \in \Pi^{\text{NORM}},$$
$$\text{for } 1 \le i \le m, \text{if } \gamma_i = P(\mathbf{t}) \text{ and } P \in \mathcal{P}_{int}(\Pi^{\text{NORM}}) \text{ then } \overline{\gamma_i} = \overline{P}(\mathbf{t}), \text{ otherwise } \overline{\gamma_i} = \gamma_i\} \quad (31)$$
$$\cup \{\bot \leftarrow P(\mathbf{x}), \overline{P}(\mathbf{x}), \quad (32)$$
$$\bot \leftarrow \mathsf{not}\, P(\mathbf{x}), \mathsf{not}\, \overline{P}(\mathbf{x}), \quad (33)$$
$$\bot \leftarrow P'(\mathbf{x}), \overline{P}(\mathbf{x}), \quad (34)$$
$$P'(\mathbf{x}) \times \overline{P}(\mathbf{x}) \leftarrow \mid P \in \mathcal{P}_{int}(\Pi^{\text{NORM}})\}, \quad (35)$$

where for each $P \in \mathcal{P}_{int}(\Pi)$, we introduce two new predicate symbols $\overline{P}$ and P'. Then Π^{LPOD} is clearly an almost positive LPOD since negation only occurs in the constraints in (33).

Intuitively, the key here is the combination of (34) and (35), which enforces $(\neg P'(\mathbf{x}) \rightarrow \overline{P}(\mathbf{x})) \wedge (\neg \overline{P}(\mathbf{x}) \rightarrow P'(\mathbf{x}))$. This has the effect of "fixing" $\overline{P}(\mathbf{x})^*$ since the "minimization" of $\overline{P}^*$ implies the "expansion" of $(P')^*$ (and vice versa). This simulates the condition that $\overline{P}(\mathbf{x})$ (which encodes "$\mathsf{not}\, P(\mathbf{x})$") will be fixed in the minimization of $\overline{P}(\mathbf{x})^*$ since we also have $(\neg P'(\mathbf{x})^* \rightarrow \overline{P}(\mathbf{x})^*) \wedge (\neg \overline{P}(\mathbf{x})^* \rightarrow P'(\mathbf{x})^*)$. On the other hand, (32) and (33) again enforces $(P(\mathbf{x}) \rightarrow \neg \overline{P}(\mathbf{x})) \wedge (\overline{P}(\mathbf{x}) \rightarrow \neg P(\mathbf{x}))$ and $(\neg P(\mathbf{x}) \rightarrow \overline{P}(\mathbf{x})) \wedge (\neg \overline{P}(\mathbf{x}) \rightarrow P(\mathbf{x}))$, respectively. □

Preferred Stable Model Semantics

As indicated by Brewka (2002; 2006), the stable models based on split programs are usually not sufficient to capture the preference semantics for a given LPOD, while a certain preference relation based on the degree of satisfaction has to be imposed on the stable models. Now we show how such preferred stable model semantics can be defined for our FO LPODs.

Definition 4 *Let* r *be a rule in some LPOD* Π, $\mathcal{M}$ *a* $\tau(\Pi)$*-structure, and* η *an assignment from the distinct tuple of variables* $\mathbf{x}$ *of* r *to* $Dom(\mathcal{M})$. *The* satisfaction degree *of* r *under the structure* $\mathcal{M}$ *and assignment* η, *denoted by* $Deg_{(\mathcal{M},\eta)}(r)$, *is defined as follows:*

$$Deg_{(\mathcal{M},\eta)}(r) := \begin{cases} 1 & \text{if } \mathcal{M} \not\models \widehat{Body(r)}\eta, \text{ otherwise} \\ i & \text{if } \mathcal{M} \models (\widehat{Body(r)} \wedge \neg\alpha_1 \wedge \neg\alpha_2 \wedge \\ & \ldots \wedge \neg\alpha_{i-1} \wedge \alpha_i)\eta. \end{cases}$$

Similarly to the propositional case, if $(\mathcal{M}, \eta)$ does not satisfy the rule r's body, then the default satisfaction degree is 1. Otherwise, the satisfaction degree is the "minimal" (i.e., most preferred) of the atoms in $\alpha_1 \times \ldots \times \alpha_k$ that $(\mathcal{M}, \mathbf{a})$ satisfies. Again as in the propositional case, this encodes that we are paying for a penalty for the "least preferred" atoms in $\alpha_1 \times \ldots \times \alpha_k$ being satisfied in the sense that, the smaller the satisfaction degree, then the better it is.

Definition 5 *Let* Π *be an LPOD and* $\mathcal{M}_1$ *and* $\mathcal{M}_2$ *be two stable models of* Π *such that* $\mathcal{M}_1 \restriction_{\tau_{ext}(\Pi)} = \mathcal{M}_2 \restriction_{\tau_{ext}(\Pi)}$. *Then we say that* $\mathcal{M}_1$ *is* Pareto-preferred *to* $\mathcal{M}_2$, *denoted by* $\mathcal{M}_1 > \mathcal{M}_2$, *if the following two conditions hold:*

1. *For each rule* $r \in \Pi$ *and assignment* η, *we have that* $Deg_{(\mathcal{M}_1,\eta)}(r) \le Deg_{(\mathcal{M}_2,\eta)}(r)$;
2. *There is a rule* $r' \in \Pi$ *and an assignment* η' *such that* $Deg_{(\mathcal{M}_1,\eta')}(r') < Deg_{(\mathcal{M}_2,\eta')}(r')$.

Example 2 *Assume* Π *to be the following LPOD with the single rule* r*:*

$$r: \; P(x) \times Q(x) \times R(x) \leftarrow S(x) \quad (36)$$

such that S *is the only extensional predicate. Now let* $\mathcal{M}_1$ *and* $\mathcal{M}_2$ *be two* $\tau(\Pi)$*-structures such that:*

$$\mathcal{M}_1 = (\{a,b\}, S^{\mathcal{M}_1} = \{a,b\}, P^{\mathcal{M}_1} = \{a\}, Q^{\mathcal{M}_1} = \{b\}, R^{\mathcal{M}_1} = \emptyset);$$
$$\mathcal{M}_2 = (\{a,b\}, S^{\mathcal{M}_2} = \{a,b\}, P^{\mathcal{M}_2} = \emptyset, Q^{\mathcal{M}_2} = \{b\}, R^{\mathcal{M}_2} = \{a\}).$$

Then we have that $\mathcal{M}_1 \restriction_{\tau_{ext}(\Pi)} = \mathcal{M}_2 \restriction_{\tau_{ext}(\Pi)}$ *and where the grounding of* Π *under the domain* $\{a,b\}$ *will be the propositional program*

$$P(a) \times Q(a) \times R(a) \leftarrow S(a) \quad (37)$$
$$P(b) \times Q(b) \times R(b) \leftarrow S(b). \quad (38)$$

Then based on the grounded Π, *it can be seen that both* $\mathcal{M}_1$ *and* $\mathcal{M}_2$ *are stable models of* Π. *In addition, since for all the assignments* $\eta_1 : x \longrightarrow a$ *and* $\eta_2 : x \longrightarrow b$ *of the variable* x *to* $\{a,b\}$, *we have that* $Deg_{(\mathcal{M}_1,\eta_1)}(r) < Deg_{(\mathcal{M}_2,\eta_1)}(r)$ *and* $Deg_{(\mathcal{M}_1,\eta_2)}(r) = Deg_{(\mathcal{M}_2,\eta_2)}(r)$, *then* $\mathcal{M}_1 > \mathcal{M}_2$, *i.e.,* $\mathcal{M}_1$ *is Pareto-preferred to* $\mathcal{M}_2$. □

Based on the notion of a Pareto-preferred stable models, we can now define the notion of a preferred stable model of an LPOD.

Definition 6 *Let Π be an LPOD and $\mathcal{M}$ its stable model. $\mathcal{M}$ is called a* preferred stable model *of Π if there does not exists another structure $\mathcal{M}'$ for which $\mathcal{M}' > \mathcal{M}$.*

Logic Formalization of Preferred Stable Models

Now we provide a logical characterization of the preferred stable models. For this purpose, let us assume the tuple of distinct intensional predicates in our signature to be $\mathbf{P} = P_1 \dots P_n$. We use $\mathbf{P'}$ to denote the tuple of distinct predicates $P'_1 \dots P'_s$ such that each P'_i $(1 \leq i \leq s)$ is a new predicate symbol.

Consider a rule r of an LPOD with the form (3) and whose atoms are predicates from $\mathbf{P}$. We use $Deg(r)^{\mathbf{P'}} \leq Deg(r)^{\mathbf{P}}$ to denote the following formula:

$$\bigwedge_{1 \leq i \leq k} \forall \mathbf{x}_r (\, (\widehat{Body(r)} \wedge \bigwedge_{1 \leq j \leq i} \neg\alpha_j)[\mathbf{P}/\mathbf{P'}] \rightarrow (\widehat{Body(r)} \wedge \bigwedge_{1 \leq j \leq i} \neg\alpha_j)\,), \quad (39)$$

where $(\widehat{Body(r)} \wedge \bigwedge_{1 \leq j \leq i} \neg\alpha_j)[\mathbf{P}/\mathbf{P'}]$ denotes the formula obtained from $(\widehat{Body(r)} \wedge \bigwedge_{1 \leq j \leq i} \neg\alpha_j)$ by replacing the occurrences of predicates from $\mathbf{P}$ by those corresponding ones in $\mathbf{P'}$.

Roughly speaking, $Deg(r)^{\mathbf{P'}} \leq Deg(r)^{\mathbf{P}}$ is a formula that encodes all instances of r under the interpretation of the predicates from $\mathbf{P'}$ is at an equal or lower satisfaction degree than those ones from $\mathbf{P}$. Indeed, (39) encodes that the degree of r under $\mathbf{P'}$ is less than or equal than those under $\mathbf{P}$. As we will see later on, the purpose of the predicates $\mathbf{P'}$ that matches $\mathbf{P}$ is it will be used as second-order variables.

We now extend this notion to a whole LPOD Π so that by $Deg(\Pi)^{\mathbf{P'}} \leq Deg(\Pi)^{\mathbf{P}}$, we denote the conjunctions $\bigwedge_{r \in \Pi}(Deg(r)^{\mathbf{P'}} \leq Deg(r)^{\mathbf{P}})$, and that we further denote by $Deg(\Pi)^{\mathbf{P'}} < Deg(\Pi)^{\mathbf{P}}$ as the conjunction

$$(Deg(\Pi)^{\mathbf{P'}} \leq Deg(\Pi)^{\mathbf{P}}) \wedge \neg(Deg(\Pi)^{\mathbf{P}} \leq Deg(\Pi)^{\mathbf{P'}}). \quad (40)$$

Intuitively, $Deg(\Pi)^{\mathbf{P'}} < Deg(\Pi)^{\mathbf{P}}$ is a formula which encodes that the interpretation $\mathbf{P'}$ satisfies Π in a more optimal manner (i.e., in the sense of Definition 5) than that of Π under $\mathbf{P}$.

The following theorem now provides a classical logic characterization of preferred stable models of LPODs via a second-order sentence.

Theorem 6 *Let Π be an LPOD with tuple of intensional predicates $\mathbf{P} = P_1 \dots P_n$ and $\mathbf{P'} = P'_1 \dots P'_n$ the fresh tuple of predicates matching $\mathbf{P}$, and $\mathcal{M}$ a $\tau(\Pi)$-structure. Then $\mathcal{M}$ is a preferred stable model of Π if and only if it satisfies the following second-order sentence:*

$$\mathrm{SM}_{\mathbf{P}}(\Pi) \wedge \neg\exists \mathbf{P'}(\, \mathrm{SM}_{\mathbf{P}}(\Pi)[\mathbf{P}/\mathbf{P'}] \wedge Deg(\Pi)^{\mathbf{P'}} < Deg(\Pi)^{\mathbf{P}}\,), \quad (41)$$

where $\mathrm{SM}_{\mathbf{P}}(\Pi)[\mathbf{P}/\mathbf{P'}]$ denotes the formula obtained from $\mathrm{SM}_{\mathbf{P}}(\Pi)$ by simultaneously replacing all predicates from $\mathbf{P}$ by those corresponding ones from $\mathbf{P'}$.

It can be showed that (41) also correctly represents Brewka's preferred stable model semantics when we restrict it to the case of propositional LPODs.

Corollary 1 *On finite structures, $\mathcal{M}$ is a preferred stable model of Π if and only if it satisfies the following second-order sentence:*

$$\mathrm{OC}_{\mathbf{P}}(\Pi) \wedge \neg\exists \mathbf{P'}\mathbf{T'}(\, \mathrm{OC}_{\mathbf{P}}(\Pi)[\mathbf{PT}/\mathbf{P'}\mathbf{T'}] \wedge Deg(\Pi)^{\mathbf{P'}\mathbf{T'}} < Deg(\Pi)^{\mathbf{QT}}\,),$$

where $\mathrm{OC}_{\mathbf{P}}(\Pi)$ is the ordered completion of Π (a first-order sentence) as defined in Definition 3, and we assume that $\mathbf{T}$ denotes the tuple of distinct comparison predicates and such that $\mathbf{T'}$ are the new predicate symbols that matches $\mathbf{T}$.

Theorem 7 *Let Π be an LPOD and $\mathcal{M}$ a $\tau(\Pi)$-structure. Then determining if $\mathcal{M}$ is a preferred stable model of Π is co-NP-complete.*

Proof: (*Sketch*) Due to a space limit, here we only present a sketch proof for the hardness. A full proof is given in our full paper. For a given normal logic program Π^{NORM} and an extensional structure $\mathcal{M}_{ext}$ of it, we reduce the problem of determining if $\mathcal{M}_{ext}$ cannot be expanded to a stable model of Π^{NORM} to the problem of determining if a stable model $\mathcal{M}^*$ of an LPOD Π^* is a preferred stable model. Let Π^{NORM} be an arbitrary normal logic program. We specify a program $\Pi^{\text{NORM}}_{\{P(a)\}}$ as follows:

$$\Pi^{\text{NORM}}_{\{P(a)\}} := \{\, \alpha \leftarrow P(a), \beta_1, \dots, \beta_l, \mathsf{not}\ \gamma_1, \dots, \mathsf{not}\ \gamma_m \mid \alpha \leftarrow \beta_1, \dots, \beta_l, \mathsf{not}\ \gamma_1, \dots, \mathsf{not}\ \gamma_m \in \Pi^{\text{NORM}} \,\},$$

where we assume that $P(a)$ is an atom with P a new predicate symbol and a a new constant symbol. Then $\Pi^{\text{NORM}}_{\{P(a)\}}$ is simply the program obtained from Π^{NORM} by adding the atom $P(a)$ (i.e., propositional atom) into each of the positive bodies of the rules of Π^{NORM}. Now by Π^{LPOD}, define the following set of rules such that:

$$\begin{aligned}
\Pi^{\text{LPOD}} := \{ \quad P(a) &\leftarrow \mathsf{not}\, Q(a), && (42)\\
Q(a) &\leftarrow \mathsf{not}\, P(a), && (43)\\
R_1(a) \times R_2(a) &\leftarrow Q(a), && (44)\\
&\leftarrow R_1(a) \quad \}, && (45)
\end{aligned}$$

where we assume here that Q, R_1, and R_2 are new predicate symbols as well. Intuitively, rules (42) and (43) are the defining (and the only defining) rules for $P(a)$ and $Q(a)$, respectively, such that at least one, and not both, must be in any stable model of Π^{LPOD}. In addition, the rule (44) is an LPOD rule with $R_1(a)$ taking preference over $R_2(a)$. Finally, the constraint (45) simply enforces to choose $R_2(a)$ (which is less preferred over $R_1(a)$) over $R_1(a)$ so that the satisfaction degree of (44) will only be as low as 1 only if $Q(a)$ is false (since $Q(a)$ false makes the body of (44) to be false as well). Thus, if we want to get the most preferred stable model of Π^{LPOD}, then it must imply $Q(a)$ to be false. Finally, we can prove the following claim, which leads to the completion of this proof.

Claim: *There exists a stable model $\mathcal{M}^*$ of program $\Pi^{\text{NORM}}_{\{P(a)\}} \cup \Pi^{\text{LPOD}}$, such that $\mathcal{M}^*$ is a preferred stable model of $\Pi^{\text{NORM}}_{\{P(a)\}} \cup \Pi^{\text{LPOD}}$ iff $\mathcal{M}_{ext}$ cannot be expanded to a stable model of Π^{NORM}.*

□

Proposition 4 *Let Π be an LPOD and $\mathcal{M}$ a corresponding extensional structure. The problem of determining if $\mathcal{M}$ can be expanded to a preferred stable model of Π is NP-complete.*

Conclusions

Preference plays an important role in commonsense reasoning, while developing an effective yet expressive mechanism of handling preference in Answer Set Programming is technically challenging, e.g., (Brewka, Truszczynski, and Woltran 2010; Delgrande, Schaub, and Tompits 2004). In this paper we have developed a formulation of fist-order LPODs which may be viewed as a natural generalization of Brewka's propositional LPODs. The relevant semantics and expressiveness results also provide important insights for us to understand this type of first-order LPODs.

The proposed both the second-order based stable model semantics and the progression semantics capture two important aspects of LPODs: their relationship to classical logic as well as the underlying reasoning feature involving ordered disjunction on the first-order level.

The translation from LPODs to first-order sentences extends the previous work of Asuncion *et al*' ordered completion and we argue that this translation will be useful in developing an effective solver for first-order LPODs, as demonstrated in (Asuncion et al. 2012) for normal logic programs. The complexity and expressiveness results confirm that LPODs remain in NP and the hardness holds even for positive LPODs, while almost positive LPODs capture the full class of normal logic programs. Our logic characterization of preferred stable model semantics reveals that we can eventually use a classical second-order sentence to precisely represent the preference relation among stable models so that such first-order preference semantics may be formalized in a unified way as LPOD first-order stable model semantics.

For future work, we are considering to develop a first-order LPOD solver based on the translation proposed in section 4. Another interesting work is to extend our semantics for first-order LPODs by allowing both ordered and unordered disjunction in the heads of rules, as discussed in (Cabalar 2011), and explore their logical properties and possible applications in practical domains.

Abstract

Extensional higher-order logic programming has been recently proposed as an interesting extension of classical logic programming. An important characteristic of the new paradigm is that it preserves all the well-known properties of traditional logic programming. In this paper we enhance extensional higher-order logic programming with *constructive negation*. We argue that the main ideas underlying constructive negation are quite close to the existing proof procedure for extensional higher-order logic programming and for this reason the two notions amalgamate quite conveniently. We demonstrate the soundness of the resulting proof procedure and describe an actual implementation of a language that embodies the above ideas. In this way we obtain the first (to our knowledge) higher-order logic programming language supporting constructive negation and offering a new style of programming that genuinely extends that of traditional logic programming.

1 Introduction

Extensional higher-order logic programming has been recently proposed (Charalambidis et al. 2010; 2013) as an interesting extension of classical logic programming. The key idea behind the new paradigm is that all predicates defined in a program (even the higher-order ones) denote sets and therefore one can use standard extensional set theory in order to understand the meaning of programs and reason about them. A consequence of this fact is that the semantics and the proof theory of extensional higher-order logic programming smoothly extend the corresponding ones for traditional (ie., first-order) logic programming.

In this paper we extend the new paradigm of extensional higher-order logic programming with *constructive negation* (Chan 1988; 1989). The combination of higher-order characteristics and constructive negation in the new language, allows the programmer to specify in a compact way many interesting problems. For example, in the new language it is quite convenient to enumerate the sets that satisfy a specific property (such as all the colorings of a graph, all the subsets of a set that satisfy a condition, and so on). In order to theoretically justify the proposed higher-order language, we define its *completion semantics* and demonstrate the soundness of the proof procedure with respect to this semantics. Finally, we describe an implementation of the new language which embodies the above ideas. In conclusion, the main contributions of the present work are the following:

- We propose the first (to our knowledge) higher-order logic programming language with constructive negation. The amalgamation of the two ideas seems quite natural and expressive (but is non-trivial from a technical point of view).
- We provide a theoretical justification of our proposal by defining the completion semantics for higher-order logic programs and by demonstrating the soundness of the proposed proof procedure with respect to this semantics. In this way we provide a promising direction for the study of the interplay between higher-order logic programming and negation-as-failure.

The rest of the paper is organized as follows. Section 2 describes the motivation behind the present work. Section 3 provides the syntax and semantics of the proposed higher-order language and Section 4 presents the corresponding proof-procedure and discusses its implementation. Section 5 demonstrates the soundness of the proof-procedure. Section 6 concludes the paper with discussion on future work.

2 Motivation

The purpose of this paper is to enhance extensional higher-order logic programming with constructive negation. These two notions prove to be very compatible, for reasons that we are going to explain in detail below.

In (Charalambidis et al. 2013) the higher-order logic programming language $\mathcal{H}$ is defined. Intuitively, $\mathcal{H}$ extends classical logic programming with higher-order user-defined predicates. The main novel characteristic of $\mathcal{H}$ with respect to other existing higher-order logic programming languages (such as Hilog (Chen, Kifer, and Warren 1993) and λ-Prolog (Miller and Nadathur 1986)) is that it has a purely extensional semantics: program predicates denote sets of objects and the semantics of the language is an extension of the traditional semantics of classical logic programming. Since predicates in $\mathcal{H}$ denote sets, the programmer is allowed to use uninstantiated predicate variables in clause bodies and in queries; when the proof-procedure of $\mathcal{H}$ encounters such

a variable, it performs a systematic enumeration of the possible values that this variable can take. For further details regarding $\mathcal{H}$ the interested reader should consult (Charalambidis et al. 2013). The following two examples motivate the language. To simplify our presentation for this section, we use an extended Prolog-like syntax. The exact syntax of the language that will be the object of our study will be specified in the next section.

Example 1. Consider the program:

```
p(Q):-Q(0),Q(1).
```

The meaning of p can be understood in set-theoretic terms, ie., p is a predicate that is true of all relations that contain (at least) 0 and 1. Thus, it is meaningful to ask the query:

```
?-p(R).
```

which will respond with an answer of the form $\texttt{R} = \{0, 1\} \cup \texttt{L}$ (having the obvious meaning described above).

Example 2. Consider the following program stating that a band is a group that has at least a singer and a guitarist:

```
band(B):-singer(S),B(S),guitarist(G),B(G).
```

Suppose that we also have a database of musicians:

```
singer(sally).
singer(steve).
guitarist(george).
guitarist(grace).
```

We can then ask the following query:

```
?-band(B).
```

which returns answers of the form $\texttt{B} = \{\texttt{sally}, \texttt{george}\} \cup \texttt{L}$, and so on.

It should be noted that in $\mathcal{H}$ one can ask queries with free predicate variables of any *order*; this means that we can have queries that return sets of sets of objects, and so on.

As demonstrated in (Charalambidis et al. 2013), one can define a sound and complete proof procedure for $\mathcal{H}$ and based on it to obtain a reasonably efficient implementation of the language. There are however certain aspects of the language that require further investigation. One basic property of all the higher-order predicates that can be defined in $\mathcal{H}$ is that they are *monotonic*. Intuitively, the monotonicity property states that if a predicate is true of a relation R then it is also true of every superset of R. In the above example, it is clear that if band is true of a relation B then it is also true of any band that is a superset of B. However, there are many natural higher-order predicates that are *non-monotonic*. For example, consider the predicate disconnected(G) which succeeds if its input argument, namely a graph G, is disconnected. A graph is simply a set of pairs, and therefore disconnected is a second-order predicate. Notice now that disconnected is obviously non-monotonic: given graphs G1 and G2 with $\texttt{G1} \subseteq \texttt{G2}$, it is possible that disconnected(G1) succeeds but disconnected(G2) fails.

The obvious idea in order to add non-monotonicity to $\mathcal{H}$ is to enhance the language with negation-as-failure. However, this is not as straightforward as it sounds, because even the simpler higher-order programs with negation face the well-known problem of *floundering* (Lloyd 1987). In classical logic programming a computation is said to *flounder* if at some point a goal is reached that contains only non-ground negative literals. In higher-order logic programming this problem is even more extended since a goal may additionally contain uninstantiated higher-order variables.

Example 3. Consider the following simple modification to the program of Example 1:

```
p(Q):-Q(0),not(Q(1)).
```

Intuitively, p is true of all relations that contain 0 but they do not contain 1. The query:

```
?-p(R).
```

will not behave correctly if a simple-minded implementation of negation-as-failure is followed; this is due to the fact that in order to answer the given query one has to answer the subquery not(R(1)). Since the relation R is not fully known at the point of this call, it is not obvious how the implementation should treat such a subquery.

Constructive negation (Chan 1988; 1989) bypasses the problem of floundering. The main idea can be explained by a simple example. Consider the program:

```
p(1).
p(2).
```

and the query:

```
?-not(p(X)).
```

The original idea (Chan 1988) behind constructive negation is that in order to answer a negative query that contains uninstantiated variables, the following procedure must be applied: we run the positive version of the query and we collect the solutions as a disjunction; we then return the negation of the disjunction as the answer to the original query. This idea can be extended even to the case where a query has an infinite number of answers (Chan 1989). In our example, the corresponding positive query (namely ?-p(X).) has the answers X=1 and X=2. The negation of their disjunction is the conjunction $(\texttt{X} \neq 1) \wedge (\texttt{X} \neq 2)$. Observe now that the procedure behind constructive negation returns as answers not only substitutions (as it happens in negationless logic programming) but also inequalities.

Generalizing the above idea to the higher-order setting requires the ability to express some form of inequalities regarding the elements of sets. Intuitively, we would like to express the property that some element *does not belong to a set*. For example, given the query in Example 3, a reasonable answer would be $\texttt{R} = \{0\} \cup \{\texttt{X} \mid \texttt{X} \neq 1\}$.

We start with the syntax of $\mathcal{H}$ as introduced in (Charalambidis et al. 2013) and extend it in order to allow negation in clause bodies. The new language, $\mathcal{H}_{cn}$, has only one limitation with respect to the initial $\mathcal{H}$: the existential predicate variables that appear in queries or in clause bodies of

$\mathcal{H}_{cn}$ can only be sets of terms (and not, for example, sets of sets, or sets of sets of sets, and so on). The reasons for our restriction are two-fold: first, it is not straightforward to express inequalities regarding the elements of a set of sets; and second, it would be much more difficult to express the proof procedure if the queries were not restricted (and the implementation would also face significant complications).

It turns out that $\mathcal{H}_{cn}$ is quite appropriate in expressing problems that require a generate-and-test of sets in order to reach a solution. For example, many graph problems require the enumeration and testing of subgraphs of a given graph. In this respect, the language $\mathcal{H}_{cn}$ appears to have an application domain that is similar to that of modern ASP languages, which are being used for specifying computationally difficult problems (Gelfond and Lifschitz 1988; Lifschitz 2008). Of course, the higher-order approach is completely different than the ASP one in terms of syntax and semantics, and a comparative evaluation of the two paradigms deserves further investigation.

Example 4. Consider the following program which defines the subset relation:

```
subset(P,Q):-not(non_subset(P,Q)).
non_subset(P,Q):-P(X),not(Q(X)).
```

and assume that we have a predicate `q` which is true of `0`, `1` and `2`. Then, given the query

```
?-subset(P,q).
```

the interpreter produces all the subsets of the set $\{0, 1, 2\}$.

Example 5. Consider the following program which defines the relation `twocolor(G,R)` which is true if `R` is a subset of the set of vertices of `G` that can be painted with the same color in a two-coloring of `G`.

```
twocolor(G,R):-subset(R,vertex_set(G)),
               not(non_twocolor(G,R)).

vertex_set(G)(X):-G(X,_).
vertex_set(G)(X):-G(_,X).

non_twocolor(G,R):-G(X,Y),R(X),R(Y).
non_twocolor(G,R):-G(X,Y),not(R(X)),not(R(Y)).
```

Assume that `g` is a binary predicate defining a graph. By asking the query:

```
?-twocolor(g,R).
```

the implementation will enumerate all the possible relations `R` that constitute valid two-colorings of `g`.

Example 6. The following program can be used to enumerate all the subgraphs of a given graph that are cliques:

```
clique(G,R):-subset(R,vertex_set(G)),
             not(non_clique(G,R)).

non_clique(G,R):-R(X),R(Y),not(G(X,Y)).
```

3 Syntax and Semantics

This section defines in a formal way the syntax and the semantics of the higher-order language $\mathcal{H}_{cn}$.

The Syntax of $\mathcal{H}_{cn}$

The language $\mathcal{H}_{cn}$ is in fact a more austere version of the ad-hoc language used for the examples of the previous section.

Example 7. The `subset` predicate of Example 4 can be expressed in $\mathcal{H}_{cn}$ as follows:

$$\texttt{subset} \leftarrow \lambda\texttt{P}.\lambda\texttt{Q}.\ \sim\exists\texttt{X}((\texttt{P X})\wedge\sim(\texttt{Q X}))$$

The `subset` predicate is defined by a λ-expression (which obviates the need to have the formal parameters of the predicate in the left-hand side of the definition). Moreover, in the right-hand side we have an explicit existential quantifier for the variable `X` (in Prolog, if a variable appears in the body of a clause but not in the head, then it is implicitly existentially quantified). Consider the query:

$$\leftarrow \texttt{subset R p}$$

Notice that here the variable `R` is not explicitly existentially quantified: we assume that the free variables of the goal are the ones for which the proof procedure will attempt to find bindings in order for the goal to be satisfied. If a variable appears explicitly existentially quantified in the goal, then the implementation will not produce a binding for it.

The type system of $\mathcal{H}_{cn}$ is based on two base types: o, the type of the boolean domain, and ι, the type of the domain of individuals (data objects). For example, every classical logic programming term is of type ι.

The basic difference in the types of $\mathcal{H}_{cn}$ from those of $\mathcal{H}$ is the existence of a type μ which restricts the set of predicate variables that can be existentially quantified or appear free in goal clauses (as explained in the previous section).

Definition 1. A type can either be *functional*, *argument*, or *predicate*, denoted by σ, ρ and π and defined as:

$$\begin{array}{lcl} \sigma & := & \iota \mid (\iota \rightarrow \sigma) \\ \rho & := & \iota \mid \pi \\ \pi & := & o \mid (\rho \rightarrow \pi) \end{array}$$

The subtypes μ and κ of ρ and π are defined as follows:

$$\begin{array}{lcl} \mu & := & \iota \mid \kappa \\ \kappa & := & \iota \rightarrow o \mid (\iota \rightarrow \kappa) \end{array}$$

The types μ and κ will be called *existential* and *set* types respectively.

The operator $\rightarrow$ is right-associative. A functional type that is different from ι will often be written in the form $\iota^n \rightarrow \iota$, $n \geq 1$. Similarly, a set type will often be written in the form $\iota^n \rightarrow o$, $n \geq 1$. It can be easily seen that every predicate type π can be written in the form $\rho_1 \rightarrow \cdots \rightarrow \rho_n \rightarrow o$, $n \geq 0$ (for $n = 0$ we assume that $\pi = o$). We proceed with the alphabet of $\mathcal{H}_{cn}$:

Definition 2. The *alphabet* of $\mathcal{H}_{cn}$ consists of:

1. *Predicate variables* of every predicate type π (denoted by uppercase letters such as $\mathsf{R}, \mathsf{Q}, \ldots$).
2. *Predicate constants* of every predicate type π (denoted by lowercase letters such as $\mathsf{p}, \mathsf{q}, \mathsf{r}, \ldots$).
3. *Individual variables* of type ι (denoted by uppercase letters such as $\mathsf{X}, \mathsf{Y}, \mathsf{Z}, \ldots$).

4. *Individual constants* of type ι (denoted by lowercase letters such as $\mathsf{a}, \mathsf{b}, \mathsf{c}, \ldots$).
5. *Function symbols* of every functional type $\sigma \neq \iota$ (denoted by lowercase letters such as $\mathsf{f}, \mathsf{g}, \mathsf{h}, \ldots$).
6. The following logical constant symbols: the propositional constants false and true of type o; the equality constant $\approx$ of type $\iota \to \iota \to o$; the generalized disjunction and conjunction constants $\bigvee_\pi$ and $\bigwedge_\pi$ of type $\pi \to \pi \to \pi$, for every predicate type π; the generalized inverse implication constants $\leftarrow_\pi$ of type $\pi \to \pi \to o$, for every predicate type π; the equivalence constants $\leftrightarrow_\pi$ of type $\pi \to \pi \to o$, for every predicate type π; the existential quantifiers $\exists_\mu$ of type $(\mu \to o) \to o$, for every existential type μ; the negation constant $\sim$of type $o \to o$.
7. The abstractor λ and the parentheses "(" and ")".

The set consisting of the predicate variables and the individual variables of $\mathcal{H}_{cn}$ will be called the set of *argument variables* of $\mathcal{H}_{cn}$. Argument variables will be usually denoted by V, U and their subscripted versions.

Definition 3. The set of *body expressions* of the higher-order language $\mathcal{H}_{cn}$ is recursively defined as follows:

1. Every predicate variable (respectively, predicate constant) of type π is a body expression of type π; every individual variable (respectively, individual constant) of type ι is a body expression of type ι; the propositional constants false and true are body expressions of type o.
2. If f is an n-ary function symbol and $\mathsf{E}_1, \ldots, \mathsf{E}_n$ are body expressions of type ι, then $(\mathsf{f}\ \mathsf{E}_1 \cdots \mathsf{E}_n)$ is a body expression of type ι.
3. If E_1 is a body expression of type $\rho \to \pi$ and E_2 is a body expression of type ρ, then $(\mathsf{E}_1\ \mathsf{E}_2)$ is a body expression of type π.
4. If V is an argument variable of type ρ and E is a body expression of type π, then $(\lambda \mathsf{V}.\mathsf{E})$ is a body expression of type $\rho \to \pi$.
5. If $\mathsf{E}_1, \mathsf{E}_2$ are expressions of type π, then $(\mathsf{E}_1 \bigwedge_\pi \mathsf{E}_2)$ and $(\mathsf{E}_1 \bigvee_\pi \mathsf{E}_2)$ are body expressions of type π.
6. If $\mathsf{E}_1, \mathsf{E}_2$ are expressions of type ι, then $(\mathsf{E}_1 \approx \mathsf{E}_2)$ is a body expression of type o.
7. If E is an expression of type o and V is an existential variable of type μ, then $(\exists_\mu \mathsf{V}\, \mathsf{E})$ is a body expression of type o.
8. If E is a body expression of type o, then $(\sim \mathsf{E})$ is a body expression of type o.

The type subscripts (such as μ in $\exists_\mu$) will often be omitted when they are obvious or immaterial in the foregoing discussion. Moreover, we will write $\wedge$ and $\vee$ instead of $\bigwedge_o$ and $\bigvee_o$. We will use $type(\mathsf{E})$ to denote the type of the body expression E. The notions of *free* and *bound* variables of a body expression are defined as usual. A body expression is called *closed* if it does not contain any free variables. Given an expression E, we denote by $fv(\mathsf{E})$ the set of all free variables of E. By overloading notation, we will also write $fv(S)$, where S is a set of expressions.

We will often write $\hat{\mathsf{A}}$ to denote a (possibly empty) sequence $\langle \mathsf{A}_1, \ldots, \mathsf{A}_n \rangle$ of expressions. For example we will write $(\mathsf{E}\ \hat{\mathsf{A}})$ to denote an application $(\mathsf{E}\ \mathsf{A}_1 \cdots \mathsf{A}_n)$; $(\lambda \hat{\mathsf{X}}.\mathsf{E})$ to denote $(\lambda \mathsf{X}_1. \cdots \lambda \mathsf{X}_n.\mathsf{E})$; $(\exists \hat{\mathsf{V}}\ \mathsf{E})$ to denote $(\exists \mathsf{V}_1 \cdots \exists \mathsf{V}_n\ \mathsf{E})$. When $\hat{\mathsf{A}}$ or $\hat{\mathsf{X}}$ or $\hat{\mathsf{V}}$ is empty, then the corresponding expression is considered identical to E.

A body expression of the form $(\mathsf{E}_1 \approx \mathsf{E}_2)$ will be called an *equality* while an expression of the form $\sim\exists\hat{\mathsf{V}}(\mathsf{E}_1 \approx \mathsf{E}_2)$ will be called an *inequality*; in the latter case $\hat{\mathsf{V}}$ may be empty (in which case the inequality is of the form $\sim(\mathsf{E}_1 \approx \mathsf{E}_2)$). Let $\hat{\mathsf{E}} = \langle \mathsf{E}_1, \ldots, \mathsf{E}_n \rangle$ and $\hat{\mathsf{E}}' = \langle \mathsf{E}'_1, \ldots, \mathsf{E}'_n \rangle$, where all $\mathsf{E}_i, \mathsf{E}'_i$ are of type ι, we will write $(\hat{\mathsf{E}} \approx \hat{\mathsf{E}}')$ to denote the expression $(\mathsf{E}_1 \approx \mathsf{E}'_1) \wedge \cdots \wedge (\mathsf{E}_n \approx \mathsf{E}'_n)$; if $n = 0$, then the conjunction is the constant true.

Definition 4. The set of *clausal expressions* of the higher-order language $\mathcal{H}_{cn}$ is defined as follows:

1. If p is a predicate constant of type π and E is a closed body expression of type π then $\mathsf{p} \leftarrow_\pi \mathsf{E}$ is a clausal expression of $\mathcal{H}_{cn}$, also called a *program clause*.
2. If E is a body expression of type o and each free variable in E is of type μ then $\mathsf{false} \leftarrow_o \mathsf{E}$ (usually denoted by $\leftarrow_o \mathsf{E}$ or just $\leftarrow \mathsf{E}$) is a clausal expression of $\mathcal{H}_{cn}$, also called a *goal clause*.
3. If p is a predicate constant of type π and E is a closed body expression of type π then $\mathsf{p} \leftrightarrow_\pi \mathsf{E}$ is a clausal expression of $\mathcal{H}_{cn}$, also called a *completion expression*.

All clausal expressions of $\mathcal{H}_{cn}$ have type o.

Notice that (following the tradition of first-order logic programming) we will talk about the "empty clause" which is denoted by $\Box$ and is equivalent to $\leftarrow \mathsf{true}$.

Definition 5. A program of $\mathcal{H}_{cn}$ is a finite set of program clauses of $\mathcal{H}_{cn}$.

We proceed by defining the completion of a program:

Definition 6. Let P be a program and let p be a predicate constant of type π. Then, the *completed definition* for p with respect to P is obtained as follows:

- if there exist exactly $k > 0$ program clauses of the form $\mathsf{p} \leftarrow_\pi \mathsf{E}_i$ where $i \in \{1, \ldots, k\}$ for p in P, then the completed definition for p is the expression $\mathsf{p} \leftrightarrow_\pi \mathsf{E}$, where $\mathsf{E} = \mathsf{E}_1 \bigvee_\pi \cdots \bigvee_\pi \mathsf{E}_k$.
- if there are no program clauses for p in P then the completed definition for p is the expression $\mathsf{p} \leftrightarrow_\pi \mathsf{E}$, where E is of type π and $\mathsf{E} = \lambda \hat{\mathsf{X}}.\mathsf{false}$.

The expression E on the right-hand side of the completed definition of p will be called the *completed expression* for p with respect to P.

We can now extend the notion of completion (Clark 1977; Lloyd 1987) to apply to our higher-order programs:

Definition 7. Let P be a program. Then, the *completion* $comp(\mathsf{P})$ of P is the set consisting of all the completed definitions for all predicate constants that appear in P.

The Semantics of $\mathcal{H}_{cn}$

In this section we introduce the semantics of $\mathcal{H}_{cn}$. We start by defining the meaning of types of $\mathcal{H}_{cn}$; for the predicate types we also define a corresponding partial order (which will be used in the definition of the semantics of $\mathcal{H}_{cn}$).

Definition 8. Let D be a non-empty set. Then the meanings of the types of our language can be specified as follows:

- $[\![\iota]\!]_D = D$;
- $[\![\iota^n \to \iota]\!]_D = D^n \to D$;
- $[\![o]\!]_D = \{false, true\}$. A partial order $\sqsubseteq_o$ can be defined on the set $[\![o]\!]_D$ as follows: $false \sqsubseteq_o true$, $false \sqsubseteq_o false$ and $true \sqsubseteq_o true$;
- $[\![\rho \to \pi]\!]_D = [\![\rho]\!]_D \to [\![\pi]\!]_D$. A partial order $\sqsubseteq_{\rho\to\pi}$ can be defined as follows: for all $f, g \in [\![\rho \to \pi]\!]_D$, $f \sqsubseteq_{\rho\to\pi} g$ if and only if $f(d) \sqsubseteq_\pi g(d)$, for all $d \in [\![\rho]\!]_D$.

It can be easily shown that for every predicate type π, $[\![\pi]\!]_D$ is a complete lattice, and therefore for every subset of $[\![\pi]\!]_D$ there exists a *lub* function (denoted by $\bigsqcup_\pi$) and a *glb* function (denoted by $\bigsqcap_\pi$).

The notions of *interpretation* and *state* can be defined in a standard way:

Definition 9. An interpretation I of $\mathcal{H}_{cn}$ consists of:

1. a nonempty set D, called the *domain* of I
2. an assignment to each individual constant symbol c, of an element $I(\mathsf{c}) \in D$
3. an assignment to each predicate constant p of type π, of an element $I(\mathsf{p}) \in [\![\pi]\!]_D$
4. an assignment to each function symbol f of type $\iota^n \to \iota$, of a function $I(\mathsf{f}) \in D^n \to D$.

Definition 10. Let D be a nonempty set. Then, a *state s of $\mathcal{H}_{cn}$ over D* is a function that assigns to each argument variable V of type ρ of $\mathcal{H}_{cn}$ an element $s(\mathsf{V}) \in [\![\rho]\!]_D$.

In the following, $s[\mathsf{V}/d]$ is used to denote a state that is identical to s the only difference being that the new state assigns to V the value d.

Definition 11. Let I be an interpretation of $\mathcal{H}_{cn}$, let D be the domain of I and let s be a state over D. Then, the semantics of expressions of $\mathcal{H}_{cn}$ with respect to I and s is defined as follows:

1. $[\![\mathsf{false}]\!]_s(I) = false$
2. $[\![\mathsf{true}]\!]_s(I) = true$
3. $[\![\mathsf{c}]\!]_s(I) = I(\mathsf{c})$, for every individual constant c
4. $[\![\mathsf{p}]\!]_s(I) = I(\mathsf{p})$, for every predicate constant p
5. $[\![\mathsf{V}]\!]_s(I) = s(\mathsf{V})$, for every argument variable V
6. $[\![(\mathsf{f}\ \mathsf{E}_1 \cdots \mathsf{E}_n)]\!]_s(I) = I(\mathsf{f})\ [\![\mathsf{E}_1]\!]_s(I) \cdots [\![\mathsf{E}_n]\!]_s(I)$, for every n-ary function symbol f
7. $[\![(\mathsf{E}_1\mathsf{E}_2)]\!]_s(I) = [\![\mathsf{E}_1]\!]_s(I)([\![\mathsf{E}_2]\!]_s(I))$
8. $[\![(\lambda\mathsf{V}.\mathsf{E})]\!]_s(I) = \lambda d.[\![\mathsf{E}]\!]_{s[\mathsf{V}/d]}(I)$, where d ranges over $[\![type(\mathsf{V})]\!]_D$
9. $[\![(\mathsf{E}_1 \bigvee_\pi \mathsf{E}_2)]\!]_s(I) = \bigsqcup_\pi\{[\![\mathsf{E}_1]\!]_s(I), [\![\mathsf{E}_2]\!]_s(I)\}$, where $\bigsqcup_\pi$ is the least upper bound function on $[\![\pi]\!]_D$
10. $[\![(\mathsf{E}_1 \bigwedge_\pi \mathsf{E}_2)]\!]_s(I) = \bigsqcap_\pi\{[\![\mathsf{E}_1]\!]_s(I), [\![\mathsf{E}_2]\!]_s(I)\}$, where $\bigsqcap_\pi$ is the greatest lower bound function on $[\![\pi]\!]_D$
11. $[\![(\mathsf{E}_1 \approx \mathsf{E}_2)]\!]_s(I) = \begin{cases} true, & \text{if } [\![\mathsf{E}_1]\!]_s(I) = [\![\mathsf{E}_2]\!]_s(I) \\ false, & \text{otherwise} \end{cases}$
12. $[\![(\exists\mathsf{V}\ \mathsf{E})]\!]_s(I) = \begin{cases} true, & \text{if there exists } d \in [\![type(\mathsf{V})]\!]_D \\ & \text{such that } [\![\mathsf{E}]\!]_{s[\mathsf{V}/d]}(I) = true \\ false, & \text{otherwise} \end{cases}$
13. $[\![(\sim\mathsf{E})]\!]_s(I) = \begin{cases} true, & \text{if } [\![\mathsf{E}]\!]_s(I) = false \\ false, & \text{if } [\![\mathsf{E}]\!]_s(I) = true \end{cases}$
14. $[\![\mathsf{p} \leftarrow_\pi \mathsf{E}]\!]_s(I) = \begin{cases} true, & \text{if } [\![\mathsf{E}]\!]_s(I) \sqsubseteq_\pi I(\mathsf{p}) \\ false, & \text{otherwise} \end{cases}$
15. $[\![\mathsf{p} \leftrightarrow_\pi \mathsf{E}]\!]_s(I) = \begin{cases} true, & \text{if } [\![\mathsf{E}]\!]_s(I) = I(\mathsf{p}) \\ false, & \text{otherwise} \end{cases}$
16. $[\![\leftarrow \mathsf{E}]\!]_s(I) = \begin{cases} true, & \text{if } [\![\mathsf{E}]\!]_s(I) = false \\ false, & \text{otherwise} \end{cases}$

Definition 12. Let S be a set of expressions of type o and let I be an interpretation of $\mathcal{H}_{cn}$. We say that I is a *model* of S if for every $\mathsf{E} \in S$ and for every state s over the domain of I, $[\![\mathsf{E}]\!]_s(I) = true$.

Clark's Equality Theory can also be added to our fragment as follows:

Definition 13. Let I be an interpretation of $\mathcal{H}_{cn}$. We will say that I satisfies *Clark's Equality Theory (CET)* if for all states s over the domain of I, all the following hold:

1. $[\![(\mathsf{f}\ \hat{\mathsf{E}}) \approx (\mathsf{f}\ \hat{\mathsf{E}}')]\!]_s(I) = [\![\hat{\mathsf{E}} \approx \hat{\mathsf{E}}']\!]_s(I)$ for every n-ary function symbol f and for all $\hat{\mathsf{E}} = \langle \mathsf{E}_1, \ldots, \mathsf{E}_n\rangle$ and for all $\hat{\mathsf{E}}' = \langle \mathsf{E}'_1, \ldots, \mathsf{E}'_n\rangle$
2. $[\![\mathsf{c} \approx \mathsf{d}]\!]_s(I) = false$ for all different individual constants c and d
3. $[\![(\mathsf{f}\ \hat{\mathsf{E}}) \approx \mathsf{c}]\!]_s(I) = false$ for every function symbol f and every individual constant c
4. $[\![(\mathsf{f}\ \hat{\mathsf{E}}) \approx (\mathsf{g}\ \hat{\mathsf{E}}')]\!]_s(I) = false$ for all different function symbols f and g and all $\hat{\mathsf{E}}$ and $\hat{\mathsf{E}}'$
5. $[\![\mathsf{X} \approx \mathsf{E}]\!]_s(I) = false$ if $\mathsf{X} \in fv(\mathsf{E})$ and $\mathsf{X} \neq \mathsf{E}$

In the rest of this paper we will often talk about "models of the completion *comp*(P) of a program P"; in every such case we will implicitly assume that our models also satisfy Clark's Equality Theory.

4 Proof Procedure

In this section we define a proof procedure for $\mathcal{H}_{cn}$ and discuss its implementation. As in the case of classical logic programming, substitutions and unifiers also play an important role in our setting. However, they need to be significantly extended, as discussed below.

Substitutions and Unifiers

In classical logic programming, a substitution is a mapping from variables to terms. Since in our case queries may contain uninstantiated variables of set types, the notion of substitution must be extended to assign to these variables expressions that represent sets. In the following we define the notion of *basic expression* which generalizes the notion of term from classical logic programming. Intuitively, a basic element is either a term or a set of terms.

Definition 14. The set of *basic expressions* of $\mathcal{H}_{cn}$ of type μ is defined recursively as follows:

1. Every expression of $\mathcal{H}_{cn}$ of type ι is a basic expression of type ι.

2. Every predicate variable of type κ is a basic expression of type κ.
3. If $\mathsf{E}_1, \mathsf{E}_2$ are basic expressions of type κ then $\mathsf{E}_1 \bigvee_\kappa \mathsf{E}_2$ and $\mathsf{E}_1 \bigwedge_\kappa \mathsf{E}_2$ are basic expressions of type κ.
4. The expressions of the following form, are basic expressions of type $\iota^n \to o$:
   - $\lambda\hat{\mathsf{X}}.\exists\hat{\mathsf{V}}(\hat{\mathsf{X}} \approx \hat{\mathsf{A}})$
   - $\lambda\hat{\mathsf{X}}.\ \sim\exists\hat{\mathsf{V}}(\hat{\mathsf{X}} \approx \hat{\mathsf{A}})$

   where $\hat{\mathsf{X}} = \langle \mathsf{X}_1, \ldots, \mathsf{X}_n\rangle$, $\hat{\mathsf{A}} = \langle \mathsf{A}_1, \ldots, \mathsf{A}_n\rangle$, each X_i is a variable of type ι, each $\hat{\mathsf{A}}_i$ is a basic expressions of type ι and $\hat{\mathsf{V}}$ is a possibly empty subset of $fv(\hat{\mathsf{A}})$.

Example 8. The basic element $\lambda\mathtt{X}.\ \sim\exists\mathtt{Y}(\mathtt{X} \approx \mathtt{Y})$ represents the empty set while $\lambda\mathtt{X}.(\mathtt{X} \approx \mathtt{a}) \bigvee \lambda\mathtt{X}.(\mathtt{X} \approx (\mathtt{f\ b}))$ represents the set $\{\mathtt{a}, (\mathtt{f\ b})\}$. The basic element $\lambda\mathtt{X}.\exists\mathtt{Y}(\mathtt{X} \approx (\mathtt{f\ Y}))$ is the set that contains all the terms of the form $(\mathtt{f}\cdots)$. The basic element $\lambda\mathtt{X}.\ \sim\exists\mathtt{Y}(\mathtt{X} \approx (\mathtt{f\ Y}))$ is the set that contains all the terms that are not of the form $(\mathtt{f}\cdots)$. The basic element $\lambda\mathtt{X}.\exists\mathtt{Y}(\mathtt{X} \approx (\mathtt{f\ Y})) \bigwedge \lambda\mathtt{X}.\ \sim(\mathtt{X} \approx (\mathtt{f\ b}))$ is the set that contains all the terms of the form $(\mathtt{f}\cdots)$ with the exception of $(\mathtt{f\ b})$.

The definition of a substitution can be extended:

Definition 15. A substitution θ is a finite set of the form $\{\mathsf{V}_1/\mathsf{E}_1, \ldots, \mathsf{V}_n/\mathsf{E}_n\}$ where V_i are different argument variables of $\mathcal{H}_{cn}$ and each E_i is a body expression of $\mathcal{H}_{cn}$ having the same type as V_i. We write $dom(\theta) = \{\mathsf{V}_1, \ldots, \mathsf{V}_n\}$ and $range(\theta) = \{\mathsf{E}_1, \ldots, \mathsf{E}_n\}$. A substitution is called *basic* if all E_i are basic expressions. A substitution is called *zero-order* if the type of V_i is ι for all $i \in \{1, \ldots, n\}$. The substitution corresponding to the empty set will be called the *identity substitution* and will be denoted by ϵ.

In the following definition (and also in the rest of the paper) we assume that if expressions $\mathsf{E}_1, \ldots, \mathsf{E}_n$ occur in a certain mathematical context, then in these expressions all bound variables are chosen to be different from the free variables. This is called the *the bound variable convention* in (Barendregt 1984, pages 26–27) (and is actually equivalent to the α-renaming operation of λ-calculus).

Definition 16. Let θ be a substitution and let E be a body expression. Then, $\mathsf{E}\theta$ is an expression obtained as follows:

- $\mathsf{E}\theta = \mathsf{E}$, if E is false, true, c, or p
- $\mathsf{V}\theta = \theta(\mathsf{V})$ if $\mathsf{V} \in dom(\theta)$; otherwise, $\mathsf{V}\theta = \mathsf{V}$
- $(\mathsf{f}\ \mathsf{E}_1 \cdots \mathsf{E}_n)\theta = (\mathsf{f}\ \mathsf{E}_1\theta \cdots \mathsf{E}_n\theta)$
- $(\mathsf{E}_1\ \mathsf{E}_2)\theta = (\mathsf{E}_1\theta\ \mathsf{E}_2\theta)$
- $(\lambda\mathsf{V}.\mathsf{E})\theta = (\lambda\mathsf{V}.\mathsf{E}\theta)$
- $(\mathsf{E}_1 \bigvee_\pi \mathsf{E}_2)\theta = (\mathsf{E}_1\theta \bigvee_\pi \mathsf{E}_2\theta)$
- $(\mathsf{E}_1 \bigwedge_\pi \mathsf{E}_2)\theta = (\mathsf{E}_1\theta \bigwedge_\pi \mathsf{E}_2\theta)$
- $(\mathsf{E}_1 \approx \mathsf{E}_2)\theta = (\mathsf{E}_1\theta \approx \mathsf{E}_2\theta)$
- $(\exists\mathsf{V}\ \mathsf{E})\theta = (\exists\mathsf{V}\ \mathsf{E}\theta)$
- $(\sim\mathsf{E})\theta = \sim\mathsf{E}\theta$

In the following, if $\hat{\mathsf{E}} = \langle \mathsf{E}_1, \ldots, \mathsf{E}_n\rangle$, we will write $\hat{\mathsf{E}}\theta$ to denote the sequence $\langle \mathsf{E}_1\theta, \ldots, \mathsf{E}_n\theta\rangle$.

Definition 17. Let $\theta = \{\mathsf{V}_1/\mathsf{E}_1, \ldots, \mathsf{V}_m/\mathsf{E}_m\}$ and $\sigma = \{\mathsf{V}'_1/\mathsf{E}'_1, \ldots, \mathsf{V}'_m/\mathsf{E}'_m\}$ be substitutions. Then the composition $\theta\sigma$ of θ and σ is the substitution obtained from the set $\{\mathsf{V}_1/\mathsf{E}_1\sigma, \ldots, \mathsf{V}_m/\mathsf{E}_m\sigma, \mathsf{V}'_1/\mathsf{E}'_1, \ldots, \mathsf{V}_n/\mathsf{E}'_n\}$ by deleting any $\mathsf{V}_i/\mathsf{E}_i\sigma$ for which $\mathsf{V}_i = \mathsf{E}_i\sigma$ and deleting any $\mathsf{V}'_j/\mathsf{E}'_j$ for which $\mathsf{V}'_j \in dom(\theta)$.

The notions of "unifier" and "most general unifier" are the same as in classical first-order logic programming.

Definition 18. Let S be a set of terms of $\mathcal{H}_{cn}$ (ie., expressions of type ι). A zero-order substitution θ will be called a *unifier* of the expressions in S if the set $S\theta = \{\mathsf{E}\theta \mid \mathsf{E} \in S\}$ is a singleton. The zero-order substitution θ will be called a *most general unifier of* S (denoted by $mgu(S)$), if for every unifier σ of the expressions in S, there exists a zero-order substitution γ such that $\sigma = \theta\gamma$.

The most general unifier of a set of terms S can be computed using the unification algorithm described in (Lloyd 1987). The output of the unification algorithm is denoted by $unify(S)$.

The following *substitution lemma* can easily be established by structural induction on E:

Lemma 1 (Substitution Lemma). *Let I be an interpretation of $\mathcal{H}_{cn}$ and let s be a state over the domain of I. Let θ be a basic substitution and E be a body expression. Then, $[\![\mathsf{E}\theta]\!]_s(I) = [\![\mathsf{E}]\!]_{s'}(I)$, where $s'(\mathsf{V}) = [\![\theta(\mathsf{V})]\!]_s(I)$ if $\mathsf{V} \in dom(\theta)$ and $s'(\mathsf{V}) = s(\mathsf{V})$, otherwise.*

The above lemma will be used in the proof of the soundness of the resolution proof procedure that follows.

The Procedure

In this subsection we describe the actual proof procedure for $\mathcal{H}_{cn}$. Intuitively, we could say that our approach generalizes to the higher-order case the constructive negation procedure proposed by D. Chan in (Chan 1989). In order to define the overall proof procedure we utilize three definitions, described as follows:

- The central definition of our procedure is Definition 20 which defines the *single-step derivation* of goals. Intuitively, the single-step derivation is an extension of the single-step derivation of classical logic programming (see for example (Lloyd 1987, pages 50–41)) in order to apply to higher-order logic programming and to constructive negation. Notice that the single-step derivation is the only one among the three that may produce substitutions (whose final composition will lead to the computed answer for the initial goal).
- The *reduction* (Definition 21) is the simplest among the three definitions. Roughly speaking it corresponds to certain simple computational steps that advance the evaluation of the goal. For example, the β-reduction step for a λ-expression belongs to this reduction relation. Another simple reduction step is the replacement of a predicate constant with its defining expression in the program.
- The *negative reduction* (Definition 22) is the most complicated among the three. Intuitively, it corresponds to what D. Chan in (Chan 1989) refers to as "the negation of

answers" and the "normalization of answers". The definition is more complicated in our case since it applies to the more demanding setting of higher-order logic programming.

One difference between the proof procedures for constructive negation (such as for example the one given in (Chan 1989)) and the traditional SLD-resolution for negationless logic programming, is the following: in classical SLD-resolution, a derivation is successful if we reach the empty goal; however, in constructive negation, a derivation may be successful if we reach a goal that consists of inequalities that can not be further simplified. Therefore, the termination condition for constructive negation is different than that of SLD-resolution. Moreover, an *answer* in classical resolution is simply a substitution for some of the variables of the goal. In constructive negation, an answer is a pair consisting of a substitution and of a conjunction of inequalities (intuitively, the inequalities that remain at the end of the derivation)[1]. In the higher-order case that we are examining, an answer is also a pair, the only difference being that the domain of the substitution may contain higher-order variables.

Before we present the actual definitions, we need the following categorization of inequalities, which is pretty standard in the area of constructive negation (see for example (Chan 1989)):

Definition 19. An inequality $\sim\exists\hat{\mathsf{V}}(\mathsf{E}_1 \approx \mathsf{E}_2)$ is considered

- *valid* if E_1 and E_2 cannot be unified;
- *unsatisfiable* if there is a substitution θ that unifies E_1 and E_2 and contains only bindings of variables in $\hat{\mathsf{V}}$;
- *satisfiable* if it is not unsatisfiable.

An inequality will be called *primitive* if it is satisfiable, non valid and either E_1 or E_2 is a variable.

In the following definition we will refer to a conjunction $\mathsf{A}_1 \wedge \cdots \wedge \mathsf{A}_n$ of expressions. We will assume that each A_i is not a conjunction itself. The conjunction of a single expression is the expression itself and the conjunction of zero expressions is the expression true.

Definition 20. Let P a program and let G_k and G_{k+1} be goal clauses. Moreover, let G_k be a conjunction $\leftarrow \mathsf{A}_1 \wedge \cdots \wedge \mathsf{A}_n$, where each A_i is a body expression of type o. Let A_i be one of the $\mathsf{A}_1, \ldots, \mathsf{A}_n$ and let us call it the *selected expression*. Let $\mathsf{A}' = \mathsf{A}_1 \wedge \cdots \wedge \mathsf{A}_{i-1} \wedge \mathsf{A}_{i+1} \wedge \cdots \wedge \mathsf{A}_n$. We say that G_{k+1} is *derived in one step* from G_k using θ (denoted as $\mathsf{G}_k \xrightarrow{\theta} \mathsf{G}_{k+1}$) if one of the following conditions applies:

1. if A_i is true and $n > 1$ then $\mathsf{G}_{k+1} = \leftarrow \mathsf{A}'$ is derived from G_k using $\theta = \epsilon$;
2. if A_i is $(\mathsf{E}_1 \vee \mathsf{E}_2)$ then $\mathsf{G}_{k+1} = \leftarrow \mathsf{A}_1 \wedge \cdots \wedge \mathsf{E}_j \wedge \cdots \wedge \mathsf{A}_n$ is derived from G_k using $\theta = \epsilon$ where $j \in \{1, 2\}$;
3. if A_i is $(\exists \mathsf{V}\ \mathsf{E})$ then $\mathsf{G}_{k+1} = \leftarrow \mathsf{A}_1 \wedge \cdots \wedge \mathsf{E} \wedge \cdots \wedge \mathsf{A}_n$ is derived[2] from G_k using $\theta = \epsilon$;
4. if $\mathsf{A}_i \rightsquigarrow \mathsf{A}_i'$ then $\mathsf{G}_{k+1} = \leftarrow \mathsf{A}_1 \wedge \cdots \wedge \mathsf{A}_i' \wedge \cdots \wedge \mathsf{A}_n$ is derived from G_k using $\theta = \epsilon$;
5. if A_i is $(\mathsf{E}_1 \approx \mathsf{E}_2)$ then $\mathsf{G}_{k+1} = \leftarrow \mathsf{A}'\theta$ is derived from G_k using $\theta = mgu(\mathsf{E}_1, \mathsf{E}_2)$;
6. if A_i is $(\mathsf{R}\ \hat{\mathsf{E}})$ and R is a predicate variable of type κ then $\mathsf{G}_{k+1} = \leftarrow \mathsf{A}'\theta$ is derived from G_k using $\theta = \{\mathsf{R}/(\lambda\hat{\mathsf{X}}.(\hat{\mathsf{X}} \approx \hat{\mathsf{E}}) \bigvee_\kappa \mathsf{R}')\}$ where R' is a fresh[3] predicate variable of type κ;
7. if A_i is $\sim\exists\hat{\mathsf{V}}\ \mathsf{E}$ and A_i is negatively-reduced to A_i' then $\mathsf{G}_{k+1} = \leftarrow \mathsf{A}_1 \wedge \cdots \wedge \mathsf{A}_i' \wedge \cdots \wedge \mathsf{A}_n$ is derived from G_k using $\theta = \epsilon$;
8. if A_i is $\sim\exists\hat{\mathsf{V}}(\mathsf{R}\ \hat{\mathsf{E}})$ and R is a predicate variable of type κ and $\mathsf{R} \notin \hat{\mathsf{V}}$ then $\mathsf{G}_{k+1} = \leftarrow \mathsf{A}'\theta$ is derived from G_k using $\theta = \{\mathsf{R}/(\lambda\hat{\mathsf{X}}.\ \sim\exists\hat{\mathsf{V}}(\hat{\mathsf{X}} \approx \hat{\mathsf{E}}) \bigwedge_\kappa \mathsf{R}')\}$ where R' is a fresh predicate variable of type κ;
9. if A_i is $\sim\exists\hat{\mathsf{V}}\ \sim(\mathsf{R}\ \hat{\mathsf{E}})$ and R is a predicate variable of type κ and $\mathsf{R} \notin \hat{\mathsf{V}}$ then $\mathsf{G}_{k+1} = \leftarrow \mathsf{A}'\theta$ is derived from G_k using $\theta = \{\mathsf{R}/(\lambda\hat{\mathsf{X}}.\exists\hat{\mathsf{V}}(\hat{\mathsf{X}} \approx \hat{\mathsf{E}}) \bigvee_\kappa \mathsf{R}')\}$ where R' is a fresh predicate variable of type κ.

Definition 21. Let P be a program and E, E' be body expressions of type o. We say that E is reduced (wrt. to P) to E' (denoted as $\mathsf{E} \rightsquigarrow \mathsf{E}'$) if one of the following conditions applies:

1. $\mathsf{p}\ \hat{\mathsf{A}} \rightsquigarrow \mathsf{E}\ \hat{\mathsf{A}}$, where E is the completed expression for p with respect to P;
2. $(\lambda\mathsf{X}.\mathsf{E})\ \mathsf{B}\ \hat{\mathsf{A}} \rightsquigarrow \mathsf{E}\{\mathsf{X}/\mathsf{B}\}\ \hat{\mathsf{A}}$;
3. $(\mathsf{E}_1 \bigvee_\pi \mathsf{E}_2)\ \hat{\mathsf{A}} \rightsquigarrow (\mathsf{E}_1\ \hat{\mathsf{A}}) \vee_o (\mathsf{E}_2\ \hat{\mathsf{A}})$;
4. $(\mathsf{E}_1 \bigwedge_\pi \mathsf{E}_2)\ \hat{\mathsf{A}} \rightsquigarrow (\mathsf{E}_1\ \hat{\mathsf{A}}) \wedge_o (\mathsf{E}_2\ \hat{\mathsf{A}})$.

Definition 22. Let P be a program and B, B' be body expressions where $\mathsf{B} = \sim\exists\hat{\mathsf{U}}(\mathsf{A}_1 \wedge \cdots \wedge \mathsf{A}_n)$ and each A_i is a body expression except from conjunction. Let A_i be the selected expression and $\mathsf{A}' = \mathsf{A}_1 \wedge \cdots \wedge \mathsf{A}_{i-1} \wedge \mathsf{A}_{i+1} \wedge \cdots \wedge \mathsf{A}_n$. Then, we say that B is *negatively-reduced* to B' if one of the following conditions applies:

1. if A_i is false then $\mathsf{B}' = \mathsf{true}$;
2. if A_i is true and $n = 1$ then $\mathsf{B}' = \mathsf{false}$ else $\mathsf{B}' = \sim\exists\hat{\mathsf{U}}\ \mathsf{A}'$;
3. if A_i is $(\mathsf{E}_1 \vee \mathsf{E}_2)$ then $\mathsf{B}' = \mathsf{B}_1' \wedge \mathsf{B}_2'$ where $\mathsf{B}_j' = \sim\exists\hat{\mathsf{U}}(\mathsf{A}_1 \wedge \cdots \wedge \mathsf{E}_j \wedge \cdots \wedge \mathsf{A}_n)$, $j \in \{1, 2\}$;
4. if A_i is $(\exists\mathsf{V}\ \mathsf{E})$ then $\mathsf{B}' = \sim\exists\hat{\mathsf{U}}\mathsf{V}(\mathsf{A}_1 \wedge \cdots \wedge \mathsf{E} \wedge \cdots \wedge \mathsf{A}_n)$;[4]
5. if $\mathsf{A}_i \rightsquigarrow \mathsf{A}_i'$ then $\mathsf{B}' = \sim\exists\hat{\mathsf{U}}(\mathsf{A}_1 \wedge \cdots \wedge \mathsf{A}_i' \wedge \cdots \wedge \mathsf{A}_n)$;
6. if A_i is $(\mathsf{E}_1 \approx \mathsf{E}_2)$, then
   (a) if $\sim\exists\hat{\mathsf{U}}(\mathsf{E}_1 \approx \mathsf{E}_2)$ is valid then $\mathsf{B}' = \mathsf{true}$;
   (b) if $\sim\exists\hat{\mathsf{U}}(\mathsf{E}_1 \approx \mathsf{E}_2)$ is non-valid and neither E_1 nor E_2 is a variable then $\mathsf{B}' = \sim\exists\hat{\mathsf{U}}(\mathsf{A}_1 \wedge \cdots \wedge \mathsf{A}_{i-1} \wedge (\hat{\mathsf{X}} \approx \hat{\mathsf{X}}\theta) \wedge \mathsf{A}_{i+1} \wedge \cdots \wedge \mathsf{A}_n)$ where $\theta = unify(\mathsf{E}_1, \mathsf{E}_2)$ and $\hat{\mathsf{X}} = dom(\theta)$;

[1] Actually, in (Chan 1989) the substitution is combined with the inequalities so as to obtain a sequence consisting of equalities and inequalities.

[2] Recall that by the Bound Variable Convention, V does not appear free in A'.

[3] This means a variable that has not appeared in goals and substitutions until this point of the derivation.

[4] Recall that by the Bound Variable Convention, V does not appear free in A'.

(c) if $\sim\exists\hat{\mathsf{U}}(\mathsf{E}_1 \approx \mathsf{E}_2)$ is unsatisfiable and either E_1 or E_2 is a variable in $\hat{\mathsf{U}}$, then $\mathsf{B}' = \sim\exists\hat{\mathsf{U}}(\mathsf{A}'\theta)$ where $\theta = \{\mathsf{X}/\mathsf{E}\}$ and X is the one expression that is a variable in $\hat{\mathsf{U}}$ and E is the other;

(d) if $\sim \exists\hat{\mathsf{U}}(\mathsf{E}_1 \approx \mathsf{E}_2)$ is primitive and $n > 1$ then $\mathsf{B}' = \sim\exists\hat{\mathsf{U}}_1\ \mathsf{A}_i \vee \exists\hat{\mathsf{U}}_1(\mathsf{A}_i \wedge \sim\exists\hat{\mathsf{U}}_2\ \mathsf{A}')$ where $\hat{\mathsf{U}}_1$ are the variables in $\hat{\mathsf{U}}$ that are free in A_i and $\hat{\mathsf{U}}_2$ the variables in $\hat{\mathsf{U}}$ not in $\hat{\mathsf{U}}_1$;

7. if A_i is $(\mathsf{R}\ \hat{\mathsf{E}})$ and R is a predicate variable, then

(a) if $\mathsf{R} \in \hat{\mathsf{U}}$ then $\mathsf{B}' = \sim\exists\hat{\mathsf{U}}'(\mathsf{A}'\theta)$ where substitution $\theta = \{\mathsf{R}/(\lambda\mathsf{X}.(\mathsf{X} \approx \mathsf{E}) \bigvee_\kappa \mathsf{R}')\}$, R' is a predicate variable of the same type with R and $\hat{\mathsf{U}}'$ is the same with $\hat{\mathsf{U}}$ but the variable R has been replaced with R';

(b) if $\mathsf{R} \notin \hat{\mathsf{U}}$ and $n > 1$ then $\mathsf{B}' = \sim\exists\hat{\mathsf{U}}_1\ \mathsf{A}_i \vee \exists\hat{\mathsf{U}}_1(\mathsf{A}_i \wedge \sim\exists\hat{\mathsf{U}}_2\ \mathsf{A}') \wedge \mathsf{B}$ where $\hat{\mathsf{U}}_1$ are the variables in $\hat{\mathsf{U}}$ that are free in A_i and $\hat{\mathsf{U}}_2$ the variables in $\hat{\mathsf{U}}$ not in $\hat{\mathsf{U}}_1$;

8. if A_i is $\sim\exists\hat{\mathsf{V}}\ \mathsf{E}$ and A_i is negatively-reduced to A'_i then $\mathsf{B}' = \sim\exists\hat{\mathsf{U}}(\mathsf{A}_1 \wedge \cdots \wedge \mathsf{A}'_i \wedge \cdots \wedge \mathsf{A}_n)$;

9. if A_i is a primitive inequality $\sim\exists\hat{\mathsf{V}}(\mathsf{E}_1 \approx \mathsf{E}_2)$ then

(a) if A_i contains free variables in $\hat{\mathsf{U}}$ and A' is a conjunction of primitive inequalities then $\mathsf{B}' = \sim\exists\hat{\mathsf{U}}\ \mathsf{A}'$;

(b) if A_i does not contain any free variables in $\hat{\mathsf{U}}$ then $\mathsf{B}' = \exists\hat{\mathsf{V}}(\mathsf{E}_1 \approx \mathsf{E}_2) \vee \sim\exists\hat{\mathsf{U}}\ \mathsf{A}'$;

10. if A_i is $\sim\exists\hat{\mathsf{V}}(\mathsf{R}\ \hat{\mathsf{E}})$ and $\mathsf{R} \notin \hat{\mathsf{V}}$ is a predicate variable, then

(a) if $\mathsf{R} \in \hat{\mathsf{U}}$ then $\mathsf{B}' = \sim \exists\hat{\mathsf{U}}'(\mathsf{A}'\theta)$ where substitution $\theta = \{\mathsf{R}/(\lambda\mathsf{X}.\ \sim\exists\hat{\mathsf{V}}(\mathsf{X} \approx \mathsf{E}) \bigwedge_\kappa \mathsf{R}')\}$, R' is a predicate variable of the same type κ with R and $\hat{\mathsf{U}}'$ is the same with $\hat{\mathsf{U}}$ but the variable R has been replaced with R';

(b) if $\mathsf{R} \notin \hat{\mathsf{U}}$ and $n > 1$ then $\mathsf{B}' = \sim\exists\hat{\mathsf{U}}_1\ \mathsf{A}_i \vee \exists\hat{\mathsf{U}}_1(\mathsf{A}_i \wedge \sim\exists\hat{\mathsf{U}}_2\ \mathsf{A}') \wedge \mathsf{B}$ where $\hat{\mathsf{U}}_1$ are the variables in $\hat{\mathsf{U}}$ that are free in A_i and $\hat{\mathsf{U}}_2$ the variables in $\hat{\mathsf{U}}$ not in $\hat{\mathsf{U}}_1$;

(c) if $\mathsf{R} \notin \hat{\mathsf{U}}$, $n = 1$ and $\hat{\mathsf{V}}$ is nonempty then $\mathsf{B}' = \exists\hat{\mathsf{V}}\ \sim\exists\hat{\mathsf{U}}(\sim(\mathsf{R}\ \hat{\mathsf{E}}) \wedge \sim\exists\hat{\mathsf{V}}'(\mathsf{R}\ \mathsf{E}'))$;

11. if A_i is $\sim\exists\hat{\mathsf{V}}\ \sim(\mathsf{R}\ \hat{\mathsf{E}})$ and R is a predicate variable and $\mathsf{R} \notin \hat{\mathsf{V}}$, then

(a) if $\mathsf{R} \in \hat{\mathsf{U}}$ then $\mathsf{B}' = \sim\exists\hat{\mathsf{U}}'(\mathsf{A}'\theta)$ where substitution $\theta = \{\mathsf{R}/(\lambda\mathsf{X}.\exists\hat{\mathsf{V}}(\mathsf{X} \approx \mathsf{E}) \bigvee_\kappa \mathsf{R}')\}$, R' is a predicate variable of the same type κ with R and $\hat{\mathsf{U}}'$ is the same with $\hat{\mathsf{U}}$ but the variable R has been replaced with R';

(b) if $\mathsf{R} \notin \hat{\mathsf{U}}$ and $n > 1$ then $\mathsf{B}' = \sim\exists\hat{\mathsf{U}}_1\ \mathsf{A}_i \vee \exists\hat{\mathsf{U}}_1(\mathsf{A}_i \wedge \sim\exists\hat{\mathsf{U}}_2\ \mathsf{A}') \wedge \mathsf{B}$;

(c) if $\mathsf{R} \notin \hat{\mathsf{U}}$, $n = 1$ and $\hat{\mathsf{V}}$ is nonempty then $\mathsf{B}' = \exists\hat{\mathsf{V}}\ \sim\exists\hat{\mathsf{U}}((\mathsf{R}\ \hat{\mathsf{E}}) \wedge \sim\exists\hat{\mathsf{V}}'\ \sim(\mathsf{R}\ \mathsf{E}'))$.

One can easily check that all the three above definitions preserve the main property of $\mathcal{H}_{cn}$ goals, namely that all the free variables in them have existential types.

We proceed by defining the notion of a *multi-step derivation* and by characterizing when a multi-step derivation is successful and the form of the computed answer. We first define the notions of terminal and primitive goals:

Definition 23. Let P be a program and $\mathsf{G} = \leftarrow \mathsf{A}$ be a goal clause. Then, G will be called *terminal* if no goals can be derived in one step from G. The goal G is called *primitive* if A is a (possibly empty) conjunction of primitive inequalities.

Notice that every primitive goal is also terminal. Notice also that the empty goal $\square$ is primitive.

Definition 24. Let $\mathsf{G} = \leftarrow \mathsf{A}_1 \wedge \cdots \wedge \mathsf{A}_n$ be a primitive goal and S be a set of variables. We say that G_S is a primitive goal obtained by restricting G to S when for each inequality A_i in G_S every free variable of A_i is in S.

Definition 25. Let P be a program and G be a goal. Assume that $\mathsf{P} \cup \{\mathsf{G}\}$ has a finite derivation $\mathsf{G}_0 = \mathsf{G}, \mathsf{G}_1, \ldots, \mathsf{G}_n$ with basic substitutions $\theta_1, \ldots, \theta_n$, such that the goal G_n is primitive. Then we will say that $\mathsf{P} \cup \{\mathsf{G}\}$ has a successful derivation of length n with primitive goal G_n and using basic substitution $\theta = \theta_1 \cdots \theta_n$.

Notice that it can easily be verified that the composition of basic substitutions is indeed a basic substitution as implied by the above definition.

We can now define the important notion of *computed answer*:

Definition 26. Let P be a program, G be a goal and assume that $\mathsf{P} \cup \{\mathsf{G}\}$ has a successful derivation with primitive goal G' and basic substitution θ. Then (σ, G'') is a *computed answer* for $\mathsf{P} \cup \{\mathsf{G}\}$ where σ is the basic substitution obtained by restricting θ to the free variables of G and G'' is the primitive goal G' restricted to the free variables of G and the variables in $fv(range(\sigma))$.

Example 9. Consider the following simple definition for the predicate `q`

$$\mathtt{q} \leftarrow \lambda\mathtt{Z}_1\,.\,\lambda\mathtt{Z}_2\,.\,(\mathtt{Z}_1 \approx \mathtt{a}) \wedge (\mathtt{Z}_2 \approx \mathtt{b})$$

that holds only for the tuple `(a, b)`. Then, consider the goal

$$\leftarrow (\mathtt{R}\ \mathtt{X}) \wedge \sim(\mathtt{q}\ \mathtt{X}\ \mathtt{Y})$$

that requests bindings for the variables `R`, `X` and `Y`.

We will underline the selected expression in each step when it is not obvious. We will also omit the substitution in a step if the rule used produces an identity substitution.

0. $\leftarrow \underline{(\mathtt{R}\ \mathtt{X})} \wedge \sim(\mathtt{q}\ \mathtt{X}\ \mathtt{Y})$
1. $\leftarrow \sim(\underline{\mathtt{q}\ \mathtt{X}\ \mathtt{Y}})$
   using rule 20.6 and $\theta_1 = \{\mathtt{R}/\lambda\mathtt{Z}.(\mathtt{Z} \approx \mathtt{X}) \bigvee \mathtt{R}'\}$
2. $\leftarrow \sim(\underline{(\lambda\mathtt{Z}_1\,.\,\lambda\mathtt{Z}_2\,.\,(\mathtt{Z}_1 \approx \mathtt{a}) \wedge (\mathtt{Z}_2 \approx \mathtt{b}))\ \mathtt{X}\ \mathtt{Y}})$
   using rules 20.7, 22.5 and then 21.1
3. $\leftarrow \underline{\sim((\mathtt{X} \approx \mathtt{a}) \wedge (\mathtt{Y} \approx \mathtt{b}))}$
   using rules 20.7, 22.5 and then 21.2
4. $\leftarrow \sim(\mathtt{X} \approx \mathtt{a}) \vee (\mathtt{X} \approx \mathtt{a}) \wedge \sim(\mathtt{Y} \approx \mathtt{a})$
   using rules 20.7 and then 22.6(d)
5. $\leftarrow \sim(\mathtt{X} \approx \mathtt{a})$
   using rule 20.2

In step 4 the procedure generates two branches. The first one terminates immediately with a primitive inequality. The computed answer is $\sim(\mathtt{X} \approx \mathtt{a})$ and $\{\mathtt{R}/\lambda\mathtt{Z}.(\mathtt{Z} \approx \mathtt{X}) \bigvee \mathtt{R}'\}$. The second branch will continue as follows:

5. $\leftarrow \underline{(\mathtt{X} \approx \mathtt{a})} \wedge \sim(\mathtt{Y} \approx \mathtt{a})$
   using rule 20.2
6. $\leftarrow \sim(\mathtt{Y} \approx \mathtt{a})$
   using rule 20.5 and $\theta_6 = \{\mathtt{X}/\mathtt{a}\}$

The procedure will now terminate successfully yielding the substitution $\{\mathtt{R}/\lambda\mathtt{Z}.(\mathtt{Z} \approx \mathtt{a}) \bigvee \mathtt{R}', \mathtt{X}/\mathtt{a}\}$ and the primitive goal $\sim(\mathtt{Y} \approx \mathtt{a})$.

Implementation

In order to verify and experiment with the ideas presented in this paper, an implementation of the proposed proof procedure has been undertaken. For our implementation we extended an existing interpreter for the language $\mathcal{H}$ introduced in (Charalambidis et al. 2010; 2013). The modified interpreter supports the language $\mathcal{H}_{cn}$ and implements exactly the proof procedure presented in this section. The current version of the interpreter can be retrieved from `https://www.github.com/acharal/hopes`.

The source language[5] of the interpreter uses an extended Prolog-like syntax, similar to the one we used for motivation purposes in Section 2. Given a source program, the interpreter first derives the types of the predicates using a specialized but relatively straightforward type-inference algorithm. The well-typed program is then transformed to $\mathcal{H}_{cn}$-like syntax. The interpreter works interactively, ie., in the same way as ordinary Prolog interpreters. Every time the user specifies a goal, the type information that has been derived from the program is used to typecheck the goal. Subsequently, the goal together with the program is passed to a prover that implements the rules of the proposed proof procedure. The interpreter has been coded in Haskell and it implements the proof procedure as-is, namely it does not apply any low level compilation or any specialized optimizations.

5 The Soundness Theorem

In this section we state the soundness theorem for the proposed proof procedure.

To specify the soundness theorem for the proof procedure, one has to first define the notion of *correct answer*:

Definition 27. Let P be a program and G be a goal. An answer (θ, Q) for $\mathsf{P} \cup \{\mathsf{G}\}$ is a basic substitution θ and a primitive goal Q.

Definition 28. Let P be a program and let $\mathsf{G} = \leftarrow \mathsf{A}$ be a goal. An answer $(\theta, \leftarrow \mathsf{A}')$ is a *correct answer* for $comp(\mathsf{P}) \cup \{\mathsf{G}\}$ if for every model M of $comp(\mathsf{P})$ and for every state s over the domain of M, $[\![\mathsf{A}\theta]\!]_s(M) \sqsupseteq_o [\![\mathsf{A}']\!]_s(M)$.

The soundness theorem (Theorem 1 below) essentially amounts to demonstrating that every computed answer is a correct answer. To establish this fact, we need a lemma for each one of Definitions 21, 20 and 22. In particular, Lemma 2 demonstrates the correctness of Definition 21, Lemma 3 shows the correctness of Definition 22, and Lemma 4 the correctness of Definition 20 regarding single-step derivations. Lemma 5 actually shows the correctness of many-step derivations. The most demanding proof is that of Lemma 3. The proof of Lemma 3 (as-well-as the proof of the auxiliary Lemma 6 that will be given below) utilize one important and common assumption that exists in all previous works on constructive negation: we assume that "the language contains an infinite number of constants and functions" (see (Chan 1989, page 478)).

Lemma 2. *Let P be a program, let E, E' be body expressions of type o and assume that E is reduced to E'. Then, for every model M of $comp(\mathsf{P})$ and for every state s over the domain of M, it holds $[\![\mathsf{E}]\!]_s(M) = [\![\mathsf{E}']\!]_s(M)$.*

Proof. Straightforward using the semantics of $\mathcal{H}_{cn}$. □

Lemma 3. *Let P be a program, let E, E' be body expressions of type o and assume that E is negatively-reduced to E'. Then, for every model M of $comp(\mathsf{P})$ and for every state s over the domain of M, it holds $[\![\mathsf{E}]\!]_s(M) = [\![\mathsf{E}']\!]_s(M)$.*

Lemma 4. *Let P be a program, let $\mathsf{G} = \leftarrow \mathsf{A}$ and $\mathsf{G}' = \leftarrow \mathsf{A}'$ be goals and let θ be a basic substitution such that $\mathsf{G} \xrightarrow{\theta} \mathsf{G}'$. Then, for every model M of $comp(\mathsf{P})$ and for every state s over the domain of M, it holds $[\![\mathsf{A}\theta]\!]_s(M) \sqsupseteq_o [\![\mathsf{A}']\!]_s(M)$.*

Proof. By case analysis and standard logical arguments. □

Lemma 5. *Let P be a program and $\mathsf{G} = \leftarrow \mathsf{A}$ be a goal. Let $\mathsf{G}_0 = \mathsf{G}, \mathsf{G}_1 = \leftarrow \mathsf{A}_1, \ldots, \mathsf{G}_n = \leftarrow \mathsf{A}_n$ be a derivation of length n using basic substitutions $\theta_1, \ldots, \theta_n$. Then, for every model M of $comp(\mathsf{P})$ and for every state s over the domain of M, $[\![\mathsf{A}\theta_1 \cdots \theta_n]\!]_s(M) \sqsupseteq [\![\mathsf{A}_n]\!]_s(M)$.*

Proof. Using Lemma 4, Lemma 1 and induction on n. □

Finally, we will need another auxiliary lemma, which will be used to obtain the Soundness theorem:

Lemma 6. *Let E be a body expression of type o and G a conjunction of primitive inequalities. Then, for all states s and interpretations I if $[\![\mathsf{E}]\!]_s(I) \sqsupseteq_o [\![\mathsf{G}]\!]_s(I)$ then $[\![\mathsf{E}]\!]_s(I) \sqsupseteq_o [\![\mathsf{G}']\!]_s(I)$ where G' is a conjunction of primitive inequalities that is obtained from G by restricting it to the free variables of E.*

Using the above, we obtain the soundness theorem:

Theorem 1 (Soundness Theorem). *Let P be a program and G be a goal. Then, every computed answer for $\mathsf{P} \cup \{\mathsf{G}\}$ is a correct answer for $comp(\mathsf{P}) \cup \{\mathsf{G}\}$.*

Proof. A direct consequence of Lemma 5 using the auxiliary Lemma 6. □

6 Future Work

We have introduced the higher-order language $\mathcal{H}_{cn}$ which supports constructive negation. There have been various proposals for higher-order logic programming languages, the most notable among them being Hilog (Chen, Kifer, and Warren 1989; 1993) and λ-Prolog (Miller and Nadathur 1986; Nadathur and Miller 1990); to our knowledge however, none of these languages has ever before been extended to support constructive negation.

[5] The language is called *HOPES* standing for Higher-Order Prolog with Extensional Semantics.

One possible direction for future work is the investigation of completeness results for the proposed proof-procedure. This is an interesting venue for research but appears to be quite demanding due to the non-trivial nature of the proof procedure (note that, to our knowledge, no completeness results have been reported for the work of (Chan 1989)). Possibly a completeness result could be obtained for the case of finite-tree queries. An easier goal for future research would be to extend the language with other useful programming features that would enhance its higher-order style of programming (such as for example, type polymorphism).

Abstract

In the past, there have been several attempts to explain logic programming under the well-founded semantics as a logic of inductive definitions. A weakness in all is the absence of an obvious connection between how we understand various types of informal inductive definitions in mathematical text and the complex mathematics of the well-founded semantics. In this paper, we close this gap. We formalize the induction process in the most common principles and prove that the well-founded model construction generalizes them all.

Introduction

Ever since the well-founded semantics was first defined (Van Gelder, Ross, and Schlipf 1991), researchers have referred to the concept of *an inductive definition*, as we know it from mathematics, to explain the intuitions behind this formal semantics. This link was made explicit in several publications (Denecker 1998; Denecker, Bruynooghe, and Marek 2001; Denecker and Ternovska 2008), where we gave various arguments that, under the well-founded semantics, each rule in a set of rules can be seen as an (inductive or base) case of an inductive definition. A weakness in all is the absence of an obvious connection between how we understand various types of informal inductive definitions in mathematical text and the complex mathematics of the well-founded semantics. This paper aims to close this gap.

To open the discussion, let us consider two prototypical examples illustrating the two most common forms of inductive definitions: the monotone inductive Definition 1 of the transitive closure of a graph and the Definition 2 of the satisfaction relation of propositional logic by induction over the sub-formula order.

Definition 1. *The reachability graph R of a directed graph G is defined inductively:*

- $(x, y) \in R$ *if* $(x, y) \in G$*;*
- $(x, y) \in R$ *if there exists a vertex z such that* $(x, z), (z, y) \in R$*.*

Definition 2. *Given a propositional vocabulary Σ, the satisfaction relation $\models$ between Σ-structures and Σ-formulas of propositional logic is defined by induction over the structure of formulas:*

- $I \models P$ *if* P *is a propositional symbol and* $P \in I$*.*
- $I \models \alpha \wedge \beta$ *if* $I \models \alpha$ *and* $I \models \beta$*.*
- $I \models \alpha \vee \beta$ *if* $I \models \alpha$ *or* $I \models \beta$ *(or both).*
- $I \models \neg\alpha$ *if* $I \not\models \alpha$*.*

(Inductive) definitions serve to define formal objects, but they are not formal objects themselves. As such, we will refer to them as *informal definitions*. They are commonly phrased in natural language as collections of informal rules, possibly with an induction order. They define a set (or more than one, in case of simultaneous induction) *in terms of* other sets, which we will call *parameters*. E.g., Definition 1 has graph G as a parameter and Definition 2 the vocabulary Σ. Informal inductive definitions are broadly used in mathematics, broadly understood and, despite their informal nature, they are of mathematical precision. The set defined by it can be characterized in two quite different ways: "non-constructively", as the least set closed under rule application, and "constructively", as the set obtained by iterated rule application. By Tarski's cherished result on the least fixpoint of monotone operators, both principles coincide.

It comes as a surprise to many but the last statement is only half true. Def. 2 is non-monotone due to its 4th rule, and Tarski's result does not apply for it. There are infinitely many minimal sets that are closed under these rules and some are just weird: e.g., in some of them $\{P\} \models \neg P$ holds (See Example 1). What this shows is that the constructive principle is the more fundamental of the two. An inductive definition defines a set by describing how to construct it through an *induction process*. This process starts from the empty set, proceeds by applying rules till the set is closed under the rules. In case of induction over a well-founded order, rules must be applied "along" the specified order. This is the intuition that we guess all of us share and that will be formalized below.

The precision of informal inductive definitions makes them an ideal target for a formal empirical study. This is what we do in the next section, We define a simple formal, rule-based syntax with atomic heads and first order logic (FO) bodies. This leads to the following representation of the above informal definitions.

$$\left\{ \begin{array}{l} \forall x \forall y (R(x, y) \leftarrow G(x, y)) \\ \forall x \forall y (R(x, y) \leftarrow \exists z (R(x, z) \wedge R(z, y)) \end{array} \right\}$$

Copyright © 2014, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

$$\left\{\begin{array}{l}\forall i \forall p(Sat(i,p) \leftarrow Atom(p) \wedge In(p,i)) \\ \forall i \forall f \forall g(Sat(i,And(f,g)) \leftarrow Sat(i,f) \wedge Sat(i,g)) \\ \forall i \forall f \forall g(Sat(i,Or(f,g)) \leftarrow Sat(i,f) \vee Sat(i,g)) \\ \forall i \forall f(Sat(i,Not(f)) \leftarrow \neg Sat(i,f))\end{array}\right\}$$

These two sets of rules, denoted respectively Δ_{TC} and $\Delta_{\models}$, will serve as examples throughout the paper. We then formalize several semantic aspects of informal inductive definitions: the induction process, the induction order, two sorts of inductive definitions and their generalization, etc. This study reveals several unexpected but fundamental aspects of inductive definitions. After that, we are on mathematical ground and we will prove that the set defined by a definition is its well-founded model.

The main contributions of the paper are then as follows. First, we provide a number of *definitions from first principles* that formalize intuitions and implicit conventions regarding informal inductive definitions. We do this for monotone inductive definitions, definitions by induction over a well-founded order as well as for their generalization, iterated inductive definitions. Second, we prove the equivalence of formal rule sets under the formalized semantics and the well-founded semantics.

Due to space restrictions, proofs are omitted.

Formal definitions and natural inductions

A vocabulary Σ consists of a set of non-logical predicate, function, constant and variable symbols. As usual, terms are built from the function, constant and variable symbols of Σ, and formulas are built from atomic formulas (a predicate symbol applied to a tuple of terms), the logical symbols $\mathbf{t}$ (true), $\mathbf{f}$ (false), $=$ (identity), connectives $\wedge, \vee, \neg$ and quantifiers $\exists, \forall$.

An occurrence of a variable x in a formula φ is free if it does not occur in a sub-formula $\exists x\psi$ or $\forall x\psi$ of φ. The set $free(\varphi)$ is the set of all variables with a free occurrence in φ. A sentence is a formula φ with $free(\varphi) = \emptyset$. An occurrence of a sub-formula φ in ψ is called *positive* in ψ if it occurs in the scope of an even number of negations, otherwise it is called *negative*. A formula φ is positive with respect to a set σ of predicate symbols if there are no atoms $P(\bar{t})$ with $P \in \sigma$ that have a negative occurrence in φ.

Σ-structures $\mathfrak{A}$ consist of a domain $D^{\mathfrak{A}}$ and an assignment of appropriate values $\tau^{\mathfrak{A}}$ to symbols $\tau \in \Sigma$. The value $P^{\mathfrak{A}}$ of a predicate symbol P/n is a function from $(D^{\mathfrak{A}})^n$ to $\{\mathbf{t}, \mathbf{f}\}$ (hence the characteristic function of a set of n-tuples). Let D be a domain. A *domain atom* of D is a pair $(P, \bar{a})$ with P/n a predicate symbol and $\bar{a} \in D^n$. Abusing notation, we write domain atoms as atoms $P(\bar{a}), Q(\bar{b})$. We use A, B, C as mathematical variables for domain atoms. We define $P(\bar{a})^{\mathfrak{A}} = P^{\mathfrak{A}}(\bar{a})$. For a given set σ of predicate symbols, we denote the set of domain atoms with predicates in σ by At_D^σ. There is a one-to-one correspondence between subsets of At_D^σ and σ-structures with domain D. We often exploit this correspondence in our notations by treating σ-structures as such sets. E.g., $\emptyset$ stands for the structure $\mathfrak{A}$ with $P^{\mathfrak{A}} = \emptyset$, for every $P \in \sigma$. We write $P(\bar{a}) \in \mathfrak{A}$ to denote that $P^{\mathfrak{A}}(\bar{a}) = \mathbf{t}$, and $\mathfrak{A} \subseteq \mathfrak{B}$ to denote that $P(\bar{a})^{\mathfrak{A}} \leq P(\bar{a})^{\mathfrak{B}}$, for every $P(\bar{a}) \in At_D^\sigma$. This order based on $\mathbf{f} < \mathbf{t}$ is sometimes called the *truth order*.

Definition 3. *A (formal)* definition *over Σ is a set of definition rules of the form*

$$\forall \bar{x}\ (P(\bar{t}) \leftarrow \phi)$$

where ϕ is a FO formula and $P(\bar{t})$ is an atomic formula over Σ such that P is not $=$.

We call $P(\bar{t})$ the head of the rule, and ϕ the body. The connective $\leftarrow$ is called *definitional implication*. Rules of this kind are similar in nature to and generalize *productions* in (Martin-Löf 1971). A predicate appearing in the head of a rule of a definition Δ is called a *defined predicate* of Δ; all other non-logical symbols in Δ are called *parameters* of Δ. The sets of defined predicates and parameters of Δ are denoted by $def(\Delta)$ and $pars(\Delta)$, respectively. We assume without loss of generality that every rule is of the form $\forall \bar{x}\ (P(\bar{x}) \leftarrow \phi)$ where $\bar{x}$ is a tuple of distinct variables. Indeed, every rule $\forall \bar{x}\ (P(\bar{t}) \leftarrow \phi)$ can be put into that form as $\forall \bar{y}\ (P(\bar{y}) \leftarrow \exists \bar{x}(\bar{y} = \bar{t} \wedge \phi))$. Below, a domain atom $P(\bar{a})$ of a defined predicate of Δ is called a *defined domain atom*. Note that this formal notion of definition does not (yet) include an induction order.

A definition is always evaluated in a *context* providing values for its parameters. We formalize this.

Definition 4. *We call a $pars(\Delta)$-structure $\mathcal{O}$ a* context *of Δ.*

Example 1. *The definition $\Delta_{\models}$ of Sat formalizes the informal Definition 2 of satisfaction. Its parameter symbols are $Atom, In, And, Or$ and Not. We view $\Delta_{\models}$ as a many-sorted definition, with two sorts for structures and formulas. Any set S of propositional symbols induces a context $\mathcal{O}_S$ which is the $pars(\Delta)$-structure defined as follows:*

- *$D^{\mathcal{O}_S} = PropF(S) \cup Struct(S)$, where $PropF(S)$ is the set of propositional formulas over S and $Struct(S)$ is the set of propositional S-structures.*
- *$And^{\mathcal{O}_S}$ is the function that maps pairs of formulas $(\psi, \phi) \in PropF^2$ to $\psi \wedge \phi$. The functions $Or^{\mathcal{O}_S}$ and $Not^{\mathcal{O}_S}$ are defined in a similar vein.*
- *Finally, $In^{\mathcal{O}_S}$ is $\{(I,p) | I \in Struct(S), p \in I\}$.*

As an example, defined domain atoms for $S = \{P\}$ are of the form $Sat(\{P\}, P), Sat(\{\}, P \wedge \neg P), \ldots$. The value $t^{\mathcal{O}_s}$ of the term $t = And(P, Not(P))$ is the formula $P \wedge \neg P$.

From here till the end of this section, we assume the presence of a definition Δ, and a context $\mathcal{O}$ for Δ with domain D. The induction process associated with Δ in context $\mathcal{O}$ will be a sequence of $def(\Delta)$-structures $\mathfrak{A}$ with domain D. By $\mathcal{O} \circ \mathfrak{A}$, we denote the structure $\mathfrak{B}$ with domain D and such that $P^{\mathfrak{B}} = P^{\mathfrak{A}}$ if $P \in def(\Delta)$ and $\tau^{\mathfrak{B}} = \tau^{\mathcal{O}}$ if $\tau \in pars(\Delta)$. In the sequel, we frequently evaluate formulas with respect to structures $\mathcal{O} \circ \mathfrak{A}$. Because $\mathcal{O}$ is given and fixed, we take the liberty to write only the "variable" part and write e.g., $\mathfrak{A} \models \varphi$ instead of $\mathcal{O} \circ \mathfrak{A} \models \varphi$, or $A^{\mathfrak{A}}$ instead of $A^{\mathcal{O} \circ \mathfrak{A}}$, etc.

The next definitions are formalizations of the concept of an element being *derivable* from a definition, and a set being *closed* or *saturated* under a definition.

Definition 5. *Given a context $\mathcal{O}$, we say that $P(\bar{a})$ is derivable from rule $\forall\bar{x}(P(\bar{x}) \leftarrow \varphi)$ in $(\mathcal{O}\circ)\mathfrak{A}$ if $\varphi^{\mathfrak{A}[\bar{x}:\bar{a}]} = \mathbf{t}$. We say that $P(\bar{a})$ is Δ-derivable in $\mathfrak{A}$ if it is derivable from a rule of Δ in $\mathfrak{A}$. Below, we denote this by $\mathfrak{A} \vdash_\Delta P(\bar{a})$.*

Definition 6. *Given a context $\mathcal{O}$, we say that $\mathfrak{A}$ is closed (or saturated) on a set S of defined domain atoms under Δ in $\mathcal{O}$ if for every $A \in S$, $\mathcal{O} \circ \mathfrak{A} \vdash_\Delta A$ implies $A \in \mathfrak{A}$. In general, $\mathfrak{A}$ is* closed *(or saturated) under Δ (in $\mathcal{O}$) if it is closed on $At_D^{def(\Delta)}$ under Δ in $\mathcal{O}$.*

Example 2. *Let Δ_{ev} be the following non-monotone definition:*

$$\left\{ \begin{array}{l} Even(0) \leftarrow \\ \forall x(Even(x+1) \leftarrow \neg Even(x)) \end{array} \right\} \quad (1)$$

It can be viewed as the formalization of an informal definition of the even numbers by induction over the standard order of numbers: 0 is even; if n is not even then n+1 is even. This definition is structurally equivalent to the first and last rule of Definition 2. For succinctness, we abbreviate $Even$ often to Ev.

The context $\mathcal{O}$ is the structure of the natural numbers, with the standard interpretation of $0, 1$ and $+$. Consider the following sets, for every $N \in \mathbb{N}$:

$$\{Ev(0), Ev(2), Ev(4), \dots\}$$
$$\{Ev(0), Ev(2), \dots, Ev(2N), Ev(2N+1), Ev(2N+3), \dots\}$$

Each of these sets is closed under Δ_{ev}. None has a subset that is closed. Thus, the defined set is not the least set closed under the rules. A similar phenomenon arises for Definition 2.

The main concept of this paper is that of the induction process. It is formalized as follows.

Definition 7. *A* natural induction *$\mathcal{N}$ of Δ in $\mathcal{O}$ (with domain D) is an increasing sequence $(\mathfrak{A}_\alpha)_{0\le\alpha\le\beta}$ of $def(\Delta)$-structures with domain D such that:*

- *$\mathfrak{A}_0$ is the empty structure $\emptyset$.*
- *For each successor ordinal $i+1 \le \beta$, for each domain atom $A \in \mathfrak{A}_{i+1} \setminus \mathfrak{A}_i$, A is derivable from Δ in $\mathfrak{A}_i$ ($\mathfrak{A}_i \vdash_\Delta A$). We say that A is derived at i and define $\|A\|_\mathcal{N} := i$, the rank of A in $\mathcal{N}$.*
- *For each limit ordinal $\lambda \le \beta$, $\mathfrak{A}_\lambda = \bigcup_{\alpha<\lambda} \mathfrak{A}_\alpha$.*

A natural induction is called terminal *if $\mathfrak{A}_\beta$ is closed under Δ (in $\mathcal{O}$).*

Natural inductions will be denoted compactly as a sequence of the (disjoint) sets of atoms that are derived at each step. E.g.,

$$\to \{A_1, \dots, A_n\} \to \{B_1, \dots, B_m\} \to \dots$$

derives the A_i's in step 0 and the B_j's in step 1. If such a set is a singleton we drop the brackets.

Example 3. *Consider the formal definition Δ_{TC} formalizing the transitive closure Definition 1. Take context $\mathcal{O}$ such that $D = \{a, b, c\}$, $G^\mathcal{O} = \{(a,a), (b,c), (c,b)\}$. All terminal natural inductions converge to $\{(a,a), (b,c), (c,b), (b,b), (c,c)\}$. E.g.,*

$$\to T(a,a) \to T(b,c) \to T(c,b) \to T(b,b) \to T(c,c)$$
$$\to \{T(c,b), T(b,c)\} \to T(c,c) \to T(b,b) \to T(a,a)$$

The example illustrates some basic points about informal inductive definitions. They indeed define the concept in terms of the parameters, by describing how to construct it through iterated rule application. The description of the construction process is however highly *non-deterministic*: rules can be applied in many orders. From a practical point of view, it is all-important that such induction sequences converge to the same fixpoint, otherwise the definition would be ambiguous. For a monotonic informal definition, such as Definition 1, the order of rule application is not important, because—given the graph G—all sequences converge to the intended set, which is the least relation that is closed under the rules. In the above framework of natural induction sequences, this can be proven formally. First we propose a formalization of the notion of monotone inductive definition.

Definition 8. *We call Δ monotone in $\mathcal{O}$ if for all pairs of $def(\Delta)$-structures $\mathfrak{A} \subseteq \mathfrak{B}$, for all defined domain atoms A, if $\mathfrak{A} \vdash_\Delta A$ then $\mathfrak{B} \vdash_\Delta A$.*

Proposition 1. *Each terminal natural induction of a monotone Δ in $\mathcal{O}$ converges to the least $def(\Delta)$-structure $\mathfrak{A}$ that is closed under Δ in $\mathcal{O}$.*

This proposition is not difficult to prove but follows from the general Theorem 3 below.

The convergence property does not hold for non-monotone definitions. The problem is that the body of a non-monotone rule may eventually become false, after it has already been true. Natural inductions that apply a rule during the "window" where its body holds will derive its head, whereas natural inductions that miss this window may not.

Example 4 (Continuation of Example 1). *Consider definition $\Delta_\models$ in the context of the structure $\mathcal{O}_S$ for the singleton vocabulary $S = \{P\}$. There are only two structures for the vocabulary S, namely, $\emptyset$ and $\{P\}$. Below is an initial segment of a stepwise natural induction that derives a wrong fact.*

$$\to Sat(\{P\}, \neg P) \to Sat(\{P\}, P) \to \dots$$

In the first step, with $\mathfrak{A}_0 = \emptyset$, all instances of the rule for negation are applicable. Here, we use it to derive $Sat(\{P\}, \neg P)$. However, the next step applies the base rule to derive $Sat(\{P\}, P)$, thus falsifying the condition of the rule that was applied in the first step.

We realize that the role of the induction order in informal definitions is to delay the application of rules until it is safe to do so, that is, until later rule applications cannot longer falsify the premise of a rule that has been applied before. We now formally define the notion of definition by induction over a well-founded order. For brevity, we call it an *ordered definition*.

Definition 9. *Given is a domain D. An ordered definition is a pair $(\Delta, \prec)$ with Δ a definition and $\prec$ a strict well-founded order on $At_D^{def(\Delta)}$.*

Recall that a strict order is irreflexive, transitive and asymmetric. A strict order $\prec$ is well-founded if it has no infinite descending chains $x_0 \succ x_1 \succ x_2 \succ \dots$.

Example 5. *The induction order of informal Definition 2 is the sub-formula order. In the context of definition $\Delta_{\models}$ and a structure $\mathcal{O}_S$, it corresponds to a strict well-founded order $\prec$ on domain atoms, where $Sat(I, \psi) \prec Sat(J, \phi)$ if $I = J$ and ψ is a strict sub-formula of ϕ.*

The induction order provided with an informal definition serves to constrain the order of rule application in natural inductions. How does this work? Intuition says that no rule should be applied to derive a fact as long as there are derivable but not yet derived facts that are strictly smaller. E.g., assume that at some point in the induction process $I \models \varphi$ is derivable. We are allowed to do so only if there is no strict subformula ϕ of φ for which $I \models \varphi$ is derivable but was not yet derived. In general, we can derive $P(\bar{a})$ if the current set $\mathfrak{A}_i$ is saturated on atoms preceding $P(\bar{a})$ in the induction order. This is formalized in the following definition.

Recall that the rank $\|A\|_{\mathcal{N}}$ of A in a natural induction $\mathcal{N}$ is the ordinal i such that $A \in \mathfrak{A}_{i+1} \setminus \mathfrak{A}_i$.

Definition 10. *A natural induction $\mathcal{N}$* respects $\prec$ *(w.r.t. Δ and $\mathcal{O}$) if for any domain atom A with $\|A\|_{\mathcal{N}} = i$, $\mathfrak{A}_i$ is saturated on $\{B \mid B \prec A\}$ (under Δ in $\mathcal{O}$).*

We say that $\mathcal{N}$ follows $\prec$ *if for every A and B derived by $\mathcal{N}$, $A \prec B$ implies $\|A\|_{\mathcal{N}} < \|B\|_{\mathcal{N}}$.*

Example 6. *The natural induction of Example 4:*

$$\rightarrow Sat(\{P\}, \neg P) \rightarrow Sat(\{P\}, P) \rightarrow \dots$$

does not respect the subformula order. The atom $Sat(\{P\}, \neg P)$ is derived in the first step, when the empty set is not saturated in $\{A \mid A \prec Sat(\{P\}, \neg P)\}$ since $Sat(\{P\}, P)$ is derivable.

In general the induction process is highly underspecified, even if an induction order is given.

Example 7. *(Example 5 continued). Natural inductions of the informal Definition 2 will derive $I \models \varphi$ only after the satisfaction of all sub-formulas has been derived. This constrains the order of rule application, but much freedom is left. There are infinitely many such natural inductions. A few non-terminal ones are:*

$$\rightarrow Sat(\{P\}, P) \rightarrow Sat(\{P\}, P \wedge P) \rightarrow Sat(\{P\}, \neg\neg P)$$

$$\rightarrow Sat(\{P\}, P) \rightarrow Sat(\{P\}, \neg\neg P) \rightarrow Sat(\{P\}, P \vee P)$$

Note that both natural inductions respect the sub-formula order and follow it. Intuition suggests that these sequences can be extended to converging terminal natural inductions, and this will be proven below.

Given our experience with informal definitions, we expect some "good" properties of natural inductions that respect the induction order $\prec$: (1) that they all converge, (2) that such a natural induction *follows* the induction order, (3) that once an element is derived, it remains derivable, and (4) that in the limit, the defined set is the intended one. However, none of these properties hold right now.

The major question is related to (1). It is essential that all natural inductions that respect $\prec$ converge. However, it is straightforward to see that this is not the case. Take the empty induction order $\emptyset$ for the definition $\Delta_{\models}$ in context $\mathcal{O}_S$. This order is a strict well-founded order and all natural inductions respect it in a trivial way. As we saw in Example 4, not all of these natural inductions converge.

As for (2), a counterexample is below.

Example 8. *Consider the order $P \prec Q$ and definition:*

$$\left\{ \begin{array}{l} Q \leftarrow \mathbf{t} \\ P \leftarrow Q \end{array} \right\}$$

Here is a terminal natural induction:

$$\rightarrow Q \rightarrow P$$

It obviously does not follow $\prec$ since $P \prec Q$. However, it respects $\prec$. In the first step, when Q is derived, the structure $\mathfrak{A}_0 = \emptyset$ is saturated on $\{A \mid A \prec Q\} = \{P\}$, since P is not derivable. In the second step, $\mathfrak{A}_1 = \{Q\}$ is trivially saturated on $\{A \mid A \prec P\} = \{\}$.

A counterexample for (3) and (4) is given below.

Example 9. *We reconsider Δ_{ev} and $\mathcal{O}$ from Example 2.*

$$\left\{ \begin{array}{l} Even(0) \leftarrow \\ \forall x(Even(x+1) \leftarrow \neg Even(x)) \end{array} \right\} \qquad (2)$$

Let $\prec$ be the order induced by the standard order on the natural numbers. That is, $Ev(n) \prec Ev(m)$ if $n < m$. This is a total order, and the unique terminal natural induction that respects and follows it constructs the set of even numbers:

$$\rightarrow Ev(0) \rightarrow Ev(2) \rightarrow Ev(4) \rightarrow \dots \rightarrow Ev(2n) \rightarrow \dots$$

Now take the following non-standard induction order:

$$Ev(1) \prec Ev(0) \prec Ev(2) \prec Ev(3) \prec \dots$$

Also this is a total strict well-founded order. The unique terminal natural induction that respects $\prec$ is:

$$\rightarrow Ev(1) \rightarrow Ev(0) \rightarrow Ev(3) \rightarrow Ev(5) \rightarrow \dots$$

Note that $Ev(1)$ is not longer derivable after step 2. Also, it clearly does not define the intended set.

In non-monotone informal definitions, we impose a well-founded induction order to obtain convergence of the induction process. However, it is clear from the above examples that in selecting the induction order, great care is required. In general, imposing an unsuitable induction order w.r.t. Δ and $\mathcal{O}$ may have a number of undesired effects as just shown.

Something clearly wrong with the second induction order in the above example is that it does not *match* the structure of the given rules. In particular, $Ev(1)$ is defined in terms of $Ev(0)$, even though $Ev(0)$ is strictly larger than $Ev(1)$ in the proposed induction order. This would be unacceptable in an informal definition.

The above examples expose one of the implicit conventions of informal inductive definitions. This is that the induction order should "match" the structure of the rules of a definition. Intuitively, this means that defined facts may only "depend" on facts that are strictly smaller in the induction order. We now formalize this.

First we formalize the notion of dependency relation. Below, for binary relation $\propto$, $\mathfrak{A}|_{\propto A}$ denotes $\mathfrak{A} \cap \{B \mid B \propto A\}$.

Definition 11. *A binary relation $\propto$ on $At_D^{def(\Delta)}$ is a* dependency relation *of Δ in $\mathcal{O}$ if $\propto$ is transitive and for all A and all $\mathfrak{A}, \mathfrak{B}$, if $\mathfrak{A}|_{\propto A} = \mathfrak{B}|_{\propto A}$ then $\mathfrak{A} \vdash_\Delta A$ iff $\mathfrak{B} \vdash_\Delta A$.*

If $\propto$ is a dependency relation, then for any defined atom A, the set $\{B \mid B \propto A\}$ is (a superset of) the set of atoms on which A depends. Indeed, in any pair of structures that coincide on this set, A is derivable in both or in none.

That an induction order "matches" the rules of a definition simply means that $\prec$ is a dependency relation.

Definition 12. *We say that $\prec$* strictly orders *Δ in $\mathcal{O}$ if $\prec$ is a strict well-founded order and a dependency relation of Δ in $\mathcal{O}$.*

Example 10. *In case of definition Δ_{ev} of even numbers and the structure $\mathcal{O}$ of Example 2, we see that the first order*

$$Ev(0) \prec Ev(1) \prec Ev(2) \prec Ev(3) \prec \dots$$

strictly orders Δ_{ev}, while the second order

$$Ev(1) \prec Ev(0) \prec Ev(2) \prec Ev(3) \prec \dots$$

does not. E.g., $\emptyset$ and $\{Ev(0)\}$ are identical on $\{B \mid B \prec Ev(1)\} = \emptyset$, but $\emptyset \vdash_\Delta Ev(1)$ while $\{Ev(0)\} \nvdash_\Delta Ev(1)$.

Natural inductions that respect an order $\prec$ that strictly orders Δ in $\mathcal{O}$ satisfy all the good properties (1-4) above, as shown by the following two propositions.

Proposition 2. *If $\prec$ strictly orders Δ then any natural induction $\mathcal{N}$ that respects $\prec$ also follows $\prec$.*

Proposition 3. *If $(\Delta, \prec)$ is an ordered definition in context $\mathcal{O}$ and $\prec$ strictly orders Δ in $\mathcal{O}$, then all terminal natural inductions that respect $\prec$ converge. Moreover the limit is independent of $\prec$. (It is the ultimate well-founded fixpoint of Δ in $\mathcal{O}$ - see Definition 19).*

Also this proposition follows from the stronger Theorem 3.

This theorem shows that an ordered definition in which $\prec$ strictly orders Δ unambiguously defines a set. The definition of an ordered definition can now be refined as follows.

Definition 13. *A definition Δ is a definition by well-founded induction over $\prec$ in $\mathcal{O}$ (or briefly, an ordered definition) if $\prec$ strictly orders Δ in $\mathcal{O}$. The structure defined by it is the limit of any terminal natural induction that respects $\prec$.*

Interestingly, the convergence property states that the limit is independent of the selected order. Sometimes this phenomenon can be seen in mathematical text.

Example 11. *We defined the satisfaction relation $\models$ over the subformula order but it is not uncommon to define it over alternative induction orders. For example, we could define $\models$ by induction on the* size *of formulas. Formally, we define $Sat(I, \psi) \prec Sat(J, \phi))$ if $I = J$ and the size of ψ (the number of nodes in its parse tree) is strictly less than the size of ϕ. Alternatively, we may define $\models$ by induction on the* depth *of formulas, i.e., the length of the longest branch in the parse tree of ϕ. The three orders lead to three variants of Definition 2. Intuition suggests that they are equivalent.*

It is indeed easy to verify that each of them strictly orders $\Delta_\models$ in $\mathcal{O}_S$: for each rule instance, the body refers to formulas that are strict subformula's, and have smaller size and depth than the formula in the head. Hence, it follows from the proposition that these definitions are indeed equivalent.

This does not mean that they have the same natural inductions. E.g., reconsider the natural induction of Example 7:

$$\rightarrow Sat(\{P\}, P) \rightarrow Sat(\{P\}, \neg\neg P) \rightarrow Sat(\{P\}, P \vee P)$$

This one respects and follows the subformula order and the size order. However, it does not respect the depth order, since $\mathfrak{A}_1$ is not saturated on $\{B \mid B \prec Sat(\{I\}, \neg\neg P)\}$. For instance, $Sat(\{P\}, P \vee P)$ is derivable but not derived and $P \vee P$ has strictly smaller depth than $\neg\neg P$.

Generalizing monotone and ordered definitions. There is an obvious similarity between Propositions 1 and 3. However, the former is not a generalization of the latter, because not all monotone definitions are ordered. For instance, there is no $\prec$ that strictly orders definition Δ_{TC} of transitive closure. Due to the transitivity rule, all defined domain atoms depend on each other; the only dependency relation is the total one and this is not a strict order. In this section, we define the more general class of *iterated inductive definitions*, which encompasses all ordered definitions as well as all monotone definitions. We will then prove a theorem for this more general class, which generalizes both of the earlier results.

The general idea of iterated inductive definitions is that they admit a dependency $\propto$ that is not a strict order. However, if atom A, B depend on each other (that is, $A \propto B \propto A$), then they depend *monotonically* on each other: deriving B may make A derivable and vice versa.

We define $A \prec_\propto B$ if $A \propto B$ and $B \not\propto A$. Since $\propto$ is transitive, $\prec_\propto$ is a strict order. $\prec_\propto$ divides the set of domain atoms into a set of strictly ordered "layers" such that, for all A, B, if $A \prec_\propto B$, then A is in a strictly lower layer than B, and if $A \propto B \propto A$, they are in the same layer.

Natural inductions of an iterated inductive definition proceed along the order $\prec_\propto$. Just as for an ordered definition, an atom A may be derived at step i only if $\mathfrak{A}_i$ is saturated on $\{B \mid B \prec_\propto A\}$. In this way, a natural induction closes layer by layer, and starts a new monotone induction in the next layer as soon as a layer is saturated. The following definition will serve to ensure that the "sub-inductions" that take place inside a single layer are monotone.

Definition 14. *A relation $\propto$ monotonically orders Δ in $\mathcal{O}$ if $\prec_\propto$ is a strict well-founded order and for all defined A, for all $\mathfrak{A}, \mathfrak{B}$ such that $\mathfrak{A}|_{\prec_\propto A} = \mathfrak{B}|_{\prec_\propto A}$ and $\mathfrak{A}|_{\propto A} \subseteq \mathfrak{B}|_{\propto A}$, if $\mathfrak{A} \vdash_\Delta A$ then $\mathfrak{B} \vdash_\Delta A$.*

Proposition 4. *If $\propto$ monotonically orders Δ in $\mathcal{O}$ then $\propto$ is a dependency relation of Δ in $\mathcal{O}$.*

Definition 15. *We say that a natural induction $\mathcal{N}$ respects (follows) a dependency relation $\propto$ if it respects (follows) $\prec_\propto$ according to Definition 10.*

Proposition 5. *If a natural induction $\mathcal{N}$ respects a relation $\propto$ that monotonically orders Δ in $\mathcal{O}$, then $\mathcal{N}$ follows $\propto$.*

Proposition 6. *Assume that $\propto$ monotonically orders Δ in $\mathcal{O}$. Then all terminal natural inductions that respect $\propto$ converge. Moreover, the limit is independent of $\propto$. (It is the ultimate well-founded fixpoint of Δ in $\mathcal{O}$.)*

Again, this proposition follows from Theorem 3.

We have already defined the concept of a monotone and ordered definition in context $\mathcal{O}$. Now, we also define the concept of an iterated inductive definition (in $\mathcal{O}$).

Definition 16. *A definition Δ is a definition by iterated induction over $\propto$ in $\mathcal{O}$ if $\propto$ monotonically orders Δ in $\mathcal{O}$. Its defined structure is the limit of any terminal natural induction.*

Now we can show that iterated inductive definitions generalize monotone and ordered definition. For a monotone definition, the entire set of all domain atoms can serve as a single layer. Let $\propto_t$ denote the total binary relation on $At_\Delta^{def(\Delta)}$. Note that $<_{\propto_t} = \emptyset$.

Proposition 7. *A definition Δ is monotone in $\mathcal{O}$ iff Δ is a definition by iterated induction over $\propto_t$ in $\mathcal{O}$. A natural induction of Δ in $\mathcal{O}$ (trivially) respects $\propto_t$.*

Proposition 8. *For a binary relation $\propto$, a definition Δ is a definition by well-founded induction over $\propto$ in $\mathcal{O}$ iff Δ is by iterated induction over $\propto$ in $\mathcal{O}$ and $\propto$ is irreflexive and asymmetric (hence, a strict order).*

As a consequence, Prop. 6 is a generalization of both Prop. 1 and Prop. 3.

Informal iterated inductive definitions are quite common in mathematical text although they are only very rarely formulated as sets of informal rules. To phrase them, formal scientists use other tools from their toolbox, for example fixpoints of operators. A well-known iterated inductive definition is the alternating fixpoint definition of the well-founded model in (Van Gelder 1993). In this theory, a (stable) operator $\mathcal{A}$ is defined on structures by defining $\mathcal{A}(\mathfrak{A})$ as the least fixpoint of a monotone operator $\lambda x T(x, \mathfrak{A})$. This stable operator is anti-monotone. The well-founded fixpoint is then characterised as the limit of an alternating fixpoint construction using $\mathcal{A}$. This is iterated induction in the sense that each of the steps involves itself a monotone inductive construction.

A rare case where iterated induction is explicitly available in rule form is in the definition of *stable theory* (Marek 1989) which is the set of modal propositional formulas closed under the standard inference rules and two additional ones:

$$\frac{\vdash \psi}{\vdash K\psi} \qquad \frac{\nvdash \psi}{\vdash \neg K\psi}$$

The second is a non-monotone rule. The set is computed by iterated induction for increasing modal nesting depth of modal formulas.

In knowledge representation, there are many applications of iterated inductive definitions that have a natural representation as rule sets. This is for instance the case in representations of dynamic systems with ramifications (Denecker and Ternovska 2007).

Summary of informal definitions. The above theory exposes several important issues of informal definitions. First, that the "non-constructive" characterization is incorrect in case of non-monotone (ordered) definitions. Second, that the induction process is highly non-deterministic, and therefore that convergence is all-important. In mathematical practice, we typically take this property for granted. In fact, it is not trivial at all. It is a fundamentally important property of inductive definitions.

Third, in mathematical texts, we have a certain degree of freedom when it comes to choosing the induction order for an inductive definition. Nevertheless, the order is far from arbitrary and needs to match the structure of the rules. Our exposition clarifies the role and nature of the induction order, and how it constrains the order of rule application.

Finally, as shown by Proposition 6, the choice of the induction order is irrelevant as long as it matches the rules. The order does not affect the semantics of the definition.

In view of this, one may wonder why an induction order is specified at all in mathematical text? One possible explanation is that it serves to help the reader better understand the definition. Moreover, the specified order may help him/her as a kind of *parity check* of the soundness of the definition. Indeed, not all sets of informal rules form sensible definitions (far from). The induction order helps in verifying that the (informal) rules indeed form a sensible definition (see also the "parity check" discussion following Corollary 1).

Developing a logic of definitions. In the mathematical logic of ordered and iterated induction (IID) presented in (Buchholz et al. 1981), an iterated inductive definition is expressed via SO formula's that express a definition Δ and, independently, an induction order $\prec$. They use this logic system to study proof-theoretic strength and expressivity of iterated definitions. From a representational point of view however, we see two problems with an approach in which the induction order is explicitly expressed. First, expressing an induction order in logic might be as complex as expressing the definition itself, if not more. It is a needless complication of the knowledge representation process. Second, it also makes the knowledge representation process more error-prone. Even though the logic of (Buchholz et al. 1981) imposes strong additional constraints on the induction process so that convergence can be guaranteed, it is still possible to express combinations of a definition and an induction order that will converge to the wrong limit. For example, one can encode the definition Δ_{ev} with the non-matching order $Ev(1) \prec Ev(0) \prec Ev(2) \prec \ldots$, in which case the unintended set $\{Ev(1), Ev(0), Ev(3), Ev(5), \ldots\}$ will be constructed.

It is preferable to design a logic of definitions in which only the rules need to be represented and the order is left implicit. Indeed, Proposition 6 gives us license to do this, because it shows that all induction orders that fit the structure of the rules of Δ produce the same unique limit of their terminal natural inductions.

Designing a logic in which all and only iterated inductive definitions can be expressed is impossible. A logic's syntax should be decidable, while it is easy to see that it is undecidable whether a rule set is a monotone, ordered or iterated definition in a structure $\mathcal{O}$. One option out is by imposing syntactical constraints. For monotone definitions, we could impose the simple syntactic criterion that only rules with

positive bodies are allowed. Beyond monotone definitions, however, this seems unfeasible. One issue is that whether a rule sets admits a $\propto$ that strictly or monotonically orders Δ in $\mathcal{O}$ may depend on the context $\mathcal{O}$.

Example 12. *The definition Δ_{ev} is an ordered inductive definition over the standard order in the natural numbers, but does not admit an induction order in the context $\mathcal{O}$ with domain $\{0,1\}$, $0^{\mathcal{O}} = 0, 1^{\mathcal{O}} = 1, +^{\mathcal{O}} = \{(0,0,0),(0,1,1),(1,0,1),(1,1,1)\}$. Indeed, in this structure, the two instances of the inductive rule are: $even(1) \leftarrow \neg even(0)$ and $even(1) \leftarrow \neg even(1)$. The least dependency relation is $even(0) \propto even(1) \propto even(1)$, but $\propto$ does not strictly or monotonically order Δ_{ev} in $\mathcal{O}$. Similarly, definition $\Delta_{\models}$ is not a legal definition in contexts where $Not^{\mathcal{O}}$ contains cycles.*

Requiring syntactic stratification is a possibility but it would eliminate interesting cases such as definition $\Delta_{\models}$. A more refined condition like local stratification (Przymusinski 1988) offers more liberty but it applies only to conjunctive rule bodies, in Herbrand contexts, is also undecidable and moreover is very brittle. Simple equivalence preserving transformations may transform a locally stratified rule set into one that is not. For instance, transforming rules $\forall \bar{x}(P(\bar{t}) \leftarrow \varphi)$ to $\forall \bar{y}(P(\bar{y}) \leftarrow \exists \bar{x}(\bar{t} = \bar{y} \wedge \varphi))$ breaks local stratification. This is not a good idea.

The alternative option is to waive any syntactic restriction but to design a "partial" semantics that assigns the "right" values to the defined predicates if Δ is a sensible inductive definition in $\mathcal{O}$ and otherwise does not assign a value. It is here that the well-founded semantics comes in. It will help us to cope with the absence of an explicit induction order in two ways. First, if this semantics assigns a value, then we can be certain that the definition is correct and that the assigned value is indeed the intended one. Second, as we will see, this semantics also provides mathematical tools that we can use to understand the workings of an inductive definition, without making reference to a specific induction order.

Well-founded inductions

The goal of this section is to show that the well-founded semantics allows us to perform the natural induction along some induction order, without actually knowing this order up front. There exist many formalizations of the well-founded semantics, but they all have in common that they construct a sequence of three-valued structures of increasing precision. This is quite different from a natural induction, which is an increasing sequence of two-valued structures. The following observation gives a clue as to how such sequences might be related.

Consider a (stepwise) natural induction of Δ in context $\mathcal{O}$ that respects $\prec_{\propto}$.

$$\rightarrow A_1 \rightarrow A_2 \rightarrow \ldots \rightarrow A_\beta$$

At each i, the structure $\mathfrak{A}_i = \{A_1, \ldots, A_i\}$ already provides the following partial information about the limit $\mathfrak{A}_\beta$:

- $A \in \mathfrak{A}_\beta$ if $A \in \mathfrak{A}_i$;
- $A \notin \mathfrak{A}_\beta$ if $\mathfrak{A}_i \nvdash_\Delta A$ and $\mathfrak{A}_i$ is saturated in $\{B | B \propto A\}$. Indeed, since $\mathfrak{A}_i$ is saturated on $\{B | B \propto A\}$, it is saturated on every $\{B \mid B \propto C\} \subseteq \{B \mid B \propto A\}$. As a consequence, no atoms $C \propto A$ will ever be derived in the future. Since A is not derivable now, it will never become derivable.
- It is unknown whether $A \in \mathfrak{A}_\beta$ otherwise.

This tells us how to construct from each $\mathfrak{A}_i$ a three-valued structure $\mathcal{I}_i$ that "approximates" the defined set $\mathfrak{A}_\beta$. As such, a natural induction implicitly specifies a sequence of three-valued structures of increasing precision, that converges to $\mathfrak{A}_\beta$. Let us explore this in a few of the examples.

Example 13. *The transitive closure definition Δ_{TC} in context $\mathcal{O}$ of Example 3 is an iterated inductive definition over the total dependency relation $\propto_t$ ($\prec_{\propto_t} = \emptyset$). This induces a unique layer consisting of all domain atoms. Consider the following terminal natural induction:*

$$\rightarrow R(a,a) \rightarrow R(b,c) \rightarrow R(c,b) \rightarrow R(b,b) \rightarrow R(c,c)$$

The intermediate structures $\mathfrak{A}_i$ ($i < 5$) in this sequence are not saturated and no negative information is available. Hence, for each $i < 5$, all atoms not in $\mathfrak{A}_i$ are unknown in $\mathcal{I}_i$. However, the limit $\mathfrak{A}_5 = R$ is saturated, and only then it can be derived that all atoms not in $\mathfrak{A}_5$ are false.

Example 14. *The definition Δ_{ev} in context $\mathcal{O}$ of Example 2 is by induction over the standard order. The unique natural induction is:*

$$\rightarrow Ev(0) \rightarrow Ev(2) \rightarrow \ldots \rightarrow Ev(2n) \rightarrow \ldots$$

At each step i, one can verify that $\mathfrak{A}_i$ is saturated on $\{Ev(j) \mid j \leq 2i-1\}$. It follows that, for $0 \leq j \leq i$, $\mathcal{I}_i \models \neg Ev(2j-1)$. The following sequence describes the derivation of positive and negative information during this natural induction:

$$\rightarrow \{\} \rightarrow Ev(0) \rightarrow \neg Ev(1) \rightarrow Ev(2) \rightarrow \neg Ev(3) \rightarrow \ldots$$

Thus, natural inductions correspond to sequences of three-valued structures $\langle \mathcal{I}_i \rangle_{0 \leq i \leq \beta}$. As we have seen, however, building a correct natural induction requires an induction order $\prec_{\propto}$. We will now show that we can exploit the additional information that is present in three-valued structures to construct $\mathcal{I}_{i+1}$ from $\mathcal{I}_i$, without using the induction order at all.

In the discussion below, we assume without loss of generality that a (finite) Δ contains exactly one rule $\forall \bar{x}(P(\bar{x}) \leftarrow \varphi)$ per defined predicate P (we can bundle finitely many multiple rules in one using a disjunction). We denote the body φ of this unique rule as φ_P. Below, when $A = P(\bar{a})$, we write $\varphi_A^{\mathfrak{A}}$ as a shorthand for $\varphi_P^{\mathfrak{A}[\bar{x}:\bar{a}]}$.

We first recall the formalization of the parametrized well-founded semantics of (Denecker and Vennekens 2007). We consider three-valued structures on $def(\Delta)$ on domain D. For each $P/n \in def(\Delta)$, $P^{\mathcal{I}}$ is a function $D^n \rightarrow \{\mathbf{t}, \mathbf{f}, \mathbf{u}\}$. The precision order on the three-valued structures is the point-wise extension of the partial order $\mathbf{u} \leq_{\mathrm{p}} \mathbf{t}$, $\mathbf{u} \leq_{\mathrm{p}} \mathbf{f}$. If U is a set of domain atoms, then $\mathcal{I}[U : \mathbf{f}]$ is identical to $\mathcal{I}$ except that every atom $A \in U$ is false; likewise for $\mathcal{I}[U : \mathbf{t}]$.

Rules are evaluated using a three-valued truth function $\varphi^{\mathcal{I}}$, defined for formulas φ and three-valued structures $\mathcal{I}$ that interpret all free symbols of φ. At this moment, this truth function is generic. All we require here is that it satisfies two properties: (1) if $\mathcal{I}_1 \leq_{\mathrm{p}} \mathcal{I}_2$ then $\varphi^{\mathcal{I}_1} \leq_{\mathrm{p}} \varphi^{\mathcal{I}_2}$ ($\leq_{\mathrm{p}}$-monotonicity) and (2) if $\mathfrak{A}$ is a (two-valued) structure, $\varphi^{\mathfrak{A}}$ is the standard truth value of φ in $\mathfrak{A}$.

Definition 17. *Given is a definition Δ and context $\mathcal{O}$. We say that $\mathcal{I}'$ is a Δ-refinement of $\mathcal{I}$ (in $\mathcal{O}$) if there is a set U of unknown domain atoms in $\mathcal{I}$ such that one of the following conditions is satisfied:*

- *for each $A \in U$, ${\varphi_A}^{\mathcal{I}} = \mathbf{t}$ and $\mathcal{I}' = \mathcal{I}[U : \mathbf{t}]$; or*
- *for each $A \in U$, ${\varphi_A}^{\mathcal{I}'} = \mathbf{f}$ and $\mathcal{I}' = \mathcal{I}[U : \mathbf{f}]$.*

As before, we used $\varphi^{\mathcal{I}}$ as a shorthand for $\varphi^{\mathcal{O} \circ \mathcal{I}}$.

Note the asymmetry: to derive A, its body must be true in $\mathcal{I}$ itself; but to derive $\neg A$, it suffices that its body is false in $\mathcal{I}[U : \mathbf{f}]$, i.e., we are free to assume that atoms are $\mathbf{f}$, as long as this prophecy turns out to fulfill itself. One recognizes the familiar concept of unfounded set in the second sort of refinement (Van Gelder, Ross, and Schlipf 1991).

Definition 18. *A* well-founded induction *of Δ in (context) $\mathcal{O}$ is a sequence $\langle \mathcal{I}_i \rangle_{0 \leq i \leq \beta}$ of three-valued $def(\Delta)$-structures with domain D such that $\mathcal{I}_0$ is $\mathbf{u}$ (the mapping of all defined domain atoms to $\mathbf{u}$), for each ordinal i, $\mathcal{I}_{i+1}$ is a Δ-refinement of $\mathcal{I}_i$ in $\mathcal{O}$, and for limit ordinals λ, $\mathcal{I}_\lambda$ is the $\leq_{\mathrm{p}}$-limit of $\langle \mathcal{I}_i \rangle_{i<\lambda}$. We call a well-founded induction terminal if its limit $\mathcal{I}_\beta$ has no strictly more precise Δ-refinement.*

A well-founded induction increases in precision, and hence, it has a $\leq_{\mathrm{p}}$-limit.

Theorem 1 ((Denecker and Vennekens 2007)). *All well-founded inductions in $\mathcal{O}$ can be extended to a terminal well-founded induction in $\mathcal{O}$. All terminal well-founded inductions in $\mathcal{O}$ converge.*

Definition 19. *The* well-founded model of Δ relative to $\mathcal{O}$ *(and the selected truth function) is the limit of any terminal well-founded induction of Δ in $\mathcal{O}$.*

We explain our intuition underlying well-founded inductions. It not only constructs elements of the defined set but also non-elements. Given such a partial set $\mathcal{I}_i$ at intermediate stage i, a new element A can be derived if what is known of the defined set, suffices to ascertain that A is derivable, that is ${\varphi_A}^{\mathcal{I}_i} = \mathbf{t}$. This explains the first refinement $\mathcal{I}_i[U : \mathbf{t}]$. A non-element A may be derived likewise, if it is certain that its condition does not hold, that is if ${\varphi_A}^{\mathcal{I}_i} = \mathbf{f}$. However, this is not enough. For example, in a positive definition such as Δ_{TC}, if we wait till ${\varphi_A}^{\mathcal{I}_i} = \mathbf{f}$ to derive that A is a non-element, we are waiting forever. A principle is needed that "looks ahead"; a principle that finds out that there are no more options to derive one or more domain atoms through natural induction from the current state. If U is such that $\mathcal{I}_i[U : \mathbf{f}]$ falsifies the premise φ_A of every $A \in U$, then no ways are left to construct such A's. This explains the second refinement $\mathcal{I}_i[U : \mathbf{f}]$.

The well-founded model is usually defined for normal logic programs, which correspond to the fragment of our rule based formalism that satisfies the following conditions: Δ is a set of normal rules (i.e., conjunctions of literals in the body), $pars(\Delta)$ contains only constant and function symbols (i.e., all predicates are defined), and $\mathcal{O}$ is the unique Herbrand interpretation of $pars(\Delta)$. If, in addition, we choose the standard Kleene three-valued truth function as our function $\varphi^{\mathcal{I}}$, then we obtain precisely the standard well-founded model of Δ.

An alternative three-valued truth function is the *supervaluation*, defined by $\varphi^{\mathcal{I}} = glb_{\leq_{\mathrm{p}}}\{\varphi^{\mathfrak{A}} \mid \mathcal{I} \leq_{\mathrm{p}} \mathfrak{A}$ and $\mathfrak{A}$ is two-valued $\}$ (van Fraassen 1966). It is more precise than Kleene's: e.g, for $P^{\mathcal{I}} = \mathbf{u}$ the supervaluation of $P \vee \neg P$ is $\mathbf{t}$ while Kleene's valuation is $\mathbf{u}$. We can also construct the well-founded model w.r.t. this truth function. This is the *ultimate* well-founded model of Δ relative to $\mathcal{O}$ (Denecker, Marek, and Truszczyński 2004). The standard well-founded model is less or equally precise than the ultimate one. This implies that if it is two-valued (i.e., maximally precise), it is also the ultimate well-founded model.

We are now ready to link well-founded and natural inductions. Let Δ be a definition by iterated induction over $\propto$ in context $\mathcal{O}$ with domain D. Let $\mathcal{N}$ be a natural induction that respects $\propto$:

$$\mathfrak{A}_0 \rightarrow \mathfrak{A}_1 \rightarrow \ldots \rightarrow \mathfrak{A}_\beta$$

With $\mathcal{N}$, we now associate the following sequence $WFI(\mathcal{N})$ of three-valued structures:

$$\mathcal{I}_0 \rightarrow \mathcal{I}_{0,1} \rightarrow \mathcal{I}_1 \rightarrow \mathcal{I}_{1,2} \rightarrow \mathcal{I}_2 \rightarrow \ldots \mathcal{I}_\beta \rightarrow \mathcal{I}_{\beta,\beta+1}$$

which we define by induction:

- $\mathcal{I}_0 = \mathbf{u}$ (for all domain atoms A, $A^{\mathcal{I}_0} = \mathbf{u}$).
- $\mathcal{I}_{i,i+1} = \mathcal{I}_i[U : \mathbf{f}]$ where $U = \{A \mid A^{\mathcal{I}_i} = \mathbf{u}, \mathfrak{A}_i \not\models_\Delta A$ and $\mathfrak{A}_i$ is saturated on $\{B \mid B \propto A\}\}$.
- $\mathcal{I}_{i+1} = \mathcal{I}_{i,i+1}[U : \mathbf{t}]$ where $U = \mathfrak{A}_{i+1} \setminus \mathfrak{A}_i$.
- $\mathcal{I}_\lambda$ is the $\leq_{\mathrm{p}}$-limit of its predecessors, for limit ordinals λ.

For the following theorem, we select supervaluation as three-valued truth function.

Theorem 2. *Let Δ be a definition by iterated induction over $\propto$ in $\mathcal{O}$. If $\mathcal{N}$ is a terminal natural induction of Δ in $\mathcal{O}$ that respects $\propto$ then the sequence $WFI(\mathcal{N})$ is a terminal well-founded induction and $\mathcal{I}_{\beta,\beta+1} = \mathfrak{A}_\beta$.*

It is on this theorem that the thesis of this paper rests. Indeed, it has the following theorem as a corollary, from which we directly obtain Proposition 6.

Theorem 3. *Let Δ be a definition by iterated induction over $\propto$ in $\mathcal{O}$. For any terminal natural induction $\mathcal{N}$ of Δ in $\mathcal{O}$ that respects $\propto$, its limit is the ultimate well-founded model of Δ in $\mathcal{O}$.*

Arguably, the construction process of a well-conceived formal or informal definition should result in a well-defined set. In our setting, this mean that the well-founded model in $\mathcal{O}$ should be two-valued. In this case we call Δ *total* in $\mathcal{O}$.

Corollary 1. *If Δ is a definition by iterated induction over $\propto$ in $\mathcal{O}$, then Δ is total in $\mathcal{O}$.*

Thus an iterated definition Δ has the desirable property of being total in $\mathcal{O}$. While the induction order has no semantical role in a definition, it gives insight in the structure of the definition and it gives a "parity check" of the correctness/totality of the definition.

From a technical point of view, Corollary 1 shows that one way to prove that a rule set has a 2-valued well-founded model is to prove that it has a dependency relation that monotonically orders it. This generalizes a condition in (Denecker and Ternovska 2008) and, to the best of our knowledge, it is the most general such condition currently known.

A comparison of natural and well-founded inductions. Below we write a well-founded induction as:

$$\rightarrow S_1 \rightarrow S_2 \rightarrow \dots$$

where S_i is either the set of atoms U such that $\mathfrak{A}_i = \mathfrak{A}_{i-1}[U : \mathbf{t}]$ or the set of negations $\neg A$ of atoms A in the set U such that $\mathfrak{A}_i = \mathfrak{A}_{i-1}[U : \mathbf{f}]$.

Example 15. *For the natural induction $\mathcal{N}$ of Example 3:*

$$\rightarrow R(a,a) \rightarrow R(b,c) \rightarrow R(c,b) \rightarrow R(b,b) \rightarrow R(c,c)$$

the corresponding well-founded induction $WFI(\mathcal{N})$ is:

$$\rightarrow \emptyset \rightarrow R(a,a) \rightarrow \emptyset \rightarrow R(b,c) \rightarrow \emptyset \rightarrow R(c,b) \rightarrow$$
$$\emptyset \rightarrow R(b,b) \rightarrow \emptyset \rightarrow R(c,c) \rightarrow \{\neg R(x,y) \mid (x,y) \notin R\}.$$

Example 16. *The natural induction of Example 2:*

$$\rightarrow Ev(0) \rightarrow Ev(2) \rightarrow \dots$$

has the corresponding well-founded induction $WFI(\mathcal{N})$:

$$\rightarrow \emptyset \rightarrow Ev(0) \rightarrow \neg Ev(1) \rightarrow Ev(2) \rightarrow \neg Ev(3) \rightarrow \dots$$

Many definitions admit well-founded inductions that are not natural inductions. Well-founded inductions can go dramatically "faster" than natural inductions.

Example 17. *A well-founded induction of the satisfaction definition $\Delta_{\models}$ that does not respect the induction order, but is nevertheless a correct well-founded induction is:*

$$\rightarrow Sat(\{P\}, P) \rightarrow \{Sat(\{P\}, P \vee \varphi) \mid \varphi \text{ a formula over } S\}$$

Indeed, after the first step $Sat(\{P\}, P)$ is true in the three-valued structure $\mathcal{I}_1$. Hence, we have $[Sat(\{P\}, P) \vee Sat(\{P\}, \varphi)]^{\mathcal{I}_1} = \mathbf{t}$ for every φ. It follows that $\mathfrak{A}_1[U : \mathbf{t}]$ is a refinement of $\mathfrak{A}_1$ for $U = \{Sat(\{P\}, P \vee \varphi) | \varphi$ a formula over $S\}$.

The well-founded induction in the example matches how humans derive $\mathfrak{A} \models \varphi \vee \psi$: if a disjunct φ is derived to be satisfied, we jump to the conclusion that $\varphi \vee \psi$ is satisfied, even if the value of ψ is unknown. Strictly speaking, here we are violating the induction order! It is nevertheless safe: any fact derived during a well-founded induction is correct.

The next example shows that there are sensible definitions that are not iterated definitions.

Example 18. *Let $\mathcal{O}$ be the natural number context of Example 2 and Δ_{ev1} the following variant definition of even numbers and an additional predicate $Next$:*

$$\left\{ \begin{array}{ll} \forall x \forall y (Next(x,y) \leftarrow x = y + 1) \\ \forall x (Even(x) & \leftarrow x = 0 \vee \\ & \quad \exists y (Next(x,y) \wedge \neg Even(y))) \end{array} \right\}$$

The definition defines and uses $Next$ as the successor predicate. Its well-founded model $\mathfrak{A}$ interprets $Next$ as the successor relation and $Even$ as the set of even numbers, as expected. However, this definition is not an iterated induction. Indeed, in any dependency relation of Δ_{ev1}, it holds that $Ev(n) \propto Ev(m)$ for all $n, m \in \mathbb{N}$. This follows from the fact that $Ev(m)$ is derivable in the structure $\{Next(m,n)\}$ but not in $\{Next(m,n), Ev(n)\}$. However, as the same two structures show, no such $\propto$ monotonically orders Δ_{ev1} in $\mathcal{O}$.

The above example shows a disturbing brittleness of the concept of a definition by iterated induction as defined in Definition 16, that fortunately is not shared with the rule formalism under the well-founded semantics.

To summarize, the concept of well-founded induction seems to provide a superior formalization of the induction process, one that is independent of the order, faster, more like humans reason on informal definitions and more robust under innocent syntactical variance.

Standard versus ultimate well-founded semantics. The result of the previous section (the convergence of natural and well-founded inductions) are formulated for the ultimate well-founded semantics, the one derived using the supervaluation. Here, we investigate to what extend the result holds for the standard well-founded semantics.

The first observation is that if the standard well-founded model is two-valued, it is the ultimate well-founded model. It follows that if the standard well-founded model of an iterated inductive definition is two-valued, it is the structure defined by this definition. In general however, an iterated inductive definition as defined here, may not have a two-valued standard well-founded model. An example is $\Delta = \{P \leftarrow P \vee \neg P\}$: it is monotone according to Definition 8 and its defined structure and ultimate well-founded model is $\{P\}$. On the other hand, P is unknown in Δ's standard well-founded model. Thus, the standard well-founded semantics is too weak for this definition.

How serious is the gap? To address this, we make two observations. First, standard and ultimate well-founded semantics break apart only in quite specific circumstances: when there is a *case splitting* involving one or multiple rule bodies leading to a loop over negation (see above example). This is a pattern that we *never* observe in our applications. In practice, standard and ultimate semantics coincide.

The second observation might explain the first one. Although our formal definitions of monotone, ordered and iterated inductive definitions admit rule sets showing such a pattern, the conventions of informal definitions seem to forbid it. Consider, for instance, a variant of the informal definition of satisfaction (Definition 2), that is obtained by replacing its first rule by the following one:

- $I \models P$ if either $I \models P$ and $P \in I$, or if $I \not\models P$ and $P \in I$;

Or after splitting this rule:

- $I \models P$ if $I \models P$ and $P \in I$;
- $I \models P$ if $I \not\models P$ and $P \in I$;

One could argue that these new rules "obviously" are equivalent to the original one by appealing to the fact that "$I \models P$

or $I \not\models P$" is tautologically true. But the modified rules mismatch the induction order and we think such a definition would not be accepted in mathematical text (we would not). This suggests that an implicit convention of informal definitions is not yet explicit in our theory: our definitions are too liberal. We think that some conventions regarding informal definitions remain to be discovered, and that their formalization will preclude rule sets of the above form and lead to a notion of iterated inductive definition that will have a two-valued standard well-founded model. In other words, we think that if one follows the conventions of informal inductive definitions while expressing them as a formal rule set, the standard well-founded model will be two-valued.

In summary, the computationally cheaper standard well-founded semantics, in practice, almost always coincides with the more expensive ultimate semantics. Moreover, in cases where they differ, it is far from obvious that the rule sets correspond to legal inductive definitions, and that the answer provided by the ultimate semantics is better than that of the standard well-founded model.

Conclusion. The paper is relevant from two angles. Informal (inductive) definitions are an important form of human expert knowledge and have many applications in scientific texts as well as in knowledge representation. In this paper we studied the general knowledge representation problem of representing informal definitions. From a very different angle, this paper studies the old but unresolved problem of the *informal semantics* of logic programming.

The first part of the paper was concerned with formalizing familiar but implicit intuitions and conventions of informal definitions. This was done by a series of definitions "from first principles" (Definitions 3-16). The central concept is our formalization of the induction process, the "natural induction". The analysis exposed non-trivial properties of informal definitions: the all-importance of convergence of the induction process, the role of the induction order, its tight link with the rules and ultimately, its irrelevance. To the best of our knowledge, our analysis provides the most detailed semantical account of the studied forms of informal definitions to date. The second part of the paper showed that the well-founded inductions underlying the well-founded semantics provide a natural, efficient and robust generalization of natural inductions. Taken together, this provides, for the first time, a direct argument why rule formalisms under the well-founded semantics correctly formalize informal inductive definitions.

We finish this paper with a speculation. Given that our conscious understanding of inductive definitions is quite partial, where does our proficiency to reason with them come from? Indeed, it is not because someone consciously (and erroneously) believes that the satisfaction relation is the least set closed under the familiar rules, that he or she is not capable to correctly reason about it. Indeed, daily practice provides ample evidence to the contrary. Arguably, this shows a gap between our conscious and subconscious understanding of inductive definitions. However, in contrast to similar gaps, e.g., in the context of reasoning on statistical information (Kahneman 2011), it is here the (slow) conscious understanding that is erroneous, and the (fast) subconscious reasoning that is correct (people do derive that $\{P\} \not\models \neg P$)! The explanation that we see for this phenomenon is that the principle(s) of inductive definition is not a primitive of human cognition, but is just a manifestation of a deeper common sense principle that is hard wired in the cognitive machinery of the human mind. As we have argued in several papers in the past, we believe that this base cognitive principle is that of causal reasoning: the induction process as a causal process that creates the defined object.

The Semantics of Gringo and Infinitary Propositional Formulas

Amelia Harrison and **Vladimir Lifschitz** and **Fangkai Yang**
University of Texas, Austin, Texas, USA

Abstract

Input languages of answer set solvers are based on the mathematically simple concept of a stable model. But many useful constructs available in these languages, including local variables, conditional literals, and aggregates, cannot be easily explained in terms of stable models in the sense of the original definition of this concept and its straightforward generalizations. Manuals written by designers of answer set solvers usually explain such constructs using examples and informal comments that appeal to the user's intuition, without references to any precise semantics. We propose to approach the problem of defining the semantics of GRINGO programs by translating them into the language of infinitary propositional formulas. This semantics allows us to study equivalent transformations of GRINGO programs using natural deduction in infinitary propositional logic, so that the properties of these programs can be more precisely characterized. In this way, we aim to create a foundation on which important issues such as the correctness of GRINGO programs and optimization methods may be more formally studied.

1 Introduction

In this note, Gringo is the name of the input language of the grounder GRINGO,[1] which is used as the front end in many answer set programming (ASP) systems. Several releases of GRINGO have been made public, and more may be coming in the future; accordingly, we can distinguish between several "dialects" of the language Gringo. We concentrate here on Version 4, released in March of 2013. (It differs from Version 3, described in the *User's Guide* dated October 4, 2010,[2] in several ways, including the approach to aggregates—it is modified as proposed by the ASP Standardization Working Group.[3])

The basis of Gringo is the language of logic programs with negation as failure, with the syntax and semantics defined in (Gelfond and Lifschitz 1988). Our goal here is to extend that semantics to a larger subset of Gringo. Specifically, we would like to cover arithmetical functions and comparisons, conditions, and aggregates.[4]

Our proposal is based on the informal and sometimes incomplete description of the language in the *User's Guide*, on the discussion of ASP programming constructs in (Gebser et al. 2012), on experiments with GRINGO, and on the clarifications provided in response to our questions by its designers.

The proposed semantics uses a translation from Gringo into the language of infinitary propositional formulas—propositional formulas with infinitely long conjunctions and disjunctions. Including infinitary formulas is essential, as we will see, when conditions or aggregates use variables ranging over infinite sets (for instance, over integers).

Alternatively, the semantics of Gringo programs can be approached using quantified equilibrium logic (Pearce and Valverde 2004) or its syntactic counterpart defined in (Ferraris, Lee, and Lifschitz 2011). This method involves translating rules into the language of first-order logic. For instance, the rule

$$p(Y) \leftarrow \mathit{count}\{X, Y : q(X, Y)\} \geq 1 \tag{1}$$

can be represented by the sentence

$$\forall y(\exists x Q(x, y) \rightarrow P(y)).$$

However, this approach is not very general. For instance, it is not clear how to represent the rule

$$\begin{array}{l}\mathit{total\_hours}(N) \\ \quad \leftarrow \mathit{sum}\{H, C : \mathit{enroll}(C), \mathit{hours}(H, C)\} = N\end{array} \tag{2}$$

from Section 3.1.10 of the Gringo 3 *User's Guide* with a first-order formula. One reason is that the aggregate *sum* is used here instead of *count*. The second difficulty is that the variable N is used in it rather than a constant.

[3] https://www.mat.unical.it/aspcomp2013/ASPStandardization.

[4] The subset of Gringo discussed in this note includes also constraints, disjunctive rules, and choice rules, treated along the lines of (Gelfond and Lifschitz 1991) and (Ferraris and Lifschitz 2005). The first of these papers introduces also "classical" (or "strong") negation—a useful feature that we do not include. Extending our semantics of Gringo to programs with classical negation is straightforward, using the process of eliminating classical negation in favor of additional atoms described in (Gelfond and Lifschitz 1991, Section 4).

General aggregate expressions allowed in Gringo can be represented by first-order formulas with generalized quantifiers. Stable models of formulas with generalized quantifiers are defined by Lee and Meng (2012a, 2012b, 2012c). The advantage of infinitary propositional formulas as the target language is that we have more mathematical results regarding the properties of these formulas. We may be able to prove, for instance, that two Gringo programs have the same stable models by observing that the corresponding infinitary formulas are equivalent in one of the natural deduction systems discussed in (Harrison, Lifschitz, and Truszczynski 2014). We give here several examples of reasoning about Gringo programs based on this idea.

The process of converting Gringo programs into infinitary propositional formulas defined in this note uses substitutions to eliminate variables. This form of grounding is quite different, of course, from the process of intelligent instantiation implemented in GRINGO and other grounders. Mathematically, it is much simpler than intelligent instantiation; as a computational procedure, it is much less efficient, not to mention the fact that sometimes it produces infinite objects. Like grounding in the original definition of a stable model (Gelfond and Lifschitz 1988), it is modular, in the sense that it applies to the program rule by rule, and it is applicable even if the program is not safe. From this perspective, GRINGO's safety requirement is an implementation restriction.

Our description of the syntax of Gringo disregards some of the features related to representing programs as strings of ASCII characters, such as using `:-` to separate the head from the body, using semicolons, rather than parentheses, to indicate the boundaries of a conditional literal, and representing falsity (which we denote here by $\bot$) as `#false`. Since the subset of Gringo discussed in this note does not include assignments, we can disregard also the requirement that equality be represented by two characters `==`.

The syntax and semantics of the fragment of Gringo studied in this note are defined in Sections 2 and 3. In Sections 4 and 5 we give examples of reasoning about stable models of Gringo programs on the basis of the proposed semantics. The semantics of aggregate expressions, based on (Ferraris 2005), is rather complicated, and in Section 6 we show how it can be simplified in the case of monotone and anti-monotone aggregate expressions. Definitions and theorems regarding stable models of infinitary formulas used in this paper are reproduced in Section 3.1 and in the appendix.

A preliminary report on this project was presented at the 2013 Workshop on Answer Set Programming and Other Computing Paradigms.

2 Syntax

We begin with a signature σ in the sense of first-order logic that includes, among others,

- numerals—object constants representing all integers,
- arithmetical functions—binary function constants $+$, $-$, $\times$,
- comparisons—binary predicate constants $<$, $>$, $\leq$, $\geq$.

We will identify numerals with the corresponding elements of the set $\mathbf{Z}$ of integers. Object, function, and predicate symbols which do not fall into any of the categories listed above will be called *symbolic*. A term over σ is *arithmetical* if it does not contain symbolic object or function constants. A ground term is *precomputed* if it does not contain arithmetical functions.

We assume that in addition to the signature, a set of symbols called *aggregate names* is specified, and that for each aggregate name α, the symbol $\widehat{\alpha}$ represents *the function denoted by* α. This function maps every tuple of precomputed terms to an element of $\mathbf{Z} \cup \{\infty, -\infty\}$.

Examples The functions denoted by the aggregate names *count*, *max*, and *sum* are defined as follows. For any set T of tuples of precomputed terms,

- $\widehat{count}(T)$ is the cardinality of T if T is finite, and ∞ otherwise;
- $\widehat{max}(T)$ is the least upper bound of the set of the integers t_1 over all tuples $(t_1, \dots, t_m)$ from T in which t_1 is an integer;
- $\widehat{sum}(T)$ is the sum of the integers t_1 over all tuples $(t_1, \dots, t_m)$ from T in which t_1 is a positive integer; it is ∞ if there are infinitely many such tuples.[5]

A *literal* is an expression of one of the forms

$$p(t_1, \dots, t_k),\ t_1 = t_2,\ t_1 \neq t_2,\ \mathit{not}\ p(t_1, \dots, t_k)$$

where p is a symbolic predicate constant of arity k, and each t_i is a term over σ, or of the form

$$t_1 \prec t_2$$

where $\prec$ is a comparison, and t_1, t_2 are arithmetical terms. A *conditional literal* is an expression of the form $H : \mathbf{L}$, where H is a literal or the symbol $\bot$, and $\mathbf{L}$ is a list of literals, possibly empty. The members of $\mathbf{L}$ will be called *conditions*. If $\mathbf{L}$ is empty then we will drop the colon after H, so that every literal can be viewed as a conditional literal.

Example If *available* and *person* are unary predicate symbols then

$$\mathit{available}(X) : \mathit{person}(X)$$

and

$$\bot : (\mathit{person}(X), \mathit{not}\ \mathit{available}(X))$$

are conditional literals.

An *aggregate expression* is an expression of the form

$$\alpha\{\mathbf{t}_1 : \mathbf{L}_1; \dots; \mathbf{t}_n : \mathbf{L}_n\} \prec s \tag{3}$$

($n > 0$), where

- α is an aggregate name,
- each $\mathbf{t}_i$ is a non-empty list of terms,
- each $\mathbf{L}_i$ is a non-empty list of literals,

[5] To allow negative numbers in this example, we would have to define summation for a set that contains both infinitely many positive numbers and infinitely many negative numbers. It is unclear how to do this in a natural way.

- $\prec$ is a comparison or one of the symbols $=, \neq$,
- s is an arithmetical term.

Example If *enroll* is a unary predicate symbol and *hours* is a binary predicate symbol then

$$sum\{H, C : enroll(C), hours(H, C)\} = N$$

is an aggregate expression.

A *rule* is an expression of the form

$$H_1 \mid \cdots \mid H_m \leftarrow B_1, \ldots, B_n \tag{4}$$

($m, n \geq 0$), where each H_i is a conditional literal, and each B_j is a conditional literal or an aggregate expression. A *program* is a finite set of rules.

If p is a symbolic predicate constant of arity k, and $\mathbf{t}$ is a k-tuple of terms, then

$$\{p(\mathbf{t})\} \leftarrow B_1, \ldots, B_n$$

is shorthand for

$$p(\mathbf{t}) \mid not\ p(\mathbf{t}) \leftarrow B_1, \ldots, B_n.$$

Example For any positive integer n,

$$\begin{array}{ll} \{p(i)\} & \leftarrow \\ & \leftarrow p(X), p(Y), p(X+Y) \end{array} \qquad (i = 1, \ldots, n), \tag{5}$$

is a program.

3 Semantics

We will define the semantics of Gringo using a syntactic transformation τ. It converts Gringo rules into infinitary propositional combinations of atoms of the form $p(\mathbf{t})$, where p is a symbolic predicate constant, and $\mathbf{t}$ is a tuple of precomputed terms. Then the stable models of a program will be defined as stable models, in the sense of (Truszczynski 2012), of the set consisting of the translations of all rules of the program. Truszczynski's definition of stable models for infinitary propositional formulas is reviewed below.

Prior to defining the translation τ for rules, we will define it for ground literals, conditional literals, and aggregate expressions.

3.1 Review: Stable Models of Infinitary Formulas

Let σ be a propositional signature, that is, a set of propositional atoms. The sets $\mathcal{F}_0^\sigma, \mathcal{F}_1^\sigma, \ldots$ are defined as follows:

- $\mathcal{F}_0^\sigma = \sigma$,
- $\mathcal{F}_{i+1}^\sigma$ is obtained from $\mathcal{F}_i^\sigma$ by adding expressions $\mathcal{H}^\wedge$ and $\mathcal{H}^\vee$ for all subsets $\mathcal{H}$ of $\mathcal{F}_i^\sigma$, and expressions $F \to G$ for all $F, G \in \mathcal{F}_i^\sigma$.

The elements of $\bigcup_{i=0}^\infty \mathcal{F}_i^\sigma$ are called *(infinitary) formulas* over σ.

A set $\mathcal{H}$ of formulas is *bounded* if it is contained in one of the sets $\mathcal{F}_i^\sigma$. For a bounded set $\mathcal{H}$ of formulas, $\mathcal{H}^\wedge$ and $\mathcal{H}^\vee$ are infinitary formulas.

The symbols $\top$ and $\bot$ will be understood as abbreviations for $\emptyset^\wedge$ and $\emptyset^\vee$ respectively; $\neg F$ stands for $F \to \bot$, and $F \leftrightarrow G$ stands for $(F \to G) \wedge (G \to F)$.

We will write $\{F, G\}^\wedge$ as $F \wedge G$, and $\{F, G\}^\vee$ as $F \vee G$. This convention allows us to view finite propositional formulas over σ as a special case of infinitary formulas. For any bounded family $\{F_\alpha\}_{\alpha \in A}$ of formulas, we denote the formula $\{F_\alpha : \alpha \in A\}^\wedge$ by $\bigwedge_{\alpha \in A} F_\alpha$, and similarly for disjunctions.

Subsets of a signature σ will be also called its *interpretations*. The satisfaction relation between an interpretation and a formula is defined in a natural way.

The *reduct* F^I of a formula F w.r.t. an interpretation I is defined as follows:

- For $p \in \sigma$, $p^I = \bot$ if $I \not\models p$; otherwise $p^I = p$.
- $(\mathcal{H}^\wedge)^I = \{G^I \mid G \in \mathcal{H}\}^\wedge$.
- $(\mathcal{H}^\vee)^I = \{G^I \mid G \in \mathcal{H}\}^\vee$.
- $(G \to H)^I = \bot$ if $I \not\models G \to H$; otherwise $(G \to H)^I = G^I \to H^I$.

An interpretation I is a *stable model* of a set $\mathcal{H}$ of formulas if it is minimal w.r.t. set inclusion among the interpretations satisfying the reducts of all formulas from $\mathcal{H}$.

3.2 Semantics of Well-Formed Ground Literals

A term t is *well-formed* if it contains neither symbolic object constants nor symbolic function constants in the scope of arithmetical functions. For instance, all arithmetical terms and all precomputed terms are well-formed; $c{+}2$ is not well-formed. The definition of "well-formed" for literals, aggregate expressions, and so forth is the same.

For every well-formed ground term t, by $[t]$ we denote the precomputed term obtained from t by evaluating all arithmetical functions, and similarly for tuples of terms. For instance, $[f(2{+}2)]$ is $f(4)$.

The translation τL of a well-formed ground literal L is defined as follows:

- $\tau(p(\mathbf{t}))$ is $p([\mathbf{t}])$;
- $\tau(t_1 \prec t_2)$, where $\prec$ is $=$, $\neq$, or a comparison is $\top$ if the relation $\prec$ holds between $[t_1]$ and $[t_2]$, and $\bot$ otherwise;
- $\tau(not\ A)$ is $\neg \tau A$.

For instance, $\tau(not\ \ p(f(2\ +\ 2)))$ is $\neg p(f(4))$, and $\tau(2{+}2{=}\,4)$ is $\top$.

Furthermore, $\tau\bot$ stands for $\bot$, and, for any list $\mathbf{L}$ of ground literals, $\tau\mathbf{L}$ is the conjunction of the formulas τL for all members L of $\mathbf{L}$.

3.3 Global Variables

About a variable we say that it is *global*

- in a conditional literal $H : \mathbf{L}$, if it occurs in H but does not occur in $\mathbf{L}$;
- in an aggregate expression (3), if it occurs in the term s;
- in a rule (4), if it is global in at least one of the expressions H_i, B_j.

For instance, the head of the rule (2) is a literal with the global variable N, and its body is an aggregate expression with the global variable N. Consequently N is global in the rule as well.

A conditional literal, an aggregate expression, or a rule is *closed* if it has no global variables. An *instance* of a rule R is any well-formed closed rule that can be obtained from R by substituting precomputed terms for global variables. For instance,

$$\begin{array}{l} \mathit{total\_hours}(6) \leftarrow \\ \quad \mathit{sum}\{H, C : \mathit{enroll}(C), \mathit{hours}(H, C)\} = 6 \end{array}$$

is an instance of rule (2). It is clear that if a rule is not well-formed then it has no instances.

3.4 Semantics of Closed Conditional Literals

If t is a term, $\mathbf{x}$ is a tuple of distinct variables, and $\mathbf{r}$ is a tuple of terms of the same length as $\mathbf{x}$, then the term obtained from t by substituting $\mathbf{r}$ for $\mathbf{x}$ will be denoted by $t^{\mathbf{x}}_{\mathbf{r}}$. Similar notation will be used for the result of substituting $\mathbf{r}$ for $\mathbf{x}$ in expressions of other kinds, such as literals and lists of literals.

The result of applying τ to a closed conditional literal $H : \mathbf{L}$ is the conjunction of the formulas

$$\tau(\mathbf{L}^{\mathbf{x}}_{\mathbf{r}}) \rightarrow \tau(H^{\mathbf{x}}_{\mathbf{r}})$$

where $\mathbf{x}$ is the list of variables occurring in $H : \mathbf{L}$, over all tuples $\mathbf{r}$ of precomputed terms of the same length as $\mathbf{x}$ such that both $\mathbf{L}^{\mathbf{x}}_{\mathbf{r}}$ and $H^{\mathbf{x}}_{\mathbf{r}}$ are well-formed. For instance,

$$\tau(\mathit{available}(X) : \mathit{person}(X))$$

is the conjunction of the formulas

$$\mathit{person}(r) \rightarrow \mathit{available}(r)$$

over all precomputed terms r;

$$\tau(\bot : p(2 \times X))$$

is the conjunction of the formulas $\neg p(2 \times i)$ over all numerals i.

When a conditional literal occurs in the head of a rule, it is translated in a different way.[6] By $\tau_h(H : \mathbf{L})$ we denote the disjunction of the formulas

$$(\tau(\mathbf{L}^{\mathbf{x}}_{\mathbf{r}}) \rightarrow \tau(H^{\mathbf{x}}_{\mathbf{r}})) \wedge \neg\neg(\mathbf{L}^{\mathbf{x}}_{\mathbf{r}})$$

where $\mathbf{x}$ and $\mathbf{r}$ are as above. For instance,

$$\tau_h(\mathit{available}(X) : \mathit{person}(X))$$

is the disjunction of the formulas

$$(\mathit{person}(r) \rightarrow \mathit{available}(r)) \wedge \neg\neg \mathit{person}(r)$$

over all precomputed terms r.

3.5 Semantics of Closed Aggregate Expressions

In this section, the semantics of ground aggregates proposed in (Ferraris 2005, Section 4.1) is adapted to closed aggregate expressions. Let E be a closed aggregate expression (3), and let $\mathbf{x}_i$ be the list of variables occurring in $\mathbf{t}_i : \mathbf{L}_i$ $(1 \leq i \leq n)$. By A_i we denote the set of tuples $\mathbf{r}$ of precomputed terms of the same length as $\mathbf{x}_i$ such that both $(\mathbf{t}_i)^{\mathbf{x}_i}_{\mathbf{r}}$ and $(\mathbf{L}_i)^{\mathbf{x}_i}_{\mathbf{r}}$ are well-formed. By A we denote the set $\{(i, \mathbf{r}) : i \in \{1, \ldots, n\}, \mathbf{r} \in A_i\}$.

About a subset Δ of A we say that it *justifies* E if the relation $\prec$ holds between $\widehat{\alpha}(\{[(\mathbf{t}_i)^{\mathbf{x}_i}_{\mathbf{r}}] : (i, \mathbf{r}) \in \Delta\})$ and $[s]$. We define τE as the conjunction of the implications

$$\bigwedge_{(i,\mathbf{r}) \in \Delta} \tau((\mathbf{L}_i)^{\mathbf{x}_i}_{\mathbf{r}}) \rightarrow \bigvee_{(i,\mathbf{r}) \in A \setminus \Delta} \tau((\mathbf{L}_i)^{\mathbf{x}_i}_{\mathbf{r}}) \qquad (6)$$

over all sets Δ that do not justify E.

Example Consider the aggregate expression

$$\mathit{count}\{X : p(X);\ N : q(2 \times N)\} > 0. \qquad (7)$$

In this case, A_1 is the set of all precomputed terms, and A_2 is the set of all numerals. Therefore, A is the set of all pairs whose first member is either 1 or 2 and whose second member is a precomputed term when the first member is 1 and is a numeral when the first member is 2. A subset Δ of A justifies (7) iff

$$\widehat{\mathit{count}}\left(\left\{X^X_{\mathbf{r}} : (1, \mathbf{r}) \in \Delta\right\} \cup \left\{N^N_{\mathbf{r}} : (2, \mathbf{r}) \in \Delta\right\}\right) > 0.$$

Since

$$\{X^X_{\mathbf{r}} : (1, \mathbf{r}) \in \Delta\} = \{\mathbf{r} : (1, \mathbf{r}) \in \Delta\}$$

and

$$\{N^N_{\mathbf{r}} : (2, \mathbf{r}) \in \Delta\} = \{\mathbf{r} : (2, \mathbf{r}) \in \Delta\}$$

we conclude that the set Δ justifies (7) iff

$$\widehat{\mathit{count}}(\Delta) > 0,$$

that is, iff the set Δ is non-empty. Since the only $\Delta \subseteq A$ that does not justify (7) is $\emptyset$, the result of applying τ to (7) has only one conjunctive term of the form (6). Its antecedent is the trivial empty conjunction; its consequent is

$$\bigvee_{x \in A_1} p(x) \vee \bigvee_{n \in A_2} q(2n).$$

If E is an aggregate expression of the form

$$\alpha\{\mathbf{t}_1 : \mathbf{L}_1; \ldots; \mathbf{t}_n : \mathbf{L}_n\} = s,$$

$E_{\leq}$ is

$$\alpha\{\mathbf{t}_1 : \mathbf{L}_1; \ldots; \mathbf{t}_n : \mathbf{L}_n\} \leq s,$$

and $E_{\geq}$ is

$$\alpha\{\mathbf{t}_1 : \mathbf{L}_1; \ldots; \mathbf{t}_n : \mathbf{L}_n\} \geq s,$$

then $\tau(E)$ has the same conjunctive terms as

$$\tau(E_{\leq}) \wedge \tau(E_{\geq}).$$

In this sense, E has the same meaning of the conjunction of $E_{\leq}$ and $E_{\geq}$.

In the special case when E has the form $\alpha\{\mathbf{t} : \mathbf{L}\} \prec s$, the definition of τE can be stated as follows. Let $\mathbf{x}$ be the list of variables occurring in $\mathbf{t} : \mathbf{L}$, and let A be the set of tuples $\mathbf{r}$ of precomputed terms of the same length as $\mathbf{x}$ such that both $\mathbf{t}^{\mathbf{x}}_{\mathbf{r}}$ and $\mathbf{L}^{\mathbf{x}}_{\mathbf{r}}$ are well-formed. A subset Δ of A *justifies* E if the relation $\prec$ holds between $\widehat{\alpha}(\{[\mathbf{t}^{\mathbf{x}}_{\mathbf{r}}] : \mathbf{r} \in \Delta\})$ and $[s]$. We define τE as the conjunction of the implications

$$\bigwedge_{\mathbf{r} \in \Delta} \tau(\mathbf{L}^{\mathbf{x}}_{\mathbf{r}}) \rightarrow \bigvee_{\mathbf{r} \in A \setminus \Delta} \tau(\mathbf{L}^{\mathbf{x}}_{\mathbf{r}})$$

[6] Torsten Schaub, Martin Gebser, and Roland Kaminski, personal communication, October 2013.

over all subsets Δ of A that do not justify E.

Examples Consider the aggregate expression

$$\mathit{sum}\{H, C : \mathit{enroll}(C), \mathit{hours}(H, C)\} = 6. \tag{8}$$

In this case, A is the set of pairs (h, c) of precomputed terms. The subset $\{(3, \mathit{cs101}), (3, \mathit{cs102})\}$ of A justifies (8), because

$$\begin{aligned}\widehat{\mathit{sum}}\left(\left\{(H,C)^{H,C}_{3,\mathit{cs101}}, (H,C)^{H,C}_{3,\mathit{cs102}}\right\}\right) &= \\ \widehat{\mathit{sum}}(\{(3, \mathit{cs101}), (3, \mathit{cs102})\}) &= 3 + 3 = 6.\end{aligned}$$

More generally, a set of pairs of precomputed terms justifies (8) whenever it contains finitely many pairs (h, c) in which h is a positive integer, and the sum of the integers h over all these pairs is 6. The conjunctive terms of τE are the formulas

$$\begin{aligned}\bigwedge_{(h,c)\in\Delta} (\mathit{enroll}(c) \wedge \mathit{hours}(h, c)) \rightarrow \\ \bigvee_{(h,c)\notin\Delta} (\mathit{enroll}(c) \wedge \mathit{hours}(h, c)).\end{aligned} \tag{9}$$

The conjunctive term corresponding to $\{(3, \mathit{cs101})\}$ as Δ says: if I am enrolled in CS101 for 3 hours then I am enrolled in at least one other course. In Section 6.1 we will see how the result of applying τ to (8) can be simplified.

As a final example illustrating the semantics of aggregate expressions, consider a pair of closed aggregate expressions of the form

$$\mathit{sum}\{1, X : \mathbf{L}\} \prec s \quad \text{and} \quad \mathit{count}\{X : \mathbf{L}\} \prec s, \tag{10}$$

where the tuple $\mathbf{L}$ of literals contains no variables other than X. Intuitively, these expressions have the same meaning; accordingly, the translation τ transforms them to identical formulas. Note first that the result of applying τ to each of them is the conjunction of implications of the form

$$\bigwedge_{r\in\Delta} \tau(\mathbf{L}^X_r) \rightarrow \bigvee_{r\in A\setminus\Delta} \tau(\mathbf{L}^X_r).$$

To check that both conjunctions extend over the same set Δ of precomputed terms, observe that

$$\widehat{\mathit{sum}}(\{(1, X)^X_r : r \in \Delta\}) = \widehat{\mathit{sum}}(\{(1, r) : r \in \Delta\})$$

and

$$\begin{aligned}\widehat{\mathit{count}}(\{X^X_r : r \in \Delta\}) &= \widehat{\mathit{count}}(\{r : r \in \Delta\}) \\ &= \widehat{\mathit{count}}(\Delta),\end{aligned}$$

so that both expressions evaluate to the cardinality of Δ.

3.6 Semantics of Rules and Programs

For any rule R, τR stands for the conjunction of the formulas

$$\tau B_1 \wedge \cdots \wedge \tau B_n \rightarrow \tau_h H_1 \vee \cdots \vee \tau_h H_m$$

for all instances (4) of R. A *stable model* of a program Π is a stable model, in the sense of (Truszczynski 2012), of the set consisting of the formulas τR for all rules R of Π.

Example Consider the rules of program (5). If R is the rule $\{p(i)\}$ then τR is

$$p(i) \vee \neg p(i) \tag{11}$$

$(i = 1, \ldots, n)$. If R is the rule

$$\leftarrow p(X), p(Y), p(X+Y)$$

then the instances of R are rules of the form

$$\leftarrow p(i), p(j), p(i+j)$$

for all numerals i, j. (Substituting precomputed ground terms other than numerals would produce a rule that is not well-formed.) Consequently τR is in this case the infinite conjunction

$$\bigwedge_{\substack{i,j,k\in\mathbf{Z}\\ i+j=k}} \neg(p(i) \wedge p(j) \wedge p(k)). \tag{12}$$

The stable models of program (5) are the stable models of formulas (11), (12), that is, sets of the form $\{p(i) : i \in S\}$ for all sum-free subsets S of $\{1, \ldots, n\}$.

4 Reasoning about Gringo Programs

As an example, we will show how we can reason about the stable models of the program Π consisting of rule (2) and an arbitrary finite set S of atoms of the forms $\mathit{hours}(h, c)$ and $\mathit{enroll}(c)$, where h is a positive integer and c is an object constant.

Let h^* be the sum of the numbers h over all pairs (h, c) such that both $\mathit{hours}(h, c)$ and $\mathit{enroll}(c)$ are in S. As could be expected, the set

$$S \cup \{\mathit{total\_hours}(h^*)\} \tag{13}$$

is the only stable model of Π.

To justify this claim, consider the result of applying τ to Π. This set of formulas consists of the atoms S and the implications

$$\begin{aligned}\tau(\mathit{sum}\{H, C : \mathit{enroll}(C), \mathit{hours}(H, C)\} = i) \\ \rightarrow \mathit{total\_hours}(i)\end{aligned} \tag{14}$$

for all numerals i. The conjunction of the formulas in $\tau\Pi$ is a supertight infinitary program (see Appendix A.1). Consequently, it is sufficient to show that (13) is the only supported model of $\tau\Pi$, which can be derived from the following fact:

Lemma *Let I be an interpretation such that S is the set of all atoms of the forms hours(h,c) and enroll(c) that are satisfied by I. For any numeral i, I satisfies the antecedent of (14) if and only if $i = h^*$.*

5 Equivalent Transformations of Gringo Programs

In this section we give examples of reasoning about Gringo programs on the basis of the semantics defined above. These examples use the theorem from (Harrison, Lifschitz, and Truszczynski 2014) reproduced in the appendix.

5.1 Simplifying a Rule from Example 3.7 of User's Guide

Consider the rule[7]

$$\mathit{weekdays} \leftarrow \mathit{day}(X) : (\mathit{day}(X), \mathit{not\ weekend}(X)). \quad (15)$$

Replacing this rule with the fact *weekdays* within any program will not affect the set of stable models. Indeed, the result of applying translation τ to (15) is the formula

$$\bigwedge_r (\mathit{day}(r) \wedge \neg \mathit{weekend}(r) \rightarrow \mathit{day}(r)) \rightarrow \mathit{weekdays}, \quad (16)$$

where the conjunction extends over all precomputed terms r. The formula

$$\mathit{day}(r) \wedge \neg \mathit{weekend}(r) \rightarrow \mathit{day}(r)$$

is intuitionistically provable. By the theorem from Section A.2, it follows that replacing (16) with the atom *weekdays* within any set of formulas does not affect the set of stable models.

5.2 Simplifying the Sorting Rule

The rule

$$\begin{aligned} \mathit{order}(X,Y) \leftarrow\ & p(X),\ p(Y),\ X<Y, \\ & \mathit{not}\ p(Z) : (p(Z), X<Z, Z<Y) \end{aligned} \quad (17)$$

can be used for sorting.[8] It can be replaced by either of the following two shorter rules within any program without changing that program's stable models.

$$\begin{aligned} \mathit{order}(X,Y) \leftarrow\ & p(X),\ p(Y),\ X<Y, \\ & \bot : (p(Z), X<Z, Z<Y) \end{aligned} \quad (18)$$

$$\begin{aligned} \mathit{order}(X,Y) \leftarrow\ & p(X),\ p(Y),\ X<Y, \\ & \mathit{not}\ p(Z) : (X<Z, Z<Y) \end{aligned} \quad (19)$$

Let's prove this claim for rule (18). By the theorem from Section A.2, it is sufficient to show that the result of applying τ to (17) is equivalent in the extended system to the result of applying τ to (18). The instances of (17) are the rules

$$\begin{aligned} \mathit{order}(i,j) \leftarrow\ & p(i),\ p(j),\ i<j, \\ & \mathit{not}\ p(Z) : (p(Z), i<Z, Z<j), \end{aligned}$$

and the instances of (18) are the rules

$$\begin{aligned} \mathit{order}(i,j) \leftarrow\ & p(i),\ p(j),\ i<j, \\ & \bot : (p(Z), i<Z, Z<j) \end{aligned}$$

where i and j are arbitrary numerals. The result of applying τ to (17) is the conjunction of the formulas

$$\begin{aligned} & p(i) \wedge p(j) \wedge \tau(i<j) \wedge \\ & \bigwedge_k (\neg p(k) \wedge \tau(i<k) \wedge \tau(k<j) \rightarrow p(k)) \rightarrow \\ & \qquad \mathit{order}(i,j) \end{aligned} \quad (20)$$

for all numerals $i,\ j$. The result of applying τ to (18) is the conjunction of the formulas

$$\begin{aligned} & p(i) \wedge p(j) \wedge \tau(i<j) \wedge \\ & \bigwedge_k (\neg p(k) \wedge \tau(i<k) \wedge \tau(k<j) \rightarrow \bot) \rightarrow \\ & \qquad \mathit{order}(i,j). \end{aligned} \quad (21)$$

[7] This rule is similar to a rule from Example 3.7 of the Gringo 3 *User's Guide* (see Footnote 2).

[8] This rule was communicated to us by Roland Kaminski on October 21, 2012.

It remains to observe that for any numerals i, j, k,

$$p(k) \wedge \tau(i<k) \wedge \tau(k<j) \rightarrow \neg p(k)$$

is intuitionistically equivalent to

$$p(k) \wedge \tau(i<k) \wedge \tau(k<j) \rightarrow \bot.$$

The proof for rule (19) is similar. Rule (18), like rule (17), is safe; rule (19) is not.

5.3 Eliminating Choice in Favor of a Conditional Literal

Replacing the rule

$$\{p(X)\} \leftarrow q(X) \quad (22)$$

with

$$p(X) \leftarrow q(X), \bot : \mathit{not}\ p(X) \quad (23)$$

within any program will not affect the set of stable models. Indeed, the result of applying translation τ to (22) is

$$\bigwedge_r (q(r) \rightarrow p(r) \vee \neg p(r)) \quad (24)$$

where the conjunction extends over all precomputed terms r, and the result of applying τ to (23) is

$$\bigwedge_r (q(r) \wedge \neg\neg p(r) \rightarrow p(r)). \quad (25)$$

Each conjunctive term of (24) is equivalent to the corresponding conjunctive term of (25) in the extension of intuitionistic logic obtained by adding the axiom schema

$$\neg F \vee \neg\neg F,$$

and consequently in the extended system presented in the appendix. It follows that (24) is equivalent to (25) in the extended system as well.

5.4 Eliminating a Trivial Aggregate Expression

Rule (1) says, informally speaking, that we can conclude $p(Y)$ once we establish that there exists at least one X such that $q(X,Y)$. Replacing this rule with

$$p(Y) \leftarrow q(X,Y) \quad (26)$$

within any program will not affect the set of stable models.

To prove this claim, we need to calculate the result of applying τ to rule (1). The instances of (1) are the rules

$$p(t) \leftarrow \mathit{count}\{X, t : q(X,t)\} \geq 1 \quad (27)$$

for all precomputed terms t. Consider the aggregate expression E in the body of (27). Any precomputed term r is admissible w.r.t. E. A set Δ of precomputed terms justifies E if

$$\widehat{\mathit{count}}(\{(r,t) : r \in \Delta\}) \geq 1,$$

that is to say, if Δ is non-empty. Consequently τE consists of only one implication (6), with the empty Δ. The antecedent of this implication is the empty conjunction $\top$,

and its consequent is the disjunction $\bigvee_u q(u,t)$ over all precomputed terms u. Then the result of applying τ to (1) is

$$\bigwedge_t \left(\bigvee_u q(u,t) \ \rightarrow \ p(t) \right). \tag{28}$$

On the other hand, the result of applying τ to (26) is

$$\bigwedge_{t,u} (q(u,t) \rightarrow p(t)).$$

This formula is equivalent to (28) in the extended system defined in the appendix (see Example 2 from (Harrison, Lifschitz, and Truszczynski 2014)).

6 Monotone and Anti-Monotone Aggregate Expressions

A closed aggregate expression E is *monotone* if for any set Δ that justifies E, all supersets of Δ also justify E. Similarly, E is *anti-monotone* if for any set Δ that justifies E, all subsets of Δ also justify E.

For example, if α is one of the symbols *count*, *max*, or *sum*, then (3) is monotone when $\prec$ is $>$ or $\geq$, and anti-monotone when $\prec$ is $<$ or $\leq$. (According to the definition for $\widehat{sum}$ given in this paper negative summands are disregarded.) As observed in Section 3.5, if $\prec$ is $=$ then E can be equivalently replaced by the pair of aggregate expressions $E_{\leq}, E_{\geq}$, which are anti-monotone and monotone respectively when α is one of the symbols listed above.

6.1 Simplifying Monotone and Anti-Monotone Aggregate Expressions

Recall that τE for a closed aggregate expression E is defined as the conjunction of the implications (6) over all sets Δ that do not justify E. The two theorems stated below show that the antecedent in (6) can be dropped if E is monotone, and the consequent can be dropped if E is anti-monotone. These equivalences can be proved in the extended system described in the appendix. The theorems are similar to the properties of monotone and anti-monotone ground aggregates stated in (Ferraris 2005).

Theorem 1 *If a closed aggregate expression E is monotone, then τE is equivalent in the extended system to*

$$\bigwedge_{\Delta} \bigvee_{(i,\mathbf{r}) \in A \setminus \Delta} \tau((\mathbf{L}_i)^{\mathbf{x}_i}_{\mathbf{r}}), \tag{29}$$

where the conjunction extends over the subsets Δ of A that do not justify E.

Theorem 2 *If a closed aggregate expression E is anti-monotone, then τE is equivalent in the extended system to*

$$\bigwedge_{\Delta} \neg \bigwedge_{(i,\mathbf{r}) \in \Delta} \tau((\mathbf{L}_i)^{\mathbf{x}_i}_{\mathbf{r}}), \tag{30}$$

where the conjunction extends over all subsets Δ of A that do not justify E.

Example We saw in Section 3.5 that the result of applying τ to (8) is the conjunction of formulas (9) over all sets Δ of pairs (h,c) of precomputed terms that do not justify (8). Theorems 1 and 2 allow us to simplify this conjunction. Note first that the result of applying τ to (8) can be rewritten as the conjunction of

$$\tau(sum\{H, C : enroll(C), hours(H,C)\} \leq 6) \tag{31}$$

and

$$\tau(sum\{H, C : enroll(C), hours(H,C)\} \geq 6). \tag{32}$$

By Theorem 1, (32) is equivalent to

$$\bigwedge_{\widehat{sum}(\Delta) < 6} \ \bigvee_{(h,c) \notin \Delta} (enroll(c) \wedge hours(h,c)),$$

and by Theorem 2, (31) is equivalent to

$$\bigwedge_{\widehat{sum}(\Delta) > 6} \ \neg \bigwedge_{(h,c) \in \Delta} (enroll(c) \wedge hours(h,c)),$$

where Δ ranges over pairs (h,c) of precomputed terms.

In Section 6.2 we show how Theorem 2 can be used for simplifying and aggregate expression. Proofs of Theorems 1 and 2 are given in Section 6.3.

6.2 Eliminating an Aggregate Expression in Favor of a Conditional Literal

We will show that the rule

$$q \leftarrow count\{X : p(X)\} < 1 \tag{33}$$

can be replaced by the rule

$$q \leftarrow \bot : p(X) \tag{34}$$

within any program without changing its stable models. The bodies of both rules express that the set p is empty, but the first uses an aggregate expression and the second a conditional literal.

Since the aggregate expression in the body of (33) is anti-monotone, by Theorem 2, the result of applying τ to it is equivalent (in the extended system) to

$$\bigwedge_{\Delta \neq \emptyset} \neg \bigwedge_{a \in \Delta} p(a) \tag{35}$$

where Δ ranges over arbitrary sets of precomputed terms.

On the other hand, the result of applying τ to the body of (34) is

$$\bigwedge_{a} \neg p(a) \tag{36}$$

where a ranges over all precomputed terms.

It remains to observe that all conjunctive terms of (35) can be derived in the extended system from the conjunctive terms in which Δ is a singleton, and that the conjunctive terms in which Δ is a singleton are identical to the conjunctive terms of (36).

6.3 Proofs of Theorems 1 and 2

Proof of Theorem 1 The implication from (29) to τE is obvious. Now, assume τE, and consider the conjunctive term of (29) corresponding to a set Δ_0 which does not justify E. Since E is monotone, from τE we can derive the conjunction of all terms (6) where $\Delta \subseteq \Delta_0$. Any formula of the form

$$\left(F \to \bigvee_{i \in I} G_i\right) \to \left(\bigvee_{i \in I} (F \to G_i)\right)$$

is provable in the extended system defined in the appendix (see Section 7 of (Harrison, Lifschitz, and Truszczynski 2014)). Consequently, we can derive the conjunction of the disjunctions

$$\bigvee_{(i,\mathbf{r}) \in A \setminus \Delta} \left(\left(\bigwedge_{(j,\mathbf{s}) \in \Delta} \tau((\mathbf{L}_j)_{\mathbf{s}}^{\mathbf{x}_j})\right) \to \tau((\mathbf{L}_i)_{\mathbf{r}}^{\mathbf{x}_i})\right)$$

over all $\Delta \subseteq \Delta_0$. By distributivity, this is equivalent in the extended system to the disjunction of the conjunctions

$$\bigwedge_{\Delta \subseteq \Delta_0} \left(\bigwedge_{(j,\mathbf{s}) \in \Delta} \tau((\mathbf{L}_j)_{\mathbf{s}}^{\mathbf{x}_j}) \to \tau\left((\mathbf{L}_{f(\Delta)})_{g(\Delta)}^{\mathbf{x}_{f(\Delta)}}\right)\right) \quad (37)$$

over all pairs of functions (f, g) defined on all subsets Δ of Δ_0 such that the pair $(f(\Delta), g(\Delta))$ is an element of $A \setminus \Delta$. Now we reason by cases, with one case corresponding to each disjunctive term (37). For a particular disjunctive term (37), we wish to show that we can derive from it $\tau((\mathbf{L}_i)_{\mathbf{r}}^{\mathbf{x}_i})$ for some pair $(i, \mathbf{r})$ in $A \setminus \Delta_0$. Consider the set Δ^* of all pairs $(i, \mathbf{r})$ such that $\tau((\mathbf{L}_i)_{\mathbf{r}}^{\mathbf{x}_i})$ is derivable from (37) in the extended system. We will show that Δ^* is not a subset of Δ_0. Assume $\Delta^* \subseteq \Delta_0$, so that

$$(f(\Delta^*), g(\Delta^*)) \in A \setminus \Delta^*, \quad (38)$$

and one of the conjunctive terms of (37) is

$$\bigwedge_{(j,\mathbf{s}) \in \Delta^*} \tau((\mathbf{L}_j)_{\mathbf{s}}^{\mathbf{x}_j}) \to \tau\left((\mathbf{L}_{f_{\Delta^*}})_{g(\Delta^*)}^{\mathbf{x}_{f(\Delta^*)}}\right).$$

By the definition of Δ^*, every conjunctive term in the antecedent of this implication is derivable from (37). It follows that the consequent is derivable as well, so that $(f(\Delta^*), g(\Delta^*))$ belongs to Δ^*, which contradicts (38). Therefore, Δ^* is not a subset of Δ_0, so that at least one disjunctive term of (29) is derivable from (37).

Proof of Theorem 2 The implication from (30) to τE is obvious. We will derive (30) from τE using the disjunction

$$\bigvee_{\Delta \subseteq A} \left(\neg \bigvee_{(i,\mathbf{r}) \in A \setminus \Delta} \tau((\mathbf{L}_i)_{\mathbf{r}}^{\mathbf{x}_i}) \wedge \neg\neg \bigwedge_{(i,\mathbf{r}) \in \Delta} \tau((\mathbf{L}_i)_{\mathbf{r}}^{\mathbf{x}_i})\right). \quad (39)$$

This is a special case of the generalized law of weak excluded middle given in Section 7 of (Harrison, Lifschitz, and Truszczynski 2014). Each disjunctive term (39) corresponds to a subset Δ of A. We will reason by cases with one case corresponding to each disjunctive term D_Δ of (39). Each D_Δ is equivalent to

$$\neg\left(\bigwedge_{(i,\mathbf{r}) \in \Delta} \tau((\mathbf{L}_i)_{\mathbf{r}}^{\mathbf{x}_i}) \to \bigvee_{(i,\mathbf{r}) \in A \setminus \Delta} \tau((\mathbf{L}_i)_{\mathbf{r}}^{\mathbf{x}_i})\right) \quad (40)$$

in the extended system described in the appendix. If Δ does not justify E then (40) contradicts one of the conjunctive terms from (6) and (30) follows. Consider now the case when Δ justifies E. Assume

$$\bigwedge_{(i,\mathbf{r}) \in \Delta_0} \tau((\mathbf{L}_i)_{\mathbf{r}}^{\mathbf{x}_i}) \quad (41)$$

for some Δ_0 that does not justify E. Since E is anti-monotone Δ_0 is not a subset of Δ. We conclude that Δ_0 and $A \setminus \Delta$ overlap on at least one element. It follows that

$$\bigvee_{(i,\mathbf{r}) \in A \setminus \Delta} \tau((\mathbf{L}_i)_{\mathbf{r}}^{\mathbf{x}_i})$$

can be derived from (41) since at least one of its disjunctive terms can be derived. This disjunction contradicts (40), and so we may conclude the negation of (41).

7 Conclusion

In this note, we approached the problem of defining the semantics of Gringo by reducing Gringo programs to infinitary propositional formulas. We argued that this approach to semantics may allow us to study equivalent transformations of programs using natural deduction in infinitary propositional logic.

In the absence of a precise semantics, it is impossible to put the study of some important issues on a firm foundation. This includes the correctness of ASP programs, grounders, solvers, and optimization methods, and also the relationship between input languages of different solvers (for instance, the equivalence of the semantics of aggregate expressions in Gringo to their semantics in the ASP Core language and in the language proposed in (Gelfond 2002) under the assumption that aggregates are used nonrecursively). As future work, we are interested in addressing some of these tasks on the basis of the semantics proposed in this note. Proving the correctness of the intelligent instantiation algorithms implemented in GRINGO will provide justification for our informal claim that for a safe program, the semantics proposed here correctly describes the output produced by GRINGO.

Acknowledgements

Many thanks to Roland Kaminski and Torsten Schaub for helping us understand the input language of GRINGO. Roland, Michael Gelfond, Yuliya Lierler, Joohyung Lee, and anonymous referees provided valuable comments on drafts of this note.

Appendix

We review here conditions for characterizing the stable models of a set of infinitary formulas in terms of supportedness

(Lifschitz and Yang 2013), and transformations of infinitary formulas which preserve their stable models (Harrison, Lifschitz, and Truszczynski 2014).

A.1 Tight Infinitary Programs

An *infinitary program* is a conjunction of (possibly infinitely many) infinitary formulas of the form $G \to A$, where A is an atom. We say that an infinitary program Π is *supertight* if it is impossible to find an infinite sequence of atoms $A_1, A_2, \dots$ such that for all i, Π contains a conjunctive term $G \to A_i$, where A_{i+1} occurs in G. We say that an interpretation I is *supported* by Π if each atom $A \in I$ is the consequent of a conjunctive term $G \to A$ of Π such that $I \models G$.

Theorem *For any model I of a supertight infinitary program Π, I is stable iff I is suported by Π.*

This theorem is a special case of Lemma 2 from (Lifschitz and Yang 2013). In the statement of that lemma Π is required to be "tight on I." That condition is significantly more general than supertightness as defined above.

A.2 Equivalent Transformations of Infinitary Formulas

The extended system of natural deduction presented in (Harrison, Lifschitz, and Truszczynski 2014) includes the axiom schema

$$F \Rightarrow F,$$

the axiom schema

$$\Rightarrow F \vee (F \to G) \vee \neg G$$

that characterizes (in the finite case) the logic of here-and-there (Hosoi 1966), and the following additional axiom schemas:

$$\Rightarrow \neg \bigwedge_{F \in \mathcal{H}} F \to \bigvee_{F \in \mathcal{H}} \neg F, \tag{42}$$

$$\Rightarrow \left(\bigwedge_{i \in I} \bigvee_{F \in \mathcal{H}_i} F \right) \to \left(\bigvee_{\{F_i\}_{i \in I}} \bigwedge_{i \in I} F_i \right), \tag{43}$$

and

$$\Rightarrow \left(\bigwedge_{\{F_i\}_{i \in I}} \bigvee_{i \in I} F_i \right) \to \left(\bigvee_{i \in I} \bigwedge_{F \in \mathcal{H}_i} F \right). \tag{44}$$

In formula (42) $\mathcal{H}$ is a bounded set of formulas. In formulas (43) and (44) $\{\mathcal{H}_i\}_{i \in I}$ is an arbitrary non-empty family of sets of formulas such that its union is bounded. The disjunction in the consequent of (43) and the conjunction in the antecedent of (44) extend over all elements $\{F_i\}_{i \in I}$ of the Cartesian product of the family $\{\mathcal{H}_i\}_{i \in I}$.

The inference rules are the introduction and elimination rules for the propositional connectives

$$(\wedge I) \quad \frac{\Gamma \Rightarrow H \quad \text{for all } H \in \mathcal{H}}{\Gamma \Rightarrow \mathcal{H}^\wedge}$$

$$(\wedge E) \quad \frac{\Gamma \Rightarrow \mathcal{H}^\wedge}{\Gamma \Rightarrow H} \quad (H \in \mathcal{H})$$

$$(\vee I) \quad \frac{\Gamma \Rightarrow H}{\Gamma \Rightarrow \mathcal{H}^\vee} \quad (H \in \mathcal{H})$$

$$(\vee E) \quad \frac{\Gamma \Rightarrow \mathcal{H}^\vee \qquad \Delta, H \Rightarrow F \quad \text{for all } H \in \mathcal{H}}{\Gamma, \Delta \Rightarrow F}$$

$$(\to I) \quad \frac{\Gamma, F \Rightarrow G}{\Gamma \Rightarrow F \to G}$$

$$(\to E) \quad \frac{\Gamma \Rightarrow F \quad \Delta \Rightarrow F \to G}{\Gamma, \Delta \Rightarrow G},$$

where $\mathcal{H}$ is a bounded set of formulas, and the weakening rule

$$(W) \ \frac{\Gamma \Rightarrow F}{\Gamma, \Delta \Rightarrow F}.$$

The set of *theorems of the extended system* is the smallest set of sequents that includes the axioms of the system and is closed under the application of its inference rules. We say that formulas F and G are *equivalent in the extended system* if $\Rightarrow F \leftrightarrow G$ is a theorem of the extended system.

Theorem *For any set $\mathcal{H}$ of formulas, if formulas F and G are equivalent in the extended system then $\mathcal{H} \cup \{F\}$ and $\mathcal{H} \cup \{G\}$ have the same stable models.*

Abstract

This paper presents a meta-algorithm for the computation of preferred labellings, based on the general recursive schema for argumentation semantics called SCC-Recursiveness. The idea is to recursively decompose a framework so as to compute semantics labellings on restricted sub-frameworks, in order to reduce the computational effort. The meta-algorithm can be instantiated with a specific "base algorithm", applied to the base case of the recursion, which can be obtained by generalizing existing algorithms in order to compute labellings in restricted sub-frameworks. We devise for this purpose a generalization of a SAT-based algorithm, and provide an empirical investigation to show the significant improvement of performances obtained by exploiting the SCC-recursive schema.

Introduction

Dung's theory of abstract argumentation (Dung 1995) is a unifying framework able to encompass a large variety of specific formalisms in the areas of nonmonotonic reasoning, logic programming and computational argumentation. It is based on the notion of argumentation framework (AF), consisting of a set of arguments and an *attack* relation between them. Different *argumentation semantics* introduce in a declarative way the criteria to determine which arguments emerge as justified from the conflict, by identifying a number of *extensions*, i.e. sets of arguments that can "survive the conflict together". In (Dung 1995) four "traditional" semantics were introduced, namely *complete*, *grounded*, *stable*, and *preferred* semantics. For an introduction on alternative semantics, see (Baroni, Caminada, and Giacomin 2011).

The main computational problems in abstract argumentation include *decision* and *construction* problems, and turn out to be computationally intractable for most of argumentation semantics (Dunne and Wooldridge 2009). In this paper we focus on the *extension enumeration* problem, i.e. constructing *all* extensions prescribed for a given AF: its solution provides complete information concerning the justification status of arguments and subsumes the solutions to the other problems.

On the practical side, few results are available on the development of efficient algorithms for abstract argumentation and their empirical assessment. In particular, in (Cerutti et al. 2013; 2014) a SAT-based approach has been proposed to solve the extension enumeration problem for preferred semantics. Preferred semantics represents the main contribution in Dung's theory, as it allows multiple extensions (differently from grounded semantics), the existence of extensions is always guaranteed (differently from stable semantics), and no extension is a proper subset of another extension (differently from complete semantics). The proposed approach basically performs a search in the space of complete extensions to enumerate the maximal ones, exploiting a SAT solver to identify the relevant search states. In (Cerutti et al. 2014) it has been shown to be competitive w.r.t. other state-of-the-art systems including ASPARTIX (Egly, Alice Gaggl, and Woltran 2010), ASPARTIX-META (Dvořák et al. 2011) and the system presented in (Nofal, Dunne, and Atkinson 2012). A limitation of this approach is that it is always applied to the AF as a whole, without dividing the enumeration problem into a number of simpler sub-problems.

In this paper, we aim at showing (i) an approach for dividing the problem of enumerating the preferred extensions into sub-problems, and (ii) that such an approach reduces the overall computational effort. In particular, we rely on the SCC-recursive schema, first introduced in (Baroni, Giacomin, and Guida 2005), which is a semantics definition schema where extensions are defined at the level of the

sub-frameworks identified by the strongly connected components. It is worth to mention that the focus of this paper is on preferred semantics, but the devised meta-algorithm can be instantiated with various specific "base algorithms" and applied to a variety of semantics.

The paper is organised as follows. After recallling some necessary background in the first section, the SCC-recursive schema is reviewed in the next one. Then the parametric meta-algorithm is presented, and the generalization of the SAT-based algorithm of (Cerutti et al. 2014) is described. Next section describes the test setting and comments the experimental results, while the last section provides a final discussion and concludes the paper. Proofs are omitted or sketched due to space limitations.

Background

An argumentation framework (Dung 1995) consists of a set of arguments[1] and a binary attack relation between them.

Definition 1. *An* argumentation framework *(AF) is a pair $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$ where $\mathcal{A}$ is a set of arguments and $\mathcal{R} \subseteq \mathcal{A} \times \mathcal{A}$. We say that $\boldsymbol{b}$* attacks *$\boldsymbol{a}$ iff $\langle \boldsymbol{b}, \boldsymbol{a} \rangle \in \mathcal{R}$, also denoted as $\boldsymbol{b} \rightarrow \boldsymbol{a}$. The set of attackers of an argument $\boldsymbol{a}$ will be denoted as $\boldsymbol{a}^- \triangleq \{\boldsymbol{b} : \boldsymbol{b} \rightarrow \boldsymbol{a}\}$, the set of arguments attacked by $\boldsymbol{a}$ will be denoted as $\boldsymbol{a}^+ \triangleq \{\boldsymbol{b} : \boldsymbol{a} \rightarrow \boldsymbol{b}\}$. We also extend these notations to sets of arguments, i.e. given $E \subseteq \mathcal{A}$, $E^- \triangleq \{\boldsymbol{b} \mid \exists \boldsymbol{a} \in E, \boldsymbol{b} \rightarrow \boldsymbol{a}\}$ and $E^+ \triangleq \{\boldsymbol{b} \mid \exists \boldsymbol{a} \in E, \boldsymbol{a} \rightarrow \boldsymbol{b}\}$.*

An argument $\mathbf{a}$ without attackers, i.e. such that $\mathbf{a}^- = \emptyset$, is said *initial*. Moreover, each argumentation framework has an associated directed graph where the vertices are the arguments, and the edges are the attacks.

The basic properties of conflict–freeness, acceptability, and admissibility of a set of arguments are fundamental for the definition of argumentation semantics.

Definition 2. *Given an AF $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$:*

- *a set $S \subseteq \mathcal{A}$ is a* conflict–free *set of Γ if $\nexists\, \boldsymbol{a}, \boldsymbol{b} \in S$ s.t. $\boldsymbol{a} \rightarrow \boldsymbol{b}$;*
- *an argument $\boldsymbol{a} \in \mathcal{A}$ is* acceptable *with respect to a set $S \subseteq \mathcal{A}$ of Γ if $\forall \boldsymbol{b} \in \mathcal{A}$ s.t. $\boldsymbol{b} \rightarrow \boldsymbol{a}$, $\exists\, \boldsymbol{c} \in S$ s.t. $\boldsymbol{c} \rightarrow \boldsymbol{b}$;*
- *a set $S \subseteq \mathcal{A}$ is an* admissible set *of Γ if S is a conflict–free set of Γ and every element of S is acceptable with respect to S of Γ.*

An argumentation semantics σ prescribes for any AF Γ a set of *extensions*, denoted as $\mathcal{E}_\sigma(\Gamma)$, namely a set of sets of arguments satisfying the conditions dictated by σ. Here we need to recall the definitions of complete (denoted as $\mathcal{CO}$), grounded (denoted as $\mathcal{GR}$) and preferred (denoted as $\mathcal{PR}$) semantics only.

Definition 3. *Given an AF $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$:*

- *a set $S \subseteq \mathcal{A}$ is a* complete extension *of Γ, i.e. $S \in \mathcal{E}_{\mathcal{CO}}(\Gamma)$, iff S is admissible and $\forall \boldsymbol{a} \in \mathcal{A}$ s.t. $\boldsymbol{a}$ is acceptable w.r.t. S, $\boldsymbol{a} \in S$;*
- *a set $S \subseteq \mathcal{A}$ is the* grounded extension *of Γ, i.e. $S \in \mathcal{E}_{\mathcal{GR}}(\Gamma)$, iff S is the minimal (w.r.t. set inclusion) complete extension of Γ. Its existence and uniqueness have been proved in (Dung, Mancarella, and Toni 2006);*
- *a set $S \subseteq \mathcal{A}$ is a* preferred extension *of Γ, i.e. $S \in \mathcal{E}_{\mathcal{PR}}(\Gamma)$, iff S is a maximal (w.r.t. set inclusion) complete extension of Γ.*

It can be noted that each extension S implicitly defines a three-valued *labelling* of arguments: an argument $\mathbf{a}$ is labelled `in` iff $\mathbf{a} \in S$; is labelled `out` iff $\exists\, \mathbf{b} \in S$ s.t. $\mathbf{b} \rightarrow \mathbf{a}$; is labelled `undec` if neither of the above conditions holds. In the light of this correspondence, argumentation semantics can be equivalently defined in terms of labellings rather than of extensions (Caminada 2006; Baroni, Caminada, and Giacomin 2011). For technical reasons, we introduce the notion of labelling both for argumentation frameworks and for arbitrary sets of arguments.

Definition 4. *Given a set of arguments S, a* labelling *of S is a total function $\mathcal{L}ab : S \longrightarrow \{\mathtt{in}, \mathtt{out}, \mathtt{undec}\}$. The set of all* labellings *of S is denoted as $\mathfrak{L}_S$. Given an AF $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$, a* labelling *of Γ is a labelling of $\mathcal{A}$. The set of all* labellings *of Γ is denoted as $\mathfrak{L}(\Gamma)$.*

In particular, complete labellings can be defined as follows.

Definition 5. *Let $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$ be an argumentation framework. A labelling $\mathcal{L}ab \in \mathfrak{L}(\Gamma)$ is a* complete labelling *of Γ iff it satisfies the following conditions for any $\boldsymbol{a} \in \mathcal{A}$:*

- *$\mathcal{L}ab(\boldsymbol{a}) = \mathtt{in} \Leftrightarrow \forall \boldsymbol{b} \in \boldsymbol{a}^- \mathcal{L}ab(\boldsymbol{b}) = \mathtt{out}$;*
- *$\mathcal{L}ab(\boldsymbol{a}) = \mathtt{out} \Leftrightarrow \exists \boldsymbol{b} \in \boldsymbol{a}^- : \mathcal{L}ab(\boldsymbol{b}) = \mathtt{in}$;*

The grounded and preferred labelling can then be defined on the basis of complete labellings.

Definition 6. *Let $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$ be an argumentation framework. A labelling $\mathcal{L}ab \in \mathfrak{L}(\Gamma)$ is* the grounded labelling *of Γ if it is the complete labelling of Γ minimizing the set of arguments labelled* `in`*, and it is a* preferred labelling *of Γ if it is a complete labelling of Γ maximizing the set of arguments labelled* `in`*.*

In order to show the connection between extensions and labellings, let us recall the definition of the function `Ext2Lab`, returning the labelling corresponding to a conflict–free set of arguments S.

Definition 7. *Given an AF $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$ and a conflict–free set $S \subseteq \mathcal{A}$, the corresponding labelling $\mathtt{Ext2Lab}(S)$ is defined as $\mathtt{Ext2Lab}(S) \equiv \mathcal{L}ab$, where*

- *$\mathcal{L}ab(\boldsymbol{a}) = \mathtt{in} \Leftrightarrow \boldsymbol{a} \in S$*
- *$\mathcal{L}ab(\boldsymbol{a}) = \mathtt{out} \Leftrightarrow \exists\, \boldsymbol{b} \in S$ s.t. $\boldsymbol{b} \rightarrow \boldsymbol{a}$*
- *$\mathcal{L}ab(\boldsymbol{a}) = \mathtt{undec} \Leftrightarrow \boldsymbol{a} \notin S \wedge \nexists\, \boldsymbol{b} \in S$ s.t. $\boldsymbol{b} \rightarrow \boldsymbol{a}$*

(Caminada 2006) shows that there is a bijective correspondence between the complete, grounded, preferred extensions and the complete, grounded, preferred labellings, respectively.

Proposition 1. *Given an an AF $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$, $\mathcal{L}ab$ is a complete (grounded, preferred) labelling of Γ if and only if there is a complete (grounded, preferred) extension S of Γ such that $\mathcal{L}ab = \mathtt{Ext2Lab}(S)$.*

[1] In this paper we consider only *finite* sets of arguments: see (Baroni et al. 2013) for a discussion on infinite sets of arguments.

The set of complete labellings of Γ is denoted as $\mathcal{L}_{\mathcal{CO}}(\Gamma)$, the set of preferred labellings as $\mathcal{L}_{\mathcal{PR}}(\Gamma)$, while $\mathcal{L}_{\mathcal{GR}}(\Gamma)$ denotes the set including the grounded labelling.

SCC-Recursiveness Revisited

In (Baroni and Giacomin 2004) it has been recognised that each argumentation framework can be partitioned into a set of sub-frameworks in such a way that most common argumentation semantics (originally defined at the global level) can be equivalently defined at the level of these sub-frameworks. In particular, an extension-based semantics definition schema has been introduced, called *SCC (strongly connected component)-recursiveness*, based on the graph-theoretical notion of SCCs i.e. the equivalence classes induced by the path equivalence (i.e. mutual reachability) relation between the nodes of the associated graph of an argumentation framework (given the direct correspondence between each AF and its associated graph, in the following we will equivalently refer to both of them as AF).

Definition 8. *Given an AF $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$, the binary relation of* path-equivalence *between nodes, denoted as $PE_\Gamma \subseteq \mathcal{A} \times \mathcal{A}$, is defined as follows:*

- $\forall \boldsymbol{a} \in \mathcal{A}, \langle \boldsymbol{a}, \boldsymbol{a} \rangle \in PE_\Gamma$;
- $\forall \boldsymbol{a}, \boldsymbol{b} \in \mathcal{A}$, $\boldsymbol{a} \neq \boldsymbol{b}$, $\langle \boldsymbol{a}, \boldsymbol{b} \rangle \in PE_\Gamma$ *iff there is a path from* $\boldsymbol{a}$ *to* $\boldsymbol{b}$ *and vice versa.*

Two main features of the SCC-recursive schema are worth remarking.

First, the SCC-recursive schema exploits the partial order of SCCs induced by the attack relation and can be regarded as a constructive procedure to incrementally build extensions following such partial order. At the beginning, the extensions of the frameworks restricted to the *initial* SCCs (i.e. those not receiving attacks from others) are computed and combined together. Then each SCC which is attacked only from initial SCCs is considered, and for each extension E already obtained, the extensions of such a SCC are locally computed and merged with E. The process is then applied to all SCCs following their partial order, until no remaining SCCs are left to process.

A second feature is that the schema, as the name suggests, is recursive. In particular, for every SCC considered in the above procedure, the local computation is performed as follows. First, all arguments attacked by the extension selected in the previous SCCs are suppressed. Then, the procedure is recursively applied to the remaining part of the SCC. The base of the recursion is reached when there is one SCC only: in this case, a base function $\mathcal{BF}$ is called. Such a function receives as input an argumentation framework $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$ and a set $C \subseteq \mathcal{A}$: Γ is a sub-framework of the original AF $\Gamma' = \langle \mathcal{A}', \mathcal{R}' \rangle$, and C contains the arguments that are "externally accepted" (i.e. their attackers in $\mathcal{A}' \setminus \mathcal{A}$ are attacked by the part of the extension constructed so far).

The following definitions introduce the SCC-recursive schema in its original extension-based form (Baroni, Giacomin, and Guida 2005).

First, let us recall the definition of *restriction* of an AF Γ to a set of arguments I, in symbol $\Gamma{\downarrow_I}$.

Definition 9. *Given an argumentation framework $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$ and a set $I \subseteq \mathcal{A}$, the restriction of Γ to I is defined as $\Gamma{\downarrow_I} \equiv (\mathcal{A} \cap I, \mathcal{R} \cap (I \times I))$.*

Then, Definition 10 introduces the function $\mathcal{GF}(\Gamma, C)$ which recursively computes the semantics extensions on the basis of the SCCs of Γ. Let us denote as SCC_Γ the set including the SCCs of an argumentation framework Γ.

Definition 10. *A given argumentation semantics σ is SCC-recursive if for any argumentation framework $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$, $\mathcal{E}_\sigma(\Gamma) = \mathcal{GF}(\Gamma, \mathcal{A}) \subseteq 2^{\mathcal{A}}$. For any $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$ and for any set $C \subseteq \mathcal{A}$, $E \in \mathcal{GF}(\Gamma, C)$ if and only if*

- $E \in \mathcal{BF}_\sigma(\Gamma, C)$ *if* $|SCC_\Gamma| = 1$
- $\forall S \in SCC_\Gamma \ (E \cap S) \in \mathcal{GF}(\Gamma{\downarrow_{S \setminus (E \setminus S)^+}}, U_\Gamma(S, E) \cap C)$ *otherwise*

where

- $\mathcal{BF}_\sigma(\Gamma, C)$ *is a function, called* base function*, that, given an argumentation framework $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$ such that $|SCC_\Gamma| = 1$ and a set $C \subseteq \mathcal{A}$, gives a subset of $2^{\mathcal{A}}$*
- $U_\Gamma(S, E) = \{\boldsymbol{a} \in S \setminus (E \setminus S)^+ \mid \forall \boldsymbol{b} \in (\boldsymbol{a}^- \setminus S), \boldsymbol{b} \in E^+\}$

As shown below, this schema is based on the notions of admissible set, complete, grounded, preferred extension of an AF *in a set of arguments*.

Definition 11. *Given an AF $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$ and a set $C \subseteq \mathcal{A}$, a set $E \subseteq \mathcal{A}$ is:*

- *an* admissible set of Γ in C *if and only if E is an admissible set of Γ and $E \subseteq C$*
- *a* complete extension of Γ in C *if and only if E is an admissible set of Γ in C, and every argument $\alpha \in C$ which is acceptable with respect to E belongs to E*
- *the* grounded extension of Γ in C *if and only if it is the least (with respect to set inclusion) complete extension of Γ in C*
- *a* preferred extension of Γ in C *if and only if it is a maximal (with respect to set inclusion) complete extension of Γ in C.*

The existence and uniqueness of the grounded extension in C, as well as the existence of at least a preferred extension in C, have been proved in (Baroni, Giacomin, and Guida 2005). The set of admissible sets in C is denoted as $\mathcal{E}_{\mathcal{AD}}(\Gamma, C)$, the set of complete extensions in C as $\mathcal{E}_{\mathcal{CO}}(\Gamma, C)$, the set of preferred extensions in C as $\mathcal{E}_{\mathcal{PR}}(\Gamma, C)$, while $\mathcal{E}_{\mathcal{GR}}(\Gamma, C)$ denotes the set including the grounded extension in C.

(Baroni, Giacomin, and Guida 2005) proves that $\mathcal{GF}(\Gamma, C)$, as defined in Def. 10, returns $\mathcal{E}_\sigma(\Gamma, C)$ (with $\sigma \in \{\mathcal{CO}, \mathcal{GR}, \mathcal{PR}\}$), provided that $\mathcal{BF}_\sigma(\Gamma, C)$ returns the complete, grounded, and preferred extensions in C, respectively. The correctness of the schema then follows from the fact that, according to Definition 11, $\mathcal{E}_\sigma(\Gamma, \mathcal{A}) = \mathcal{E}_\sigma(\Gamma)$.

A Parametric Meta-Algorithm to Enumerate Preferred Labellings

In this section, we develop a "meta-algorithm" based on the SCC-recursive schema for the computation of preferred labellings. We use the term meta-algorithm since it is parametric w.r.t. an algorithm B-PR to compute the base function

Algorithm 1 Enumerating the preferred labellings of an AF

PREF(Γ)

1: **Input:** $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$
2: **Output:** $E_p \in 2^{\mathfrak{L}(\Gamma)}$
3: **return R-PREF**$(\Gamma, \mathcal{A})$

$\mathcal{BF}_{\mathcal{PR}}$, without committing on the way B-PR performs its computation.

The meta-algorithm consists of Algorithms 1 and 2. It represents an implementation of the SCC-recursive schema with two main improvements. First, the schema has been adapted to the labelling-based approach: the following definition introduces the labelling-based counterpart of the complete, grounded and preferred extension in C.

Definition 12. *Given an AF $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$ and a set $C \subseteq \mathcal{A}$, a labelling $\mathcal{L}ab \in \mathfrak{L}(\Gamma)$ is a* complete (grounded, preferred) labelling of Γ in C *if there is a complete (grounded, preferred) extension S of Γ in C such that $\mathcal{L}ab = \texttt{Ext2Lab}(S)$. The set of complete and preferred labellings of Γ in C are denoted as $\mathcal{L}_{\mathcal{CO}}(\Gamma, C)$ and $\mathcal{L}_{\mathcal{PR}}(\Gamma, C)$, respectively, and the set including the grounded labelling of Γ in C is denoted as $\mathcal{L}_{\mathcal{GR}}(\Gamma, C)$.*

Finally, a pre-processing step computing the grounded labelling $\mathcal{L}ab^*$ in C is performed. The labellings of the whole argumentation framework can then be obtained by extending $\mathcal{L}ab^*$, on the basis to the following result.

Proposition 2. *Let $\langle \mathcal{A}, \mathcal{R} \rangle$ be an argumentation framework and let $C \subseteq \mathcal{A}$ a set of arguments. Considering the grounded labelling $\mathcal{L}ab^*$ of Γ in C and the set U including the* undec*-labelled arguments according to $\mathcal{L}ab^*$, it holds that $\mathcal{L}_{\mathcal{PR}}(\Gamma, C) = \{\mathcal{L}ab^* \cup E \mid E \in \mathcal{L}_{\mathcal{PR}}(\Gamma{\downarrow_U}, C \cap U)\}$.*

Sketch of proof. This extends the known result (Baroni, Caminada, and Giacomin 2011) that the grounded extension is a subset of the intersections of preferred extensions. □

Let us turn to the description of the meta-algorithm. The function PREF (Algorithm 1) receives as input an argumentation framework $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$ and returns the set of preferred labellings of Γ. This is simply achieved by invoking (at line 3) R-PREF$(\Gamma, \mathcal{A})$, where the function R-PREF ($\mathcal{GF}$ in Def. 10) receives as input an argumentation framework $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$ and a set $C \subseteq \mathcal{A}$, and computes the set $\mathcal{L}_{\mathcal{PR}}(\Gamma, C)$, i.e. the set of preferred labellings of Γ in C.

Algorithm 2 implements the function R-PREF. First, a pre-processing step which computes the grounded labelling in C is executed at line 3 by means of the call $(\mathcal{L}ab, U) =$ GROUNDED(Γ, C).

The procedure GROUNDED (Alg. 3) receives as input an argumentation framework $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$ and a set $C \subseteq \mathcal{A}$, and returns $\mathcal{L}ab$ and U: $\mathcal{L}ab$ is the restriction of the grounded labelling to the arguments that are `in` or `out`-labelled; U is the set including the remaining (`undec`-labelled) arguments. The GROUNDED procedure iteratively labels `in` each argument $\mathbf{a} \in C$ which either is initial, or receives attacks from arguments labelled `out`, and then labels `out` each argument attacked by $\mathbf{a}$.

Algorithm 2 Enumerating the preferred labellings in a set C of an AF

R-PREF(Γ, C)

1: **Input:** $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle, C \subseteq \mathcal{A}$
2: **Output:** $E_p \in 2^{\mathfrak{L}(\Gamma)}$
3: $(\mathcal{L}ab, U) =$ GROUNDED(Γ, C)
4: $E_p := \{\mathcal{L}ab\}$
5: $\Gamma = \Gamma{\downarrow_U}$
6: $(S_1, \ldots, S_n) :=$ SCCSSEQ(Γ)
7: **for** $i \in \{1, \ldots, n\}$ **do**
8: $\quad E'_p := \emptyset$
9: $\quad$ **for** $\mathcal{L}ab \in E_p$ **do**
10: $\quad\quad (O, I) :=$ BOUNDCOND$(\Gamma, S_i, \mathcal{L}ab)$
11: $\quad\quad$ **if** $I = \emptyset$ **then**
12: $\quad\quad\quad \mathcal{L}ab = \mathcal{L}ab \cup \{(\mathbf{a}, \texttt{out}) \mid \mathbf{a} \in O\} \cup \{(\mathbf{a}, \texttt{undec}) \mid \mathbf{a} \in S_i \setminus O\}$
13: $\quad\quad\quad E'_p = E'_p \cup \{\mathcal{L}ab\}$
14: $\quad\quad$ **else**
15: $\quad\quad\quad$ **if** $O = \emptyset$ **then**
16: $\quad\quad\quad\quad E_* =$ B-PR$(\Gamma{\downarrow_{S_i}}, I \cap C)$
17: $\quad\quad\quad$ **else**
18: $\quad\quad\quad\quad \mathcal{L}ab = \mathcal{L}ab \cup \{(\mathbf{a}, \texttt{out}) \mid \mathbf{a} \in O\}$
19: $\quad\quad\quad\quad E_* =$ R-PREF$(\Gamma{\downarrow_{S_i \setminus O}}, I \cap C)$
20: $\quad\quad\quad$ **end if**
21: $\quad\quad\quad E'_p = E'_p \cup (\mathcal{L}ab \otimes E_*)$
22: $\quad\quad$ **end if**
23: $\quad$ **end for**
24: $\quad E_p := E'_p$
25: **end for**
26: **return** E_p

After the computation of $\mathcal{L}ab$ and U, Alg. 2 initialises the variable E_p to $\{\mathcal{L}ab\}$ at line 4. E_p stores the set of labellings that are incrementally constructed. Then the computation proceeds by considering the argumentation framework $\Gamma{\downarrow_U}$ (line 5).

At line 6 the strongly connected components of the argumentation framework are identified. We assume that an algorithm is available, denoted as SCCSSEQ, which receives as input an argumentation framework Γ and returns as output a sequence $(S_1, \ldots, S_n)$ including the strongly connected components of Γ in a topological order, i.e. if $\exists \mathbf{a} \in S_i, \mathbf{b} \in S_j$ such that $\mathbf{a} \rightarrow \mathbf{b}$ then $i \leq j$. This can be done in linear time under the number of attacks (Cormen et al. 2009, p. 617).

The incremental construction of the preferred labellings is performed by the outer loop (lines 7-25), which iteratively selects the i-th SCC. At the beginning of the iteration, E_p includes the partial labellings constructed for $S_1 \cup \ldots \cup S_{i-1}$.Then the inner loop is entered, which extends any labelling $\mathcal{L}ab \in E_p$ to S_i (lines 9-23) storing the labellings thus obtained in E'_p (initialised at line 8). At line 10 variable O is set to include arguments of S_i that are attacked by "outside" `in`-labelled arguments according to $\mathcal{L}ab$, and variable I is set to include arguments of S_i that are only attacked by "outside" `out`-labelled arguments. Formally, BOUNDCOND$(\Gamma, S_i, \mathcal{L}ab)$ returns (O, I) where

Algorithm 3 Determining the grounded labelling of an AF in a set C

GROUNDED(Γ, C)

1: **Input:** $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle, C \subseteq \mathcal{A}$
2: **Output:** $(\mathcal{L}ab, U) : U \subseteq \mathcal{A}, \mathcal{L}ab \in \mathfrak{L}_{\mathcal{A} \setminus U}$
3: $\mathcal{L}ab := \emptyset$
4: $U := \mathcal{A}$
5: **repeat**
6: $initialfound := \bot$
7: **for a** $\in C$ **do**
8: **if** $\{\mathbf{b} \in U \mid \mathbf{b} \to \mathbf{a}\} = \emptyset$ **then**
9: $initialfound := \top$
10: $\mathcal{L}ab := \mathcal{L}ab \cup \{(\mathbf{a}, \mathtt{in})\}$
11: $U := U \setminus \mathbf{a}$
12: $C := C \setminus \mathbf{a}$
13: **for b** $\in (U \cap \mathbf{a}^+)$ **do**
14: $\mathcal{L}ab := \mathcal{L}ab \cup \{(\mathbf{b}, \mathtt{out})\}$
15: $U := U \setminus \mathbf{b}$
16: $C := C \setminus \mathbf{b}$
17: **end for**
18: **end if**
19: **end for**
20: **until** $(initialfound)$
21: **return**$(\mathcal{L}ab, U)$

$O = \{\mathbf{a} \in S_i \mid \exists \mathbf{b} \in S \cap \mathbf{a}^- : \mathcal{L}ab(\mathbf{b}) = \mathtt{in}\}$ and $I = \{\mathbf{a} \in S_i \mid \forall\, \mathbf{b} \in S \cap \mathbf{a}^-, \mathcal{L}ab(\mathbf{b}) = \mathtt{out}\}$, with $S \equiv S_1 \cup \ldots \cup S_{i-1}$.

If $I = \emptyset$ then no argument of S_i can be labelled `in`, in particular each argument in O is labelled `out` and each arguments in $S_i \setminus O$ is labelled `undec`. Accordingly, $\mathcal{L}ab$ is extended with such a labelling (line 12) and included in E'_p (line 13). Then a new iteration of the loop is entered to process a new labelling $\mathcal{L}ab \in E_p$ (if any).

Otherwise, two cases are considered. If $O = \emptyset$ then there are no arguments to suppress from S_i, thus the base case of the recursion applies. This is a small improvement w.r.t. Def. 10 which allows to avoid an unnecessary recursive step. In the base case, the preferred labellings of $\Gamma{\downarrow_{S_i}}$ in $S_i \cap C$ are computed by means of the algorithm B-PR, and assigned to E_* (line 16). If $O \neq \emptyset$ then each argument in O is labelled `out`, and the R-PREF procedure is recursively invoked on $\Gamma{\downarrow_{S_i \setminus O}}$ and $I \cap C$ (line 19). In both cases, line 21 extends the labelling $\mathcal{L}ab$ to cover the whole component S_i — by combining it with all labelling of E_* — and update E'_p. Indeed, $\mathcal{L}ab \otimes E_*$ denotes the set $\{\mathcal{L}ab \cup \mathcal{L}ab^* \mid \mathcal{L}ab^* \in E_*\}$.

After the inner loop is exited, i.e. when all labellings of E_p have been considered, the obtained labellings E'_p are those covering $S_1, \ldots, S_i$, thus E_p is set to E'_p at line 24. After the outer loop is exited all strongly connected components have been processed, thus E_p is returned as the set of preferred labellings in C (line 26).

The following theorem shows that Algorithm 2 (and thus Algorithm 1) is correct

Theorem 1. *Given an AF $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$ and a set $C \subseteq \mathcal{A}$, Algorithm 1 returns $E_p = \mathcal{L}_{\mathcal{PR}}(\Gamma, C)$.*

A SAT-Based Approach for the Base Case

R-PREF (Alg. 2) relies on an external algorithm (B-PR) for enumerating the preferred labellings of Γ in a set of arguments C. In order to empirically prove the improvements obtained using Alg. 2, in this section we discuss a specific implementation of B-PR generalizing the approach of (Cerutti et al. 2014).

The proposed algorithm performs a search in the space of complete extensions in C, in order to maximise the set of `in` arguments (cf. Definitions 12 and 11). Each step of the search process requires to encode in a propositional formula the constraints corresponding to complete labellings of an AF in C, with opportune modifications due to the search process. Then, a SAT solver checks whether the formula is satisfiable, i.e. there exists a truth assignment of the variables such that the formula evaluates to $\top$, and if this is the case returns such an assignment.

As a first step to identify the encoding, here we provide the definition of *complete labelling of Γ in C* in a more algorithmic way than Definition 12.

Definition 13. *Let $\langle \mathcal{A}, \mathcal{R} \rangle$ be an argumentation framework and $C \subseteq \mathcal{A}$ be a set of arguments. A total function $\mathcal{L}ab : \mathcal{A} \mapsto \{\mathtt{in}, \mathtt{out}, \mathtt{undec}\}$ is a* complete labelling of Γ in C *iff it satisfies the following conditions for any $\boldsymbol{a} \in C$:*

$\mathcal{L}^1_C$*:* $\mathcal{L}ab(\boldsymbol{a}) = \mathtt{in} \Leftrightarrow \forall \boldsymbol{b} \in \boldsymbol{a}^- \mathcal{L}ab(\boldsymbol{b}) = \mathtt{out}$*;*
$\mathcal{L}^2_C$*:* $\mathcal{L}ab(\boldsymbol{a}) = \mathtt{out} \Leftrightarrow \exists \boldsymbol{b} \in (\boldsymbol{a}^- \cap C) : \mathcal{L}ab(\boldsymbol{b}) = \mathtt{in}$*;*
$\mathcal{L}^3_C$*:* $\mathcal{L}ab(\boldsymbol{a}) = \mathtt{undec} \Leftrightarrow \forall \boldsymbol{b} \in (\boldsymbol{a}^- \cap C), \mathcal{L}ab(\boldsymbol{b}) \neq \mathtt{in} \wedge \exists \boldsymbol{c} \in \boldsymbol{a}^- : \mathcal{L}ab(\boldsymbol{c}) = \mathtt{undec}$*;*

and the following conditions for any $\boldsymbol{a} \in (\mathcal{A} \setminus C)$:

$\mathcal{L}^1_{\mathcal{A} \setminus C}$*:* $\mathcal{L}ab(\boldsymbol{a}) = \mathtt{out} \Leftrightarrow \exists \boldsymbol{b} \in (\boldsymbol{a}^- \cap C) : \mathcal{L}ab(\boldsymbol{b}) = \mathtt{in}$*;*
$\mathcal{L}^2_{\mathcal{A} \setminus C}$*:* $\mathcal{L}ab(\boldsymbol{a}) = \mathtt{undec} \Leftrightarrow \forall \boldsymbol{b} \in (\boldsymbol{a}^- \cap C), \mathcal{L}ab(\boldsymbol{b}) \neq \mathtt{in}$*.*

The following proposition shows that Definition 13 actually identifies the complete labellings in C as introduced in Definition 12.

Proposition 3. *Given an an AF $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$ and a set $C \subseteq \mathcal{A}$, $\mathcal{L}ab$ satisfies the conditions of Definition 13 if and only if there is a complete extension S of Γ in C such that $\mathcal{L}ab = \mathtt{Ext2Lab}(S)$.*

Sketch of proof. The proof generalizes (Cerutti et al. 2014, Proposition 2), to take into account the parameter C. □

The Complete Labelling Formula of Γ in C

Given an AF $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$ and a set $C \subseteq \mathcal{A}$, we are interested in identifying a boolean formula in conjunctive normal form (as required by the SAT solver), called *complete labelling formula of Γ in C* and denoted as $\Pi_{\Gamma, C}$, such that the satisfying assignments of the formula are in one-to-one correspondence with the complete labellings of Γ in C.

To this purpose, we have to introduce some notation. Let ϕ be a bijection $\phi : \{1, \ldots, |\mathcal{A}|\} \mapsto \mathcal{A}$ (the inverse map will be denoted as ϕ^{-1}): ϕ is an indexing of $\mathcal{A}$. Argument $\phi(i)$ will be sometimes referred to as argument i for brevity. For each argument i we define three boolean variables, I_i, O_i,

and U_i, with the intended meaning that I_i is $\top$ when argument i is labelled `in`, $\bot$ otherwise (and analogously O_i and U_i correspond to labels `out` and `undec`). Formally, given $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$ we define the corresponding set of variables as $\mathcal{V}(\Gamma) \triangleq \cup_{i \in \phi^{-1}(\mathcal{A})} \{I_i, O_i, U_i\}$.

The following definition expresses the constraints of Definition 5 in terms of the variables $\mathcal{V}(\Gamma)$.

Definition 14. *Given an AF $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$ with $|\mathcal{A}| = k$ and a set $C \subseteq \mathcal{A}$, let $\phi : \{1, \ldots, k\} \mapsto \mathcal{A}$ be an indexing of $\mathcal{A}$. The ENC_{all}* encoding *defined on the variables in $\mathcal{V}(\Gamma)$ is given by the conjunction of the formulae listed below:*

$$\bigwedge_{i \in \phi^{-1}(C)} \Big((I_i \vee O_i \vee U_i) \wedge (\neg I_i \vee \neg O_i) \wedge (\neg I_i \vee \neg U_i) \wedge (\neg O_i \vee \neg U_i) \Big) \tag{1}$$

$$\bigwedge_{i \in \phi^{-1}(C)} \left(I_i \vee \left(\bigvee_{\{j | \phi(j) \rightarrow \phi(i)\}} (\neg O_j) \right) \right) \tag{2}$$

$$\bigwedge_{i \in \phi^{-1}(C)} \left(\bigwedge_{\{j | \phi(j) \rightarrow \phi(i)\}} \neg I_i \vee O_j \right) \tag{3}$$

$$\bigwedge_{i \in \phi^{-1}(C)} \left(\bigwedge_{\{j \in \phi^{-1}(C) | \phi(j) \rightarrow \phi(i)\}} \neg I_j \vee O_i \right) \tag{4}$$

$$\bigwedge_{i \in \phi^{-1}(C)} \left(\neg O_i \vee \left(\bigvee_{\{j \in \phi^{-1}(C) | \phi(j) \rightarrow \phi(i)\}} I_j \right) \right) \tag{5}$$

$$\bigwedge_{i \in \phi^{-1}(C)} \Big(\bigwedge_{\{k | \phi(k) \rightarrow \phi(i)\}} \Big(U_i \vee \neg U_k \vee \Big(\bigvee_{\{j \in \phi^{-1}(C) | \phi(j) \rightarrow \phi(i)\}} I_j \Big) \Big) \Big) \tag{6}$$

$$\bigwedge_{i \in \phi^{-1}(C)} \Big(\Big(\bigwedge_{\{j \in \phi^{-1}(C) | \phi(j) \rightarrow \phi(i)\}} (\neg U_i \vee \neg I_j) \Big) \wedge \Big(\neg U_i \vee \Big(\bigvee_{\{k | \phi(k) \rightarrow \phi(i)\}} U_k \Big) \Big) \Big) \tag{7}$$

$$\bigwedge_{i \in \phi^{-1}(\mathcal{A} \setminus C)} \Big(\neg I_i \wedge (O_i \vee U_i) \wedge (\neg O_i \vee \neg U_i) \Big) \tag{8}$$

$$\bigwedge_{i \in \phi^{-1}(\mathcal{A} \setminus C)} \left(\bigwedge_{\{j \in \phi^{-1}(C) | \phi(j) \rightarrow \phi(i)\}} \neg I_j \vee O_i \right) \tag{9}$$

$$\bigwedge_{i \in \phi^{-1}(\mathcal{A} \setminus C)} \left(\neg O_i \vee \left(\bigvee_{\{j \in \phi^{-1}(C) | \phi(j) \rightarrow \phi(i)\}} I_j \right) \right) \tag{10}$$

$$\bigwedge_{i \in \phi^{-1}(\mathcal{A} \setminus C)} \left(U_i \vee \left(\bigvee_{\{j \in \phi^{-1}(C) | \phi(j) \rightarrow \phi(i)\}} I_j \right) \right) \tag{11}$$

$$\bigwedge_{i \in \phi^{-1}(\mathcal{A} \setminus C)} \left(\bigwedge_{\{j \in \phi^{-1}(C) | \phi(j) \rightarrow \phi(i)\}} \neg U_i \vee \neg I_j \right) \tag{12}$$

Formulas (1) and (8) encode the fact that $\mathcal{L}ab$ is a total function. The other formulas are in direct correspondence with the conditions of Definition 13:

- formulas (2) and (3) encode $\mathcal{L}^1_C$;
- formulas (4) and (5) encode $\mathcal{L}^2_C$;
- formulas (6) and (7) encode $\mathcal{L}^3_C$;
- formulas (9) and (10) encode $\mathcal{L}^1_{\mathcal{A} \setminus C}$;
- formulas (11) and (12) encode $\mathcal{L}^2_{\mathcal{A} \setminus C}$.

The following proposition shows that ENC_{all} is a complete labelling formula of Γ in C, i.e. every satisfying assignment of the ENC_{all} encoding corresponds to a complete extension in C, and vice versa. For ease of notation, if a variable is not assigned to $\top$ then it is $\bot$.

Proposition 4. *Let $\langle \mathcal{A}, \mathcal{R} \rangle$ be an argumentation framework and $C \subseteq \mathcal{A}$ be a set of arguments. If $\mathcal{L}ab$ is a complete labelling of Γ in C, then the assignment $\Phi_{\mathcal{V}(\Gamma)} \equiv \{(I_i, \top) \mid \mathcal{L}ab(\phi(i)) = \texttt{in}\} \cup \{(O_i, \top) \mid \mathcal{L}ab(\phi(i)) = \texttt{out}\} \cup \{(U_i, \top) \mid \mathcal{L}ab(\phi(i)) = \texttt{undec}\}$ satisfies the ENC_{all} encoding of Definition 14. Conversely, if $\Phi_{\mathcal{V}(\Gamma)}$ is a satisfying assignment of the ENC_{all} encoding, then the labelling $\mathcal{L}ab \equiv \{(\boldsymbol{a}, \texttt{in}) \mid I_{\phi^{-1}(\boldsymbol{a})} \in \Phi_{\mathcal{V}(\Gamma)}\} \cup \{(\boldsymbol{b}, \texttt{out}) \mid O_{\phi^{-1}(\boldsymbol{b})} \in \Phi_{\mathcal{V}(\Gamma)}\} \cup \{(\boldsymbol{c}, \texttt{undec}) \mid U_{\phi^{-1}(\boldsymbol{c})} \in \Phi_{\mathcal{V}(\Gamma)}\}$ is a complete labelling of Γ in C.*

Sketch of proof. The result derives from Proposition 3 by transforming logical implications in AND/OR. □

Several syntactically different encodings can be devised which, while being logically equivalent, can significantly affect the performance of the overall process (Cerutti et al. 2014). The following proposition shows the 20 non redundant encodings (i.e. it is not possible to drop out some clauses so as to obtain a simpler logically equivalent encoding) equivalent to ENC_{all}.

Proposition 5. *Let $\langle \mathcal{A}, \mathcal{R} \rangle$ be an argumentation framework and $C \subseteq \mathcal{A}$ be a set of arguments. Referring to the formulae listed in Definition 14, let us define the following formulae (for the arguments in C):*

$C_1^a : (1) \wedge (2) \wedge (3) \wedge (4) \wedge (5)$
$C_1^b : (1) \wedge (4) \wedge (5) \wedge (6) \wedge (7)$
$C_1^c : (1) \wedge (2) \wedge (3) \wedge (6) \wedge (7)$

$C_2: (1) \wedge (3) \wedge (5) \wedge (7)$
$C_3: (1) \wedge (2) \wedge (4) \wedge (6)$

as well as the following ones (for the arguments in $\mathcal{A} \setminus C$):

$NC_1^a: (8) \wedge (9) \wedge (10)$
$NC_1^b: (8) \wedge (11) \wedge (12)$
$NC_2: (8) \wedge (10) \wedge (12)$
$NC_3: (8) \wedge (9) \wedge (11)$

Any encoding of the form $C \wedge NC$, where $C \in \{C_1^a, C_1^b, C_1^c, C_2, C_3\}$ and $NC \in \{NC_1^a, NC_1^b, NC_2, NC_3\}$, is equivalent to ENC_{all}, i.e. it has the same satisfying assignments of the variables in $\mathcal{V}(\Gamma)$.

Sketch of proof. The proof exploits the fact that $\mathcal{L}ab$ is a total function and shows that the conditions in $C \wedge NC$ entail those included in ENC_{all}. □

Corollary 1. *Let $\langle \mathcal{A}, \mathcal{R} \rangle$ be an argumentation framework and $C \subseteq \mathcal{A}$ be a set of arguments. Any encoding of the form $C \wedge NC$ (see Proposition 5) is a complete labelling formula of Γ in C.*

The SAT_basepref Algorithm

We are now able to describe the proposed procedure to implement B-PR. The procedure, called SAT_basepref, resorts to five external functions: SS, I-ARGS, O-ARGS, U-ARGS and LAB. SS is a SAT solver able to prove unsatisfiability too: it accepts as input a CNF formula and returns a variable assignment satisfying the formula if it exists, ε otherwise. All the other functions accept as input a variable assignment concerning $\mathcal{V}(\Gamma)$: I-ARGS returns the corresponding set of arguments labelled as `in`, O-ARGS returns the corresponding set of arguments labelled as `out`, U-ARGS returns the corresponding set of arguments labelled as `undec`, while LAB returns the labelling corresponding to the input variable assignment. Moreover, INC_C denotes the clause $\bigvee_{i \in \phi^{-1}(C)} I_i$.

The SAT_basepref procedure (Alg. 4) initialises, at line 3, the variable E_p which stores the generated labellings. Then cnf is initialized to $\Pi_{\Gamma,C} \wedge INC_C$: $\Pi_{\Gamma,C}$ is a complete labelling formula of Γ in C, e.g. one of the equivalent encodings shown in Proposition 5, while INC_C restricts the search process to a non empty labelling (this is non restrictive due to the check of line 34). The search process is carried out by two nested **repeat-until** loops. Roughly, the inner loop (lines 8–24) resembles a depth-first search which, starting from a non-empty complete labelling in C, produces a sequence of complete labellings in C strictly ordered by set inclusion. When the sequence can no more be extended, its last element corresponds to a complete labelling in C maximizing the set of `in`-labelled arguments, namely to a preferred labelling. The outer loop (lines 5–33) drives the search: it ensures, through proper settings of the variables, that the inner loop is entered with different initial conditions, so that all preferred labellings in C are found.

The following theorem shows that Algorithm 4 is correct.

Theorem 2. *Given an AF $\Gamma = \langle \mathcal{A}, \mathcal{R} \rangle$ and a set $C \subseteq \mathcal{A}$, Algorithm 4 returns $\mathcal{L}_{\mathcal{PR}}(\Gamma, C)$.*

Algorithm 4 Enumerating the preferred labellings in a set C of a AF

35: $\quad E_p = \{(\mathbf{a}, \texttt{undec}) \mid \mathbf{a} \in \mathcal{A}\}$
36: **end if**
37: **return** E_p

The Empirical Analysis

In this section, we present the results of a large experimental study examining the reduction of computational effort in enumerating preferred extensions due to the application of the proposed meta-algorithm (Alg. 1) instantiated with Alg. 4 as B-PR.

Experimental Setup

The experiments were performed on AMD Opteron™ 2.4 Ghz, 8 Gb of RAM and Linux operating system. As in the International Planning Competition (IPC) (Jiménez et al. 2012), a limit of 15 minutes was imposed to compute the preferred labellings for each AF. No limit was imposed on the RAM usage, but a run fails at saturation of the available memory. Moreover, we adopted the IPC speed score,

also borrowed from the planning community, which is defined as follows. For each AF, each system gets a score of $1/(1+\log_{10}(T/T^*))$, where T is its execution time and T^* the best execution time among the compared systems, or a score of 0 if it fails in that case. Runtimes below 0.01 sec get by default the maximal score of 1.

In order to evaluate PREF, we compared it with the implementation of the approach discussed in (Cerutti et al. 2014), which has been proved to be competitive w.r.t other state-of-the-art systems. In the following we refer to SCC-P as the prototype implementing the algorithm PREF with C_2 and NC_2, and SAT-P as the current version (rev. 128) of the software presented in (Cerutti et al. 2014) with C_2. We chose to compare SCC-P not with the implementation of Alg. 4 called as PREF$(\Gamma, \mathcal{A})$, but with SAT-P in order to give additional strength to this empirical evaluation. Both SCC-P and SAT-P are implemented in C++ and both adopt Glucose (Audemard and Simon 2009; 2012) as integrated SAT solver.

We designed three experiments aimed at addressing the following hypotheses:

$I1$: on Γ s.t. $|\text{SCC}_\Gamma| = 1$, SCC-P performs worse than SAT-P;

$I2$: there exists a value χ such that on Γ where $|\text{SCC}_\Gamma| > \chi$, SCC-P performs better that SAT-P;

$I3$: on Γ s.t. $|\text{SCC}_\Gamma| > \chi$, the greater $|\mathcal{E}_{\mathcal{PR}}(\Gamma)|$, the more SAT-P performs worse than SCC-P.

To check the first hypothesis, we conducted an experiment on 790 randomly generated AFs (Γ), s.t. $|\text{SCC}_\Gamma| = 1$, varying $\mathcal{A}$ between 25 and 250 with a step of 25.

Coming to the second hypothesis, we randomly generated 720 AFs varying $|\text{SCC}_\Gamma|$ between 5 and 45 with a step of 5. The size of the SCCs is determined by normal distributions with means between 20 and 40 with a step of 5, and with a fixed standard deviation of 5. We similarly varied the probability of having attacks between arguments among SCCs.

Finally, we addressed the third hypothesis conducting an experiment on 2800 AFs randomly generated as before, such that $50 \leq |\text{SCC}_\Gamma| \leq 80$ with a step of 5.

In the following we rely on the Wilcoxon Signed-Rank Test (WSRT) in order to identify significant subset of data.

Experiments on Γ s.t. $|\text{SCC}_\Gamma| = 1$

Figure 1 depicts the significant ($p < 0.05$) IPC values (normalised to 100) for SCC-P and SAT-P when $|\text{SCC}_\Gamma| = 1$ varying $|\mathcal{A}|$ and $|\mathcal{E}_{\mathcal{PR}}(\Gamma)|$. From this, we can observe that there is a significant statistical evidence supporting hypothesis $I1$. It is worth to mention that when $|\text{SCC}_\Gamma| = 1$, PREF (i) identifies the presence of a single SCC, (ii) calls the B-PR on the single computed SCC. Since B-PR is a variation (cf. Alg. 4) of the algorithm SAT-P, the great difference of performance shown in Fig. 1 suggests that refining the prototypical implementation we used in these experiments would lead to better results.

Experiments on Γ s.t. $5 \leq |\text{SCC}_\Gamma| \leq 45$

Figure 2 summarises the results obtained in the experiment aimed at proving hypothesis $I2$, about the existence of a number χ such that on Γ with $|\text{SCC}_\Gamma| > \chi$, SCC-P performs better than SAT-P.

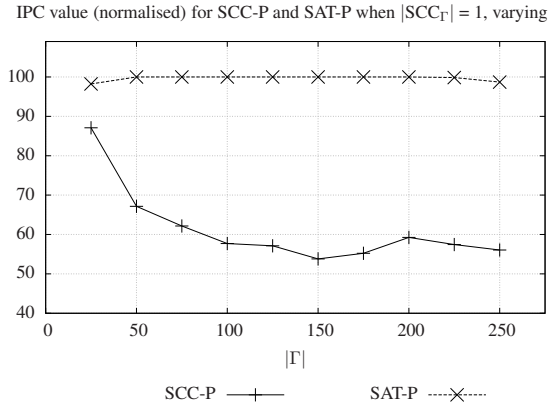

Figure 1: Significant ($p < 0.05$) IPC values (normalised) for SCC-P and SAT-P when $|\text{SCC}_\Gamma| = 1$ varying $|\mathcal{A}|$.

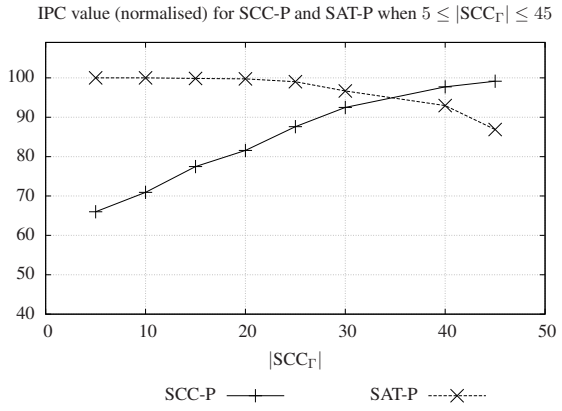

Figure 2: Significant ($p < 0.05$) IPC values (normalised) for SCC-P and SAT-P when $5 \leq |\text{SCC}_\Gamma| \leq 45$ varying $|\text{SCC}_\Gamma|$.

In particular, it turns out that:

- for $|\text{SCC}_\Gamma| = 30$, $Md(\text{SCC-P}) = 6.43$, $Md(\text{SAT-P}) = 5.63$, $z = -2.87$, $p < 0.01$;
- for $|\text{SCC}_\Gamma| = 35$, $Md(\text{SCC-P}) = 8.81$, $Md(\text{SAT-P}) = 8.53$, $z = -0.35$, $p = 0.73$;
- for $|\text{SCC}_\Gamma| = 40$, $Md(\text{SCC-P}) = 10.49$, $Md(\text{SAT-P}) = 12.53$, $z = -3.56$, $p < 0.01$;

where $Md(\cdot)$ indicates the median of execution times.

In other terms, when $|\text{SCC}_\Gamma| = 35$, the performances of SCC-P and SAT-P are statistically indistinguishable ($p = 0.73 > 0.05$). However, for $|\text{SCC}_\Gamma| > 35$, Fig. 2 shows that SCC-P performs significantly ($p < 0.05$) better than SAT-P.

Experiments on Γ s.t. $50 \leq |\text{SCC}_\Gamma| \leq 80$

Figure 3 depicts the medians of significant execution times of SCC-P and SAT-P varying the number of computed labellings. It illustrates a dependency of the execution times

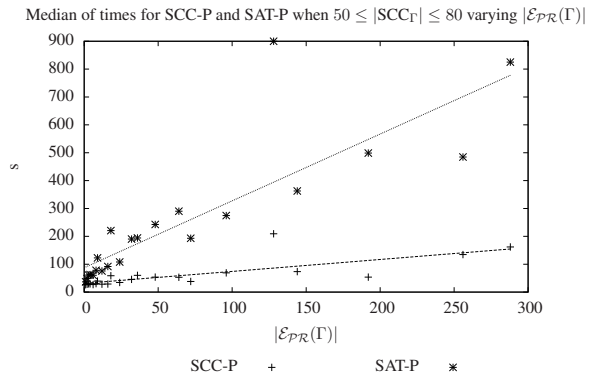

Figure 3: Significant median values for SCC-P and SAT-P when $50 \leq |\text{SCC}_\Gamma| \leq 80$ varying $|\mathcal{E}_{\mathcal{PR}}(\Gamma)|$, and their regression to the function $f(x) = a\ x + b$: SCC-P, $a = 0.43$, $b = 31.33$; SAT-P, $a = 2.40$, $b = 87.53$.

on the number of computed preferred labellings. Given the linear regression of these data, it turns out that the execution times of SAT-P grows $\approx 2 \cdot |\mathcal{E}_{\mathcal{PR}}(\Gamma)|$, while SCC-P grows $\approx \frac{1}{2} \cdot |\mathcal{E}_{\mathcal{PR}}(\Gamma)|$, thus supporting hypothesis $I3$.

Moreover, the third experiment provides additional statistically significant ($p < 0.05$) evidence in support of hypothesis $I2$, as Figure 3 summarises. Roughly speaking, computing the increment of performance as the average of the difference of execution times normalised on the maximum time between SCC-P and SAT-P, we can conclude that there is a significant increment of performances up to 56%.

Conclusions

In this paper we devised and evaluated a general parametric algorithm in order to decompose the preferred extensions enumeration problem into restricted subframeworks. To this purpose, several research challenges have been tackled.

First, an efficient algorithmic implementation of the SCC-recursive schema, originally introduced in a declarative form, has been developed, also leading to a labelling-based formulation. Let us notice that, recently, an approach has been proposed in (Liao, Lei, and Dai 2013) which partially exploits the SCC-recursive schema. In particular, while it borrows from (Baroni, Giacomin, and Guida 2005) the idea of decomposing the argumentation framework into its SCCs, it does not exploit the recursion step to achieve a deeper decomposition of the AF. Other "splitting" techniques have been proposed in literature. In particular, in the context of argumentation dynamics (Baumann et al. 2012) introduces a decomposition of an argumentation framework into two parts, while (Dvořák, Pichler, and Woltran 2012) exploits a tree-based decomposition. A general study of decomposability properties w.r.t. arbitrary partitions of an argumentation framework is also presented in (Baroni et al. 2012). Comparing different approaches for dividing an AF in subframeworks represents an interesting future work.

A second contribution of the present paper is the generalization of the approach in (Cerutti et al. 2014) to the computation of labellings in a restricted sub-framework, which is mandatory for applying the SCC-recursive schema. As acknowledged in (Cerutti et al. 2014), the relationship between argumentation semantics and the satisability problem has been already considered in the literature, e.g. in (Besnard and Doutre 2004; Dvořák et al. 2012; Arieli and Caminada 2013), where different encodings for labellings of an AF according to several semantics have been introduced. Generalizing these proposals in order to integrate them into the SCC-recursive schema is another challenge for future work.

Finally, an empirical investigation has been carried out to show a statistical evidence in favour of the reduction of computational effort by the exploitation of the SCC-recursive schema. In particular, as shown in the previous section, despite the fact that the current prototypical implementation needs further refinements (cf. the results of experiments on Γ s.t. $|\text{SCC}_\Gamma| = 1$), for Γ with $|\text{SCC}_\Gamma| > \chi = 35$ there is a statistical evidence showing how implementing the SCC-recursive schema reduces the computational effort of enumerating the preferred labellings. Moreover, as depicted in Fig. 3, the execution time of the SCC-recursive implementation is less sensible to the number of labellings, i.e. its execution time grows less than the non SCC-recursive implementation when the number of computed preferred labellings increases. This suggests to explore an hybrid approach where, at each recursion step, a choice is made on whether computing the preferred labellings with a direct call to B-PR or applying the SCC-recursive schema. Such choice can be based on an heuristic to estimate the number of SCCs and labellings, and can be easily implemented with an additional step after line 5 of Alg. 2.

Several other future works are envisaged. First, we want to strengthen the statistical evidence in favour of the SCC-recursive schema by exploiting and comparing different encodings of complete labellings derived from ENC_{all}, including the redundant ones. Moreover, Alg. 2 can be instantiated with a different B-PR algorithm, e.g. generalizing the algorithms presented in (Egly, Alice Gaggl, and Woltran 2010; Nofal, Atkinson, and Dunne 2014; Dvořák et al. 2014) for computing labellings in sub-frameworks.

Finally, we intend to apply the devised meta-algorithm to stable and CF2 semantics, which directly fit the SCC-recursive schema (Baroni, Giacomin, and Guida 2005), as well as to semi-stable and ideal semantics by exploiting the relationship with preferred semantics.

Abstract

In this paper, we investigate the revision of argumentation systems à la Dung. We focus on revision as minimal change of the arguments status. Contrarily to most of the previous works on the topic, the addition of new arguments is not allowed in the revision process, so that the revised system has to be obtained by modifying the attack relation only. We introduce a language of revision formulae which is expressive enough for enabling the representation of complex conditions on the acceptability of arguments in the revised system. We show how AGM belief revision postulates can be translated to the case of argumentation systems. We provide a corresponding representation theorem in terms of minimal change of the arguments statuses. Several distance-based revision operators satisfying the postulates are also pointed out, along with some methods to build revised argumentation systems. We also discuss some computational aspects of those methods.

Introduction

In this paper, we investigate the revision issue for abstract argumentation systems à la Dung (Dung 1995). Argumentation systems are directed graphs, where nodes correspond to arguments and arcs to attacks between arguments. In such systems, the status (acceptance) of each argument depends on the chosen acceptability semantics (grounded, preferred, stable – among others).

In his book, Gärdenfors (1988) introduced abstractly belief change as the operation allowing to change the epistemic status of a piece of information with respect to the epistemic state of an agent. There are three possible statuses: accepted, rejected or undetermined. And revision, contraction and expansion are defined as the possible transitions between these statuses, as illustrated by Figure 1.

In order to instantiate Gärdenfors' general definition of belief change within Dung's argumentation theory, it is first necessary to define what are the available pieces of information and what these statuses mean. In Dung's argumentation theory, the basic pieces of information are the arguments of the system, and their statuses depend on the acceptability semantics under consideration. Thus, following Gärdenfors, it does not make sense to study the revision of argumentation systems directly on the attack graph, independently of any semantics. Stated otherwise, the revision of a given argumentation system under two different semantics may easily lead to two different results. For instance, in the case of the argumentation system AF given in Figure 2, we note that under the stable and preferred semantics, d belongs to every extension, whereas d does not belong to any extension in the case of the grounded semantics. So, revising AF in order to accept d does not need any change for the stable or the preferred semantics, but a change is required for the grounded semantics.

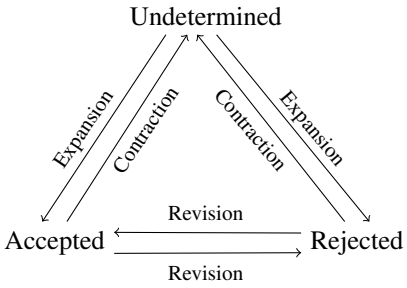

Figure 1: Gärdenfors' epistemic transitions

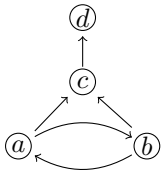

Figure 2: Revising AF may lead to different results.

In this paper, we focus on revision as minimal change of the arguments statuses. To be more precise, under a chosen semantics, given an argumentation system and a revision formula expressing how the statuses of some arguments has to be changed, we want to derive argumentation systems which satisfy the revision formula, and are such that the corresponding extensions are as close as possible to the extensions of the input system. In most of the previous works on the topic, the change in the input system is a

modification of the set of arguments. Contrarily to those works, we do not allow the addition of new arguments in the revision process, so that the revised system has to be obtained by modifying the attack relation, only. Especially, the revision formula does not indicate *why* the statuses of arguments have changed, which makes sense in cases when the agent learns an unjustified information from a trustworthy source. More details can be found in Section "Discussion".

Minimal change of the attack graph can be considered as a criterion for defining the revised systems, but the acceptance statuses of arguments is more fundamental information. Accordingly, ensuring a minimal change of these statuses is more important than (and not compatible with)[1] ensuring a minimal change of the attack graph.

To ensure such a minimal change of arguments statuses, we define revision as two step process: first, we revise extensions, without considering the attack relation. Then, from the output of this first step, we generate argumentation systems such that their extensions are the expected ones. This second step may use minimal change on the argumentation graph, as a second criterion.

The rest of the paper is organized as follows. After a short introduction to Dung's theory of abstract argumentation, we introduce a language of revision formulae which is expressive enough for enabling the representation of complex conditions on the acceptability of arguments in the revised system. Then we show how AGM belief revision postulates can be translated to the case of argumentation systems. We provide a corresponding representation theorem in terms of minimal change of the arguments statuses. Several distance-based revision operators satisfying the postulates are pointed out. Then we present methods for associating argumentation systems with the obtained sets of extensions. We discuss some computational aspects of the revision process. Proofs are omitted for space reasons.

Preliminaries

We start with a very short introduction to Dung's theory of argumentation (see (Dung 1995) for more details). A (finite) argumentation system (also referred to as an argumentation framework) is a pair $AF = \langle A, R\rangle$ where A is a (finite and non empty) set of so-called arguments and R is a binary relation over A (a subset of $A \times A$). In the following, A is supposed to contain at least two elements and the attack relation R is supposed to be irreflexive, i.e., self-contradicting arguments are rejected. AFs_A denotes the set of all such systems on the set of arguments A.

Arguments and attacks are considered in an abstract way as atomic concepts. Especially we do not assume any underlying logical setting in which arguments and attacks would be defined.

An argument $a \in A$ is acceptable with respect to a set of arguments $S \subseteq A$ whenever it is defended by S, i.e., for every $b \in A$ s.t. $(b, a) \in R$, there exists $c \in S$ such that $(c, b) \in R$. We say that a subset S of A is conflict-free if and only if for every $a, b \in S$, we have $(a, b) \notin R$. A subset S of A is admissible for AF if and only if S is conflict-free and acceptable with respect to S. "Solutions" of an argumentation systems are sets S of arguments accepted together. Some semantics σ (especially, the complete, the preferred, the stable, and the grounded semantics) can be considered for capturing formally this notion, and each of them gives rise to a specific notion of extension. For instance:

- S is a complete extension of AF if and only if it is an admissible set and every argument which is acceptable with respect to S belongs to S,
- S is a preferred extension of AF if and only if it is maximal (with respect to set inclusion) in the set of admissible sets for AF,
- S is a stable extension of AF if and only if S is conflict-free and $\forall a \in A \setminus S$, $\exists b \in S$ such that $(b, a) \in R$,
- S is the grounded extension of AF if and only if it is the smallest element (with respect to set inclusion) among the complete extensions.

$Ext_\sigma(AF)$ denotes the set of extensions of AF for the semantics σ. In this work, we focus on the skeptical policy to define the epistemic status of an argument. Thus, the epistemic status of any argument $a \in A$ with respect to the epistemic state represented by AF is given by: a is accepted if a belongs to every $\varepsilon \in Ext_\sigma(AF)$, a is refused if a does not belong to any $\varepsilon \in Ext_\sigma(AF)$, and a is undefined in the remaining case.

Moreover, we use the following notation about minimal elements of a set. For any pre-order $\leq$ over a set E, $<$ denotes the strict part of $\leq$ and $\simeq$ denotes the indifference relation associated with $\leq$. Given a set E and a pre-order $\leq$, the minimal elements of E w.r.t. $\leq$ are $\min(E, \leq) = \{e \in E | \nexists e' \in E, e' < e\}$.

On Revision Formulae

We want to define a revision setting for Dung's argumentation systems in which sophisticated revision formulae can be taken into account, and not only the fact that a given argument should be accepted or refused. To this end, we consider a logical language $\mathcal{L}_A$, where negation is used to denote the fact that a given argument should be refused, and formulae can be connected using conjunction and disjunction.

Definition 1. *Given $A = \{\alpha_1, \ldots, \alpha_k\}$ a set of arguments, $\mathcal{L}_A$ is the language generated by the following context-free grammar in BNF:*

$$\begin{array}{lll} arg & ::= & \alpha_1 | \ldots | \alpha_k \\ \Phi & ::= & arg | \neg\Phi | (\Phi \wedge \Phi) | (\Phi \vee \Phi) \end{array}$$

For instance, $\varphi_1 = (a \wedge b \wedge c) \vee (a \wedge \neg b \wedge \neg c)$ expresses that in the revised epistemic state, a must be accepted and b and c must be both accepted or both refused. The epistemic status of such a formula φ from $\mathcal{L}_A$ in an argumentation system $AF \in \mathsf{AFs}_A$ for a given semantics σ is given by:

Definition 2. *Let $\varepsilon \subseteq A$ and $\varphi \in \mathcal{L}_A$. The concept of* satisfaction *of φ by ε, noted $\varepsilon \mid\!\sim \varphi$, is defined inductively as follows:*

[1] See Section "Revision at the System Level" for details.

- *If* $\varphi = a \in A$*, then* $\varepsilon \vdash\!\sim \varphi$ *iff* $a \in \varepsilon$*,*
- *If* $\varphi = (\varphi_1 \wedge \varphi_2)$*,* $\varepsilon \vdash\!\sim \varphi$ *iff* $\varepsilon \vdash\!\sim \varphi_1$ *and* $\varepsilon \vdash\!\sim \varphi_2$*,*
- *If* $\varphi = (\varphi_1 \vee \varphi_2)$*,* $\varepsilon \vdash\!\sim \varphi$ *iff* $\varepsilon \vdash\!\sim \varphi_1$ *or* $\varepsilon \vdash\!\sim \varphi_2$*,*
- *If* $\varphi = \neg\psi$*,* $\varepsilon \vdash\!\sim \varphi$ *iff* $\varepsilon \not\vdash\!\sim \psi$*.*

Then for any AF *in* AFs_A*, and any semantics* σ*, we say that:*

- φ *is* accepted *w.r.t.* AF*, noted* $AF \vdash\!\sim_\sigma \varphi$*, if* $\varepsilon \vdash\!\sim \varphi$ *for every* $\varepsilon \in Ext_\sigma(AF)$*,*
- φ *is* refused *w.r.t.* AF*, noted* $AF \vdash\!\sim_\sigma \neg\varphi$*, if* $\varepsilon \vdash\!\sim \varphi$ *for no* $\varepsilon \in Ext_\sigma(AF)$*,*
- φ *is* undefined *w.r.t.* AF *in the remaining case.*

Inference $\vdash\!\sim_\sigma$ *can be extended to the case of a set* S *of argumentation systems by considering* $Ext_\sigma(S) = \bigcup_{AF \in S} Ext_\sigma(AF)$*.*

This language, used in next sections to define the revision of an argumentation framework, allows to change the status of an information φ to accepted (revise by φ) or rejected (revise by $\neg\varphi$), but not to undetermined. It is normal: Gärdenfors defines the change of status of a belief from accepted or rejected to undetermined as a *contraction*, as explained in the Introduction (see Fig. 1).

From now on we call *candidate*[2] any subset ε of A. Candidates can be interpreted as *interpretations* of revision formulae. Continuing the previous example, if $A = \{a, b, c\}$, φ_1 is satisfied by the candidates from $\{\{a\}, \{a, b, c\}\}$. Thus, for the grounded semantics, φ_1 is accepted w.r.t. AF_1 with $R_1 = \{(b, c), (c, b)\}$ but is refused w.r.t. AF_2 with $R_2 = \{(a, b), (b, a)\}$.

We define consistency in a classical way:

Definition 3. *Given a formula* φ*,* $\mathcal{A}_\varphi$ *denotes the set of candidates satisfying* φ*.* φ *is said to be* consistent *iff* $\mathcal{A}_\varphi \neq \emptyset$*.*

In the general case, $\mathcal{A}_\varphi$ is not the set of all σ-extensions of an AF in AFs_A. Consider for instance, $A = \{a, b, c\}$ and $\varphi_1 = (a \wedge b \wedge c) \vee (a \wedge \neg b \wedge \neg c)$. $\mathcal{A}_{\varphi_1} = \{\{a\}, \{a, b, c\}\}$, and there is no AF in AFs_A such that $Ext_\sigma(AF) = \mathcal{A}_{\varphi_1}$ for $\sigma =$ grounded, $\sigma =$ preferred or $\sigma =$ stable.

In this case, it is enough to choose two argumentation frameworks to cover the extensions $\{\{a\}, \{a, b, c\}\}$ (for instance, in the first AF a attacks b and c, and in the second AF the attack relation is empty). Note that in the general case, increasing the number of frameworks is not enough to capture the expected extensions. In order to characterize formulae that can be associated to a set of frameworks and a semantics, a concept of σ-representability can be defined as follows:

Definition 4. *A set* $\mathcal{C}$ *of candidates is* σ-representable *iff there exists a set* $\mathcal{S}$ *of argumentation systems in* AFs_A *such that* $C = Ext_\sigma(S)$*.*
A formula $\varphi \in \mathcal{L}_A$ *is* σ-representable *iff* $\mathcal{A}_\varphi$ *is* σ-representable*.*

When $A = \{a, b, c\}$, $\varphi_1 = (a \wedge b \wedge c) \vee (a \wedge \neg b \wedge \neg c)$ is σ-representable for $\sigma =$ grounded, $\sigma =$ preferred or $\sigma =$ stable since $\{\{a\}, \{a, b, c\}\} = Ext_\sigma(AF_3) \cup Ext_\sigma(AF_4)$ where $R_3 = \{(a, b), (a, c)\}$ and $R_4 = \emptyset$. Contrastingly, $\varphi_2 = \neg a \wedge \neg b \wedge \neg c$ is grounded-representable and preferred-representable but not stable-representable. $\varphi_3 = a \wedge \neg a$ is neither grounded-representable nor preferred-representable, but is stable-representable (consider AF_5 such that $R_5 = \{(a, b), (b, c), (c, a)\}$).

A form of consistency can be defined to take account for the semantics:

Definition 5. *Given* σ *a semantics, a formula* $\varphi \in \mathcal{L}_A$ *is* σ*-consistent iff* φ *is consistent and* φ *is* σ*-representable.*

From σ-consistency, we define a notion of model:

Definition 6. *Given a formula* $\varphi \in \mathcal{L}_A$ *and a semantics* σ*, the set of models of* φ *is defined by*

$$\mathcal{A}^\sigma_\varphi = \{\varepsilon \in \mathcal{A}_\varphi | \{\varepsilon\} \textit{ is } \sigma\textit{-representable}\}.$$

A last point about formulae is the definition of equivalence. Two formulae $\varphi, \psi \in \mathcal{L}_A$ are said σ-equivalent, noted $\varphi \equiv_\sigma \psi$, if and only if $\mathcal{A}^\sigma_\varphi = \mathcal{A}^\sigma_\psi$.

Revision at the Extension Level

In order to define revision operators, our approach follows a two-step process. Intuitively, the process first selects from models of φ those as close as possible to the σ-extensions of AF. This selection has to ensure the minimal change of arguments statuses. Then, the second step generates the argumentation systems such that the union of their σ-extensions precisely coincides with the selected candidates.

We define a revision operator on argumentation systems as a mapping associating a set of argumentation systems with the input argumentation system and the input revision formula:

Definition 7. *Given any set of arguments* A*, a* revision operator *on argumentation systems* $\star$ *is a mapping from* $\mathsf{AFs}_A \times \mathcal{L}_A$ *to* 2^{AFs_A}*.*

Clearly, the result of the revision of an argumentation system is not a unique argumentation system in the general case, but a set of argumentation systems. The reason is quite simple: there can be several possible results which have exactly the same maximum plausibility. So in this case there is no reason to select just one of them (we will return to this point later on). If this is problematic for a particular application, a selection function can be used as a tie-break rule for ensuring the unicity of the result (just like, for instance, the maxichoice selection function considered in AGM belief revision (Gärdenfors 1988)).

Of course, each mapping from $\mathsf{AFs}_A \times \mathcal{L}_A$ to 2^{AFs_A} is not a reasonable revision operator. For instance, the constant, yet trivial operator defined by $AF \star \varphi = \emptyset$ should be discarded.

In order to identify interesting revision operators, we have to identify the logical properties which guarantee a rational behaviour. Such an axiomatic approach is standard in

[2] That is to say "candidate to be an extension".

logic, and the AGM postulates (Alchourrón, Gärdenfors, and Makinson 1985; Katsuno and Mendelzon 1991) have been pointed out for characterizing valuable revision operators in a logical setting. As in (Qi, Liu, and Bell 2006), we can revisit these postulates in a set-theoretic framework, here suited to the argumentation case.

Let $\mathcal{S}$ be a set of argumentation systems AF in AFs_A. The counterpart of AGM postulates in the argumentation case is given by:

(AE1) $Ext_\sigma(AF \star \varphi) \subseteq \mathcal{A}^\sigma_\varphi$

(AE2) If $Ext_\sigma(AF) \cap \mathcal{A}^\sigma_\varphi \neq \emptyset$, then $Ext_\sigma(AF \star \varphi) = Ext_\sigma(AF) \cap \mathcal{A}^\sigma_\varphi$

(AE3) If φ is σ-consistent, then $Ext_\sigma(AF \star \varphi) \neq \emptyset$

(AE4) If $\varphi \equiv_\sigma \psi$, then $Ext_\sigma(AF \star \varphi) = Ext_\sigma(AF \star \psi)$

(AE5) $Ext_\sigma(AF \star \varphi) \cap \mathcal{A}^\sigma_\psi \subseteq Ext_\sigma(AF \star (\varphi \wedge \psi))$

(AE6) If $Ext_\sigma(AF \star \varphi) \cap \mathcal{A}^\sigma_\psi \neq \emptyset$, then $Ext_\sigma(AF \star (\varphi \wedge \psi)) \subseteq Ext_\sigma(AF \star \varphi) \cap \mathcal{A}^\sigma_\psi$

(AE1) states that the σ-extensions of the resulting set of argumentation systems must be among the models of φ. **(AE2)** demands that if there are σ-extensions of the input system satisfying φ, then the resulting σ-extensions must coincide with them. **(AE3)** requires the resulting set of σ-extensions to be non-empty as soon as φ is σ-consistent. **(AE4)** concerns the irrelevance of syntax: the revision by two formulae must be identical if the formulae are equivalent. The last two postulates **(AE5)** and **(AE6)** express a minimal change principle with respect to the arguments statuses: changes of the statuses of the arguments are expected to be minimal with respect to the input system. In particular, these postulates give the expected behaviour of the operator when an argumentation system is revised by a conjunction of formulae.

Interestingly, as in the logical case, we can derive a representation theorem which characterizes exactly the revision operators satisfying the postulates in a more constructive way. To this end, we first need to present a counter-part of the notion of faithful assignment (Katsuno and Mendelzon 1991) in the argumentation setting:

Definition 8. *A* faithful assignment *is a mapping associating any argumentation system $AF = \langle A, R\rangle$ (under a semantics σ) with a total pre-order $\leq^\sigma_{AF}$ on the set of candidates such that:*

1. *if $\varepsilon_1 \in Ext_\sigma(AF)$ and $\varepsilon_2 \in Ext_\sigma(AF)$, then $\varepsilon_1 \simeq^\sigma_{AF} \varepsilon_2$,*
2. *if $\varepsilon_1 \in Ext_\sigma(AF)$ and $\varepsilon_2 \notin Ext_\sigma(AF)$, then $\varepsilon_1 <^\sigma_{AF} \varepsilon_2$.*

The representation theorem can then be stated as follows:

Proposition 1. *Given a semantics σ, a revision operator $\star$ satisfies the rationality postulates **(AE1)** - **(AE6)** iff there exists a faithful assignment which maps every system $AF = \langle A, R\rangle$ to a total pre-order $\leq^\sigma_{AF}$ so that*

$$Ext_\sigma(AF \star \varphi) = \min(\mathcal{A}^\sigma_\varphi, \leq^\sigma_{AF}).$$

This theorem is important for defining operators satisfying the rationality postulates, as the ones presented in the next section.

Distance-Based Revision

Let us now present some (pseudo-)distance-based revision operators satisfying the rationality postulates **(AE1)** - **(AE6)**.

Let d be any pseudo-distance[3] on 2^A, for instance, the Hamming distance given by $d_H(\varepsilon_1, \varepsilon_2) = |(\varepsilon_1 \setminus \varepsilon_2) \cup (\varepsilon_2 \setminus \varepsilon_1)|$. Given $\varepsilon \in 2^A$ and $\mathcal{E} \subseteq 2^A$, d can be extended to a "distance" between ε and $\mathcal{E}$, by stating that $d(\varepsilon, \mathcal{E}) = \min_{\varepsilon' \in \mathcal{E}} d(\varepsilon, \varepsilon')$. For any argumentation system $AF \in \mathsf{AFs}_A$, this distance induces a total pre-order between candidates $\varepsilon_1, \varepsilon_2 \in 2^A$ given by

$$\varepsilon_1 \leq^{\sigma,d}_{AF} \varepsilon_2 \text{ iff } d(\varepsilon_1, Ext_\sigma(AF)) \leq d(\varepsilon_2, Ext_\sigma(AF)).$$

On this ground, revision operators can be defined by:

Definition 9. *Let σ be any given semantics. A* pseudo-distance-based revision operator $\star^d$ *is any revision operator for which there exists a pseudo-distance d on 2^A such that for every AF and every φ, we have $Ext_\sigma(AF \star^d \varphi) = \min(\mathcal{A}^\sigma_\varphi, \leq^{\sigma,d}_{AF})$.*

Proposition 2. *Let σ be any semantics. Any pseudo-distance-based revision operator $\star^d$ satisfies the rationality postulates **(AE1)** - **(AE6)**.*

Let us now define another family of pseudo-distance-based operators, which take advantage of labellings. Let us first recall that, instead of using extensions, the solutions of an argumentation system can be expressed using the concept of labelling (Caminada 2006).

Formally, a labelling is a mapping L associating a label in, $undec$ or out with every argument of the set A. The stronger notion of reinstatement labelling depends on the attack relation R: an argument a is labelled in iff every argument attacking a is out; an argument a is out iff there exists an argument in attacking a; an argument is $undec$ iff it is neither in nor out. These reinstatement labellings correspond to Dung's complete extensions in a bijective way. Thus, for any complete extension ε, the associated reinstatement labelling is such that every argument $a \in \varepsilon$ is in, every argument attacked by an argument in is out, every other argument is $undec$. Conversely, for every reinstatement labelling L, the corresponding extension $E(L)$ is the set of arguments labelled in by the labelling. All usual semantics can also be encoded with labellings.

We introduce some notation: L_φ is the set of labellings L such that $E(L) \in \mathcal{A}^\sigma_\varphi$. Given a set of labellings Lab, $E(Lab) = \{E(L) | L \in Lab\}$. Finally, given a system AF and a semantics σ, $Labs_\sigma(AF)$ denotes the set of labellings corresponding to the σ-extensions of AF.

Labellings, which bring richer information than extensions, can be used to define interesting pseudo-distance-based revision operators. Indeed, consider the following notion of edition pseudo-distance:

[3] A pseudo-distance d on a set S is defined as a binary relation on S which satisfies:

- $d(x, y) = d(y, x)$;
- $d(x, y) = 0$ iff $x = y$.

Definition 10. *Let m, n, o be three integers and let L_1 and L_2 be two labellings.*
An edition pseudo-distance $d_{(m,n,o)}$ *between labellings is defined as:*

$$d_{(m,n,o)}(L_1, L_2) = \sum_{a \in A} ad(L_1(a), L_2(a)),$$

where

- $ad(in, in) = ad(out, out) = ad(undec, undec) = 0$
- $ad(in, out) = ad(out, in) = m$
- $ad(in, undec) = ad(undec, in) = n$
- $ad(out, undec) = ad(undec, out) = o$

Proposition 3. *Let m, n, o be three integers. $d_{(m,n,o)}$ is a pseudo-distance.*

Interestingly, these edition pseudo-distances are not necessarily neutral or symmetric. We call neutral an edition pseudo-distance such that $ad(in, undec) + ad(undec, out) = ad(in, out)$ and symmetric a pseudo-distance such that $ad(in, undec) = ad(undec, out)$. Defining non-symmetric edition pseudo-distances is a way for instance to favor acceptance of arguments over rejection (see Example 1).

For any pseudo-distance $d_{\mathcal{L}}$ between labellings, we can define a pre-order $\leq_{AF}^{\sigma, d_{\mathcal{L}}}$ between labellings as we did it for candidates:

$L_1 \leq_{AF}^{\sigma, d_{\mathcal{L}}} L_2$ iff $d_{\mathcal{L}}(L_1, L_\sigma(AF)) \leq d_{\mathcal{L}}(L_2, L_\sigma(AF))$.

Definition 11. *Let σ be any given semantics. A* labelling-pseudo-distance-based revision operator $\star_{d^{\mathcal{L}}}$ *is any revision operator for which there exists a pseudo-distance $d^{\mathcal{L}} = d_{(m,n,o)}$ on 2^A such that for every AF and every φ, we have $Labs_\sigma(AF \star_{d^{\mathcal{L}}} \varphi) = \min(L_\varphi, \leq_{AF}^{\sigma, d_{\mathcal{L}}})$.*

The following example illustrates the impact of the chosen pseudo-distance on the revised system:

Example 1. *Let σ be the stable semantics. We revise the system AF_6 below by the formula $\varphi = (\neg d \wedge \neg e)$.*

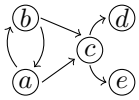

Figure 3: The system AF_6

$Ext_\sigma(AF_6) = \{\{a, d, e\}, \{b, d, e\}\}$, the associated stable labellings are $\{(a, in), (b, out), (c, out), (d, in), (e, in)\}$ and $\{(a, out), (b, in), (c, out), (d, in), (e, in)\}$. When we revise AF_6 by φ using the pseudo-distance-based operator induced by the pseudo-distance $d_{(1,9,10)}$ on labellings, the obtained result is a system with the following labellings: $\{(a, in), (b, out), (c, out), (d, out), (e, out)\}$ and $\{(a, out), (b, in), (c, out), (d, out), (e, out)\}$. When the pseudo-distance $d_{(9,1,10)}$ is used, we get $\{(a, in), (b, out), (c, out), (d, undec), (e, undec)\}$ and $\{(a, out), (b, in), (c, out), (d, undec), (e, undec)\}$ as labellings of the result systems.

If the second step of the process, i.e. the generation of the resulting argumentation systems, as expected, takes account for the labellings, the structure of the resulting graphs will be different: when the refused arguments are out, it means that there exists an attack from an accepted argument to a refused argument. When the arguments are $undec$, those attacks do not exist.
With the first pseudo-distance $d_{(1,9,10)}$, it is cheaper to change an argument from in to out than to $undec$. Such a pseudo-distance allows for choosing candidates which refuse arguments. Contrarily, the pseudo-distance $d_{(9,1,10)}$ allows for choosing candidates which accept more arguments.

Like operators based on extensions, pseudo-distance-based operators using labelling exhibit good logical properties:

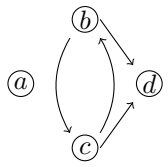
Proposition 4. *Let σ be any semantics. Any labelling-pseudo-distance-based revision operator $\star_{d^{\mathcal{L}}}$ satisfies the rationality postulates **(AE1)** - **(AE6)**.*

Revision at the System Level

The operators defined in the previous section focus on the candidates that are as close as possible to the extensions of the input system. However, they do not indicate how to generate the corresponding argumentation systems, *i.e.*, the argumentation systems such that the union of their extensions coincides with the selected candidates. This task is the second step in the definition of the revision operator.

In order to achieve this task, we consider a mapping $\mathcal{AF}_\sigma$ from $2^{2^{\mathcal{A}}}$ to 2^{AFs_A}, called generation operator, that associates with any set $\mathcal{C}$ of candidates a set of argumentation systems such that $Ext_\sigma(\mathcal{AF}_\sigma(\mathcal{C})) = \mathcal{C}$.

An important point we would like to discuss is the fact that a revision operator $\star$ outputs a set of argumentation systems, and not a single argumentation system in the general case. Actually, this is a consequence of the expressiveness of the language of revision formulae we want to consider. In order to illustrate it, consider $A = \{a, b, c, d\}$, and AF_7 as represented in Figure 4.



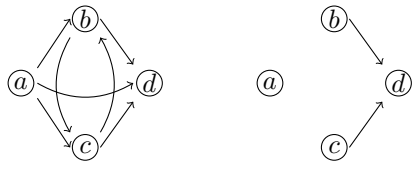


Figure 4: The system AF_7

AF_8 AF_9

Figure 5: Revision of AF_7

The extensions of AF_7 are the same ones for the stable and preferred semantics, $Ext_\sigma(AF_7) = \{\{a, b\}, \{a, c\}\}$. Let $\varphi_4 = (\neg b \vee c) \wedge (\neg c \vee b)$. Observe that b and c play symmetric roles, both in AF_7 and in φ_4. When computing the result of the revision with the revision operator based on Hamming distance between candidates, we obtain two candidates $\{a\}$ and $\{a, b, c\}$. We present in the following generation operators leading to the two corresponding argumentation systems AF_8 (corresponding to candidate $\{a\}$) and AF_9 (corresponding to candidate $\{a, b, c\}$). Clearly, choosing one of these systems would require to accept some arbitrariness given the symmetric roles of b and c.

Let us now show that for every semantics σ, generation operators $\mathcal{AF}_\sigma$ do exist.

Proposition 5. *Whatever the semantics σ, for every non-empty set $\mathcal{C}$ of candidates from 2^A, such that $\emptyset \notin \mathcal{C}$, there exists a finite set $\mathcal{S} \subseteq \mathsf{AFs}_A$ such that $\mathcal{C} = Ext_\sigma(S)$.*

For instance, for every candidate C, we can build the naive system $\langle A, R_C\rangle$ with $R_C = \{(x, y) \in A \times A | x \in C, y \notin C\}$.

So now we can define our revision operators:

Definition 12. *Given a semantics σ, a faithful assignment that matches every argumentation system to a total pre-order $\leq^\sigma_{AF}$, and a generation operator $\mathcal{AF}_\sigma$, the corresponding revision operator $\star$ is defined by:*

$$AF \star \varphi = \mathcal{AF}_\sigma(\min(\mathcal{A}^\sigma_\varphi, \leq^\sigma_{AF})).$$

One of the key results of the paper is that:

Proposition 6. *Every revision operator $\star$ defined following Definition 12 satisfies the postulates **(AE1)-(AE6)**.*

By construction, our revision operators are ensured to deal with minimality of change of arguments statuses, but not with minimality of change of the attack relation. Indeed, the rationality postulates ask for preserving as much as possible the statuses of arguments in the input system: doing so while ensuring that the revision formula is satisfied does not usually imply a minimal change of the attack relation, and vice-versa. As a matter of illustration, consider the argumentation systems AF_{10}, AF_{11}, AF_{12}, and AF_{13}.

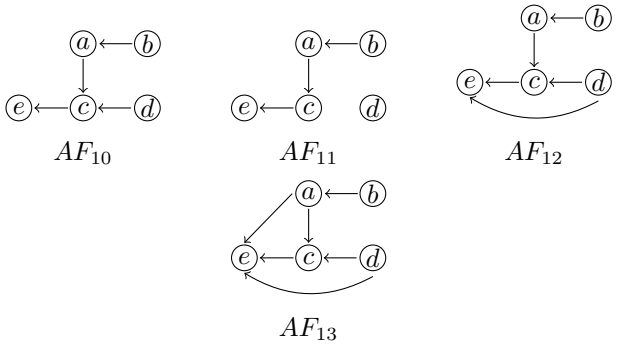

Figure 6: Minimal Change

Suppose that our goal is to reject e, that is to get a system so that e does not appear in any extension. So we consider the revision formula $\varphi_5 = \neg e$. A minimal change on the attack relation of AF_{10} leads to AF_{11} or AF_{12}: each of them differs with AF_{10} on a single attack. This contrasts with AF_{13} since the change on the attack relation required to go from AF_{10} to AF_{13} is strictly greater than the change on the attack relation required to go from AF_{10} to AF_{12}. Each of these four systems has a unique extension for the usual semantics[4]: $\{b, d, e\}$ for AF_{10}, $\{b, c, d\}$ for AF_{11}, and $\{b, d\}$ for AF_{12} and AF_{13}. Hence, the change on the statuses of arguments achieved when going from AF_{10} to AF_{12} or AF_{13} is strictly smaller than the change on the statuses of arguments achieved when going from AF_{10} to AF_{11}.

During the generation process, minimization can actually be considered in at least two ways: either minimizing change on the attack relation, or minimizing the number of output systems. In fact, these ways can be combined, either with a more important role to minimal change of the attack relation, or with a more important consideration for minimization of the cardinality.

Thus, a notion of minimal change on the attack relation can be defined through a notion of pseudo-distance dg on the attack relation. Such a pseudo-distance can be for instance the Hamming distance, given by $dg_H(AF_1, AF_2) = |(\mathcal{R}_1 \setminus \mathcal{R}_2) \cup (\mathcal{R}_2 \setminus \mathcal{R}_1)|$. The dg_H distance between two argumentation systems corresponds to the number of attacks that must be added or removed to make them identical. But we can consider more elaborated edition pseudo-distances such as those given in (Coste-Marquis et al. 2007). Each pseudo-distance dg induces a pre-order between argumentation systems, defined by $AF_1 \leq^{dg}_{AF} AF_2$ iff $dg(AF_1, AF) \leq dg(AF_2, AF)$.
We can easily extend this notion to a distance between a system AF and a set of systems AFs: $dg(AF, AFs) = \min_{AF_i \in AFs}(dg(AF, AF_i))$.

To give priority to minimal change on the attack relation, we define a generation operator that builds sets of argumentation systems which cover the candidates; then chooses the ones which minimize a function of the pseudo-distance dg; and finally retains the sets which are minimal in terms of cardinality.

Definition 13. *Given $\mathcal{C}$ a set of candidates, σ a semantics, dg a pseudo-distance between graphs and AF an argumentation system, $\mathcal{AF}^{dg,AF}_\sigma$ is defined as:*

$$\mathcal{AF}^{dg,AF}_\sigma(\mathcal{C}) = \bigcup\{AFs \in sets | card(AFs) \textit{ is minimal}\}$$

with

$$sets = \{AFs \quad | \quad Ext_\sigma(AFs) = \mathcal{C} \textit{ and } \sum_{AF_i \in AFs} dg(AF, AF_i) \textit{ is minimal}\}.$$

[4]For instance, for the complete, the preferred, the stable and the grounded semantics.

A second approach consists in giving priority to the minimality of the output cardinality. It builds first sets of systems that cover the set of candidates with a minimal number of systems, and then chooses the sets which minimize the change on the attack relation.

Definition 14. *Given $\mathcal{C}$ a set of candidates, σ a semantics, dg a pseudo-distance between graphs and AF an argumentation system, $\mathcal{AF}_\sigma^{card,AF}$ is defined by:*
$\mathcal{AF}_\sigma^{card,AF}(\mathcal{C}) = \bigcup\{AFs \in sets | \sum_{AF_i \in AFs} dg(AF, AF_i)$ *is minimal*$\}$
with

$$sets = \{AFs \quad | \quad Ext_\sigma(AFs) = \mathcal{C} \text{ and } card(AFs) \text{ is minimal}\}.$$

These two approaches are not equivalent:

Proposition 7. *The generation operators $\mathcal{AF}_\sigma^{dg,AF}$ and $\mathcal{AF}_\sigma^{card,AF}$ are distinct.*

Example 2. *Let us now give an example of revision with the approaches previously defined. The input system AF_{14} is given on Figure 7.*

Figure 7: The framework AF_{14}

Its unique stable extension is $\{a, b, c\}$. The revision formula is $\varphi_6 = (a \vee b) \wedge (\neg a \vee \neg b)$, the revision operators are $\star_{dg}$ such that

$$AF \star_{dg} \varphi = \mathcal{AF}_\sigma^{dg,AF}(\min(\mathcal{A}_\varphi^\sigma, \leq_{AF}^{\sigma,d_H}))$$

and $\star_{card}$ such that

$$AF \star_{card} \varphi = \mathcal{AF}_\sigma^{card,AF}(\min(\mathcal{A}_\varphi^\sigma, \leq_{AF}^{\sigma,d_H}))$$

both based on the Hamming distance on candidates and the Hamming distance on attack relations. Each one uses one of the previously defined generation operators.
Let us first compute the revised candidates. It is easy to find that $\{a, c\}$ and $\{b, c\}$ are the minimal models of φ_6 with respect to the Hamming distance and the stable extension of the input system.
Now we present the result for the two revision operators. When minimizing the change on attack relation, the generation step produces two argumentation systems, AF_{15} and AF_{16}, each one with a single difference from the input graph.

Figure 8: $AF_{14} \star_{dg} \varphi_6$

Contrastingly, the revision of AF_{14} with operator $\star_{card}$ gives as output a unique argumentation system AF_{17} with two differences with respect to the Hamming distance on the attack relation.

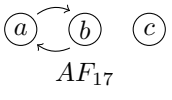

Figure 9: $AF_{14} \star_{card} \varphi_6$

While the two approaches exemplified here use the sum to aggregate the pseudo-distances, any aggregation function can be used instead. For instance, the $\min$, the $\max$, or any OWA (Ordered Weighted Average (Yager 1988)). These kind of aggregation function allows to combined distance and cardinality without giving priority to one of them. For instance, a specific ordered weighted average OWA_b is given by:

- $v(S) = (dg(AF_1, AF), \ldots, dg(AF_k, AF))$[5] with $S = \{AF_1, \ldots, AF_n\}$ and k the cardinal of the largest set (the vectors corresponding to smaller sets are normalized by adding the appropriate number of zeroes in front of the vector).
- $w_i = 2^{i-1}$
- $\text{OWA}_b(E) = \sum_{i=1}^k w_i v(E)[i]$

With the OWA_b function, a set of frameworks E_1 such that the vector of pseudo-distances is $v_1 = (1, 1, 4)$ is less preferred than a set E_2 with $v_2 = (1, 2, 3)$, because $\text{OWA}_b(E_1) = 19 > \text{OWA}_b(E_2) = 17$.
A set E_2, with three argumentation systems, can also be preferred to a set E_3 with only two systems, if those two systems are too far from the input systems. For instance, if the vector of pseudo-distances is $(1, 4)$, once normalized to $v_3 = (0, 1, 4)$, $\text{OWA}_b(E_3) = 18$, and so E_2 is still preferred in spite of its larger cardinality.

It is worthwhile to note that aggregation functions can also be used alone to define a generation operator. Given an aggregation function f, we define a pre-order $\leq_f$ such that $E_1 \leq_f E_2$ iff $f(E_1) \leq f(E_2)$. For any aggregation function on sets of argumentation systems, a generation operator is AF_σ^f given by

$$\mathcal{AF}_\sigma^f(\mathcal{C}) \in \min(\{E = \{AF_i\} | Ext_\sigma(E) = \mathcal{C}\}, \leq_f\}.$$

All proposed approaches cannot guarantee to produce a single set of argumentation systems. For instance, two sets may have the same cardinality and the same pseudo-distance from the input system with respect to the pseudo-distance dg.
The result can then be defined following one of the two options below:

- The result is defined as the union of all the sets. The reason is that these sets represent the uncertain result of the revision, so we keep all of them to avoid arbitrary choice. The main default of this method is that the size of the result is increased.
- A tie-break rule is used to select a single set of AFs. The agent is obliged to do an arbitrary choice. Note that it

[5] We suppose that the vector is sorted in increasing order.

does not prevent the revision operator from satisfying rationality postulates (because the postulates deal with extensions, not with attack relations).

Some Computational Aspects

A first interesting question concerns the size of the output of revision operators. The first step of the revision can lead to an exponential number of candidates, in terms of the number n of arguments in the input system. It is directly related to the revision formula. Given a pseudo-distance-based revision operator, the size of the output depends also on the generation operator which is used at the second step of the process. In the worst case, the number of argumentation systems which are generated is exponential in n:

Proposition 8. *If $\star$ is a revision operator based on the generation operator $\mathcal{AF}_{\sigma}^{dg,AF}$, then the size of $AF \star \varphi$ can be exponential in $|A|$.*

The complexity of the inference problem has also to be identified. Given a revision operator $\star$ for argumentation systems and a semantics σ, the *inference problem* from a revised argumentation system is the following decision problem:

- **Input:** An argumentation system AF on A, and two formulae $\varphi, \psi \in \mathcal{L}_A$.
- **Query:** Does $AF \star \varphi \mathrel{|\!\sim}_{\sigma} \psi$ hold?

Unsurprisingly, provided that σ ensures the existence of an extension for every AF, the inference problem from a revised argumentation system $AF \star \varphi$ is at least as hard as the inference problem from AF. In formal terms:

Proposition 9. *Let C be a complexity class which is closed under polynomial-time reductions. Suppose that $\star$ satisfies **(AE1)** to **(AE6)**, and that the semantics σ ensures the existence of an extension for every AF. If the inference problem from an argumentation system is C-hard, then the inference problem from a revised argumentation system is C-hard as well.*

Clearly enough, it can be the case that the inference problem from a revised argumentation system $AF \star \varphi$ is strictly harder than the inference problem from AF (unless $\mathsf{P} = \mathsf{NP}$). For instance, under the restriction when the queries ψ are restricted to arguments (or more generally, CNF formulae on A), it is easy to show that the inference problem from AF w.r.t. the grounded semantics can be solved in polynomial time. Contrastingly:

Proposition 10. *Suppose that $\star$ satisfies **(AE1)** and **(AE3)**. The inference problem from a revised argumentation system w.r.t. the grounded semantics is coNP-hard, even under the restriction when the queries ψ are restricted to CNF formulae on A.*

Our results show that the revision of argumentation systems is comparable to the revision of propositional formulae from a computational point of view. Especially, it may lead to harder computational problems: on the one hand, the revision of an argumentation system may require exponentially many systems for being represented (this is reminiscent to the non-compilability of some belief revision operators (Cadoli et al. 1999)); on the other hand, inference may also become harder (Nebel 1998).

Related Work

Some previous works have already considered the change issue for argumentation systems à la Dung. Thus, Boella, Kaci and Van der Torre, (2009a; 2009b) have studied abstraction and refinement principles. An abstraction is a reduction of the attack relation or of the set of arguments, whereas a refinement is the addition of attacks or arguments to the system. The authors focused on the study of semantics which ensure the existence of a unique extension (for instance, the grounded extension), and they formulated some principles of the form "if we do this particular change, then the extension of the result is like this". They identified some principles satisfied by the grounded semantics.

Cayrol, Dupin de Saint-Cyr and Lagasquie-Schiex (2010) studied the addition of an argument to an argumentation system. They stated some properties that can be satisfied when a change occurs in an argumentation system, and pointed out those which are satisfied (and under which conditions) when an argument (and the attacks concerning it) is added to the graph. With Bisquert, they did a similar study about the deletion of an argument (Bisquert et al. 2011).

In (Kontarinis et al. 2013), the authors studied the problem of minimal change to satisfy a goal based on arguments acceptance. The main difference between this work and our approach is that minimal change for them refers to the number of changes to perform on the attack relation, while we focus on arguments statuses.

Baumann (2012) also studied the minimal change problem in abstract argumentation. He reported some bounds on the number of modifications of the attack relation to make so as to enforce a given set of arguments. These bounds depend on the semantics and the type of change allowed.

Discussion

An abstract argumentation system à la Dung is defined by a set of arguments and an attack relation. All the works discussed in the previous section generate changes in an argumentation system by adding new arguments, while trying to minimize the modifications of the attack relation. Contrastingly, if we consider that the meaning of an argumentation system is given by the set of arguments that are accepted or rejected, then minimal change means to minimize the change on the (status of the) set of arguments.

Giving the priority on the minimization of the attack relation or on the minimization of the arguments status is really a question of considering the status of the arguments as first-class citizen of argumentation systems or only as a by-product of the graph. Whereas this last option received considerable attention these last years, there is no work except this one which concentrates on the first optic.

In addition, previous works also suppose that one can add as many arguments as one wants in order to modify the status of some arguments. In some cases this is perfectly sensible, but in other cases it is difficult to assume that such

arguments are available. Consider for instance the case of big society debates, where political parties, economists, and other specialists have already put forward all the arguments in favor of or against some decision (for example whether the state has to increase or decrease individual taxation). If a political leader wants to change the current decision, then he will need to be very brilliant in order to find an argument that has not been already pointed out by experts. More probably she will rather try to change the beliefs (or preferences) of the people on the fact that some arguments do or do not attack other ones.

Let us now mention some contexts where allowing only changes of the attack relation is very natural.

A first example of application for the revision process without adding new arguments is the reception of a unjustified but trustworthy information (which is a particular case of argument from authority). This scenario is frequent in applications of argumentation on social network debates (Gabbriellini and Torroni 2013). When an agent A initiates a debate about an argument α, if another agent B does not agree with A about α but considers that A is trustworthy, B has to revise her beliefs to accept α. In this case, agent B can change her beliefs even if agent A has not introduced a new argument in the debate. So, B has to reconsider the attacks between some arguments, but not the set of arguments itself.

A second example concerns applications of argumentation on public opinion, and is related to the society debates motivation we discussed above: suppose that an argumentation system represents the opinion of some groups of agents, where an attack between arguments exists if the majority of the group supports it. If a group leader wants to modify the statuses of arguments, then she can perform a revision of the input system. The resulting argumentation systems may help her to determine the attacks she has to focus on so as to modify the majoritarian opinion.

A third context concerns preference-based argumentation (see (Amgoud and Cayrol 2002)). In such argumentation systems some arguments attacks each other (in particular if the arguments are based on logical formulae and rebuttal, attack is symmetric), and the preference relation determines if an attack succeeds or not. So it is possible to modify the attack relation just by modifying the preferences of the agent. A similar case of revision can occur with value-based argumentation frameworks (Bench-Capon 2002): each argument is mapped to a value, and a value can be "stronger" than another. Comparison of values can lead an attack to fail. In this case, a change of values leads to a change of the (succeeding) attacks.

A final point we want to discuss is the fact that our revision methods output a set of argumentation systems instead of a single one. At the beginning of Section "Revision at the System Level", we advocated the fact that this is necessary to avoid arbitrary choices. We want to add that obtaining a set as result of a revision process is just usual in most belief revision settings. It is important to note that the canonical representation of AGM contraction/revision operators by use of relational partial-meet functions (Alchourrón, Gärdenfors, and Makinson 1985) defines the result of the process as a set of minimal theories. It turns out that the language used makes it possible to produce a single theory from this set using intersection (conjunction). But in languages where this is not possible it seems natural to keep a set as result. For instance (Fagin et al. 1986) defines *flocks* that are the set of logical databases which result of the revision of a single logical database. Flocks have also been used as sets of possible results for combination/merging operators (Baral, Kraus, and Minker 1991; Baral et al. 1992; Konieczny 2000).

Conclusion and Future Work

In this paper, we investigated the revision problem for abstract argumentation systems à la Dung. We focused on revision as minimal change of the arguments statuses. We introduced a language of revision formulae which is expressive enough for enabling the representation of complex conditions on the acceptability of arguments in the revised system. We showed how AGM belief revision postulates can be translated to the case of argumentation systems. We provided a corresponding representation theorem in terms of minimal change of the arguments status, and pointed out several pseudo-distance-based revision operators satisfying the postulates. We investigated some computational aspects of revision of argumentation systems.

We are currently encoding our revision operators by representing argumentation systems with logical constraints (in a similar way to (Besnard and Doutre 2004)), so as to be able to benefit from the power of constraint solvers to compute revised systems. At the time of writing this paper, the revision of the stable extensions of an AF by a logical constraint is encoded. Some future work is to define an encoding for other semantics, and to encode some generation operators. Informations about this work is available here: http://www.cril.fr/DynArgs/revision.html.

There are some things still to do concerning this topic. Let us quote some of them now.

Designing revision approaches which allow to combine the two kinds of revision operators of argumentation systems would be useful: the ones that allow only addition of new arguments and no change of the attack relation, and the ones that allow only changes of the attack relation and no addition of new arguments. Allowing both changes in a sensible way is an interesting question, especially in the presence of constraints (stating for instance that some arguments must remain accepted, or that some attacks cannot be changed).

Associating a minimal set of argumentation systems with a set of candidates is another important issue, not only for our revision purpose. It is related to the problem of realizability (Dunne et al. 2013), where the question is to find a (unique) argumentation system that corresponds to a set of candidates. This problem can also be studied in the case of labellings, and used for the generation of argumentation systems from a set of labellings, exploiting labelling-distance-based revision operators defined in this paper.

Finally, it is interesting to study if some restriction on the faithful assignment could allow to guarantee that the output of the revision operator is a single AF, in a similar way to (Delgrande and Peppas 2011).

A Dynamic Logic Framework for Abstract Argumentation

IRIT - Université de Toulouse

Abstract

We provide a logical analysis of abstract argumentation frameworks and their dynamics. Following previous work, we express attack relation and argument status by means of propositional variables and define acceptability criteria by formulas of propositional logic. We here study the dynamics of argumentation frameworks in terms of basic operations on these propositional variables, viz. change of their truth values. We describe these operations in a uniform way within a well-known variant of Propositional Dynamic Logic PDL: the Dynamic Logic of Propositional Assignments, DL-PA. The atomic programs of DL-PA are assignments of propositional variables to truth values, and complex programs can be built by means of the connectives of sequential and nondeterministic composition and test. We start by showing that in DL-PA, the construction of extensions can be performed by a DL-PA program that is parametrized by the definition of acceptance. We then mainly focus on how the acceptance of one or more arguments can be enforced and show that this can be achieved by changing the truth values of the propositional variables describing the attack relation in a minimal way.

Introduction

Argumentation is a reasoning model based on the construction and on the evaluation of arguments. The seminal approach by Dung (Dung 1995) represents an argumentation framework $\mathcal{AF}$ as a set of abstract arguments, the structure and origin of which are left unspecified, along with an attack relationship between arguments. This paper builds on this framework. Dung and his followers have defined semantics for the evaluation of the acceptability of arguments (see (Baroni and Giacomin 2009) for a comprehensive overview). We focus in this paper on extension-based semantics, that define collectively acceptable sets of arguments, called extensions.

Dung's $\mathcal{AF}$ has already been represented in various logics, notably in propositional logic, starting with (Besnard and Doutre 2004). There, $\mathcal{AF}$ is described by means of a boolean formula in a logical language whose propositional variables represent the attacks (the *attack variables*). Furthermore, extensions of the $\mathcal{AF}$ under a given semantics σ can also be described by means of boolean formulas constraining valuations to correspond to the extensions under the semantics. This is done in an extension of the language of attack variables by variables representing argument acceptance.

Based on such a logical representation, several authors have recently investigated the dynamics of the $\mathcal{AF}$, such as (Baumann 2012; Booth et al. 2013; Bisquert et al. 2013; Coste-Marquis et al. 2013). They start by distinguishing several kinds of modification of the $\mathcal{AF}$, such as the addition or the removal of attacks, or the enforcement of the acceptability of an argument a (e.g. such that a is part of at least one extension). All these papers build on previous work in belief change, either referring to AGM theory (Alchourrón, Gärdenfors, and Makinson 1985), such as (Booth et al. 2013; Coste-Marquis et al. 2013), or to KM theory (Katsuno and Mendelzon 1992), such as (Bisquert et al. 2013). They express the modification as a logical formula describing some *goal*, i.e., a property that $\mathcal{AF}$ should satisfy: the task is to revise/update $\mathcal{AF}$ so that this formula is true.

The above papers do not provide a single framework encompassing at the same time $\mathcal{AF}$, the logical definition of the enforcement constraint and the change operations: there is usually one language for representing $\mathcal{AF}$ and another language for representing constraints, plus some definitions in the metalanguage connecting them. This has motivated us to provide a general, unified logical framework for the representation and the update of argumentation frameworks. We make use of a flexible yet simple logic: Dynamic Logic of Propositional Assignments, abbreviated DL-PA (Balbiani, Herzig, and Troquard 2013). DL-PA is a simple instantiation of Propositional Dynamic Logic PDL (Harel 1984; Harel, Kozen, and Tiuryn 2000) whose atomic programs are assignments of propositional variables to either true or false. Complex programs are built then from atomic programs by the standard PDL program operators of sequential composition, nondeterministic composition, and test. We here moreover add a less frequently considered PDL program operator, namely the converse operator. The language of DL-PA has formulas of the form $\langle\pi\rangle\varphi$ and $[\pi]\varphi$, where π is a program and φ is a formula. The former expresses that φ is true after *some* possible execution of π, and the latter expresses that φ is true after *every* possible execution of π. It is shown in (Balbiani, Herzig, and Troquard 2013) that every DL-PA formula can be reduced to an equivalent propositional formula. The reduction extends to the converse operator in a straight-

forward manner and provides a syntactical representation of the modified belief base.

We start by showing that the construction of extensions under a given semantics can be performed by a DL-PA program that is parametrized by the formula describing the semantics. Then we consider modifications of the attack relation and/or of the extensions. Modifications of the extensions are enforced by changing the attack relation only (addition or removal of attacks between the existing arguments). This can be achieved by changing the truth values of the attack variables. More precisely, to every input formula A describing the desired modification we associate a DL-PA program π_A implementing the update by A. We can then check whether a formula C is true in all (resp. in some) extensions of (the argumentation framework resulting from) the update of $\mathcal{AF}$ by the goal A.

The paper is organized as follows. In the next section we recall the definitions of an argumentation framework and of various semantics as well as their encoding in propositional logic. We then introduce DL-PA and show how to use it to construct extensions, before applying it to the modification of the attack relation and of the extensions. After that, we discuss several ways to extend our framework in order to capture other kinds of modifications. The last section discusses related work and concludes.[1]

Representing Argumentation Frameworks

In the present section we set the stage for our paper: we recall the definition of argumentation frameworks and provide a logical language to reason about them.

Argumentation Frameworks An abstract argumentation framework as defined by Dung in (Dung 1995) is a pair $\mathcal{AF} = (\mathcal{A}, R)$ where $\mathcal{A}$ is a finite set of abstract arguments and $R \subseteq \mathcal{A} \times \mathcal{A}$ is a binary relation on $\mathcal{A}$, called the attack relation: $(a, b) \in R$ means that a attacks b. So an argumentation framework is a directed graph with arguments as vertices and attacks as edges.

An argumentation framework $\mathcal{AF}$ can be represented in propositional logic as follows. First, a set of *attack variables* is associated to the set of arguments $\mathcal{A}$:

$$\mathtt{ATT}_{\mathcal{A}} = \{\mathsf{Att}_{a,b} \ : \ (a, b) \in \mathcal{A} \times \mathcal{A}\}$$

Let $\mathcal{L}_{\mathsf{Att}}$ be the set of all formulas that are built from attack variables. The theory of $\mathcal{AF} = (\mathcal{A}, R)$ is the boolean formula

$$\mathsf{Th}_{\mathcal{AF}} = \left(\bigwedge_{(a,b)\in R} \mathsf{Att}_{a,b}\right) \wedge \left(\bigwedge_{(a,b)\notin R} \neg\mathsf{Att}_{a,b}\right)$$

Example 1. *Consider the set of arguments $\mathcal{A}_1 = \{a, b\}$ and the two argumentation frameworks $\mathcal{AF}_1 = (\mathcal{A}_1, R_1)$ and $\mathcal{AF}_2 = (\mathcal{A}_1, R_2)$, with $R_1 = \{(a, b)\}$ and $R_2 = \{(a, b), (b, a)\}$. They are depicted in Figure 1.*

$\mathcal{AF}_1$ and $\mathcal{AF}_2$ are described by the theories

$$\mathsf{Th}_{\mathcal{AF}_1} = \mathsf{Att}_{a,b} \wedge \neg\mathsf{Att}_{b,a} \wedge \neg\mathsf{Att}_{a,a} \wedge \neg\mathsf{Att}_{b,b}$$
$$\mathsf{Th}_{\mathcal{AF}_2} = \mathsf{Att}_{a,b} \wedge \ \mathsf{Att}_{b,a} \wedge \neg\mathsf{Att}_{a,a} \wedge \neg\mathsf{Att}_{b,b}$$

[1] A longer version of the paper including proofs is available at: http://www.irit.fr/~Laurent.Perrussel/kr14long.pdf

Figure 1: $\mathcal{AF}_1$ (on the left) and $\mathcal{AF}_2$ (on the right)

Argumentation Semantics Many semantics have been defined for acceptability. Some of them are extension-based, some others are labelling-based. In this paper we only consider the first: they prevail in the literature, and moreover equivalent extension-based formulations of labelling-based semantics are available (Baroni and Giacomin 2009).

For a given $\mathcal{AF}$, a semantics identifies sets of acceptable arguments, called extensions. There may be none, one or several such extensions. In order to characterize extensions we associate to $\mathcal{A}$ a second set of propositional variables:

$$\mathtt{IN}_{\mathcal{A}} = \{\mathsf{In}_a \ : \ a \in \mathcal{A}\}$$

where In_a stands for "argument a is in the extension".

As proposed in (Besnard and Doutre 2004) and as extensively discussed in (Gabbay 2011), several semantics can be captured in propositional logic. Among such semantics, we consider at first the well-known *stable*, *admissible* and *complete* semantics.[2]

We write the propositional formulas capturing these semantics in a language that is built from the set of propositional variables $\mathbb{P} = \mathtt{ATT}_{\mathcal{A}} \cup \mathtt{IN}_{\mathcal{A}}$ by means of the boolean connectives in the usual way. Let $\mathcal{L}_{\mathsf{Att},\mathsf{In}}$ be our language of Boolean formulas.

A *stable* extension of $\mathcal{AF} = (\mathcal{A}, R)$ is a set $S \subseteq \mathcal{A}$ such that it does not exist two arguments a and b in S such that $(a, b) \in R$ (that is, S is *conflict-free*), and for each argument $b \notin S$, there exists $a \in S$ such that $(a, b) \in R$ (any argument outside the extension is attacked by the extension). This can be rephrased in propositional logic as follows (Besnard and Doutre 2004):

$$\mathsf{Stable}_{\mathcal{A}} = \bigwedge_{a\in\mathcal{A}} \left(\mathsf{In}_a \leftrightarrow \neg \bigvee_{b\in\mathcal{A}} (\mathsf{In}_b \wedge \mathsf{Att}_{b,a})\right)$$

An *admissible* set of $\mathcal{AF} = (\mathcal{A}, R)$ is a conflict-free set $S \subseteq \mathcal{A}$ that *defends* all its elements: for all $a \in S$, if there exists b such that $(b, a) \in R$, then there is some argument $c \in S$ such that $(c, b) \in R$.

$$\mathsf{Adm}_{\mathcal{A}} = \bigwedge_{a\in\mathcal{A}} \left(\mathsf{In}_a \rightarrow \bigwedge_{b\in\mathcal{A}} \left(\mathsf{Att}_{b,a} \rightarrow \left(\neg\mathsf{In}_b \wedge \bigvee_{c\in\mathcal{A}} (\mathsf{In}_c \wedge \mathsf{Att}_{c,b})\right)\right)\right)$$

A *complete* extension of $\mathcal{AF} = (\mathcal{A}, R)$ is an admissible set $S \subseteq \mathcal{A}$ that contains all the arguments it defends, that is: if an argument a is such that, for all b such that $(b, a) \in R$,

[2] Admissibility is usually considered to be a building brick of other, stronger semantics, but we consider it here as a semantics on its own, the construction of admissible sets following the same process as the construction of extensions.

there exists some $c \in S$ such that $(c, b) \in R$, then $a \in S$.

$$\mathsf{Complete}_{\mathcal{A}} = \bigwedge_{a \in \mathcal{A}} \Big(\big(\mathsf{In}_a \rightarrow \neg \bigvee_{b \in \mathcal{A}} (\mathsf{In}_b \wedge \mathsf{Att}_{b,a}) \big) \wedge \big(\mathsf{In}_a \leftrightarrow \bigwedge_{b \in \mathcal{A}} \big(\mathsf{Att}_{b,a} \rightarrow \bigvee_{c \in \mathcal{A}} (\mathsf{In}_c \wedge \mathsf{Att}_{c,b}) \big) \big) \Big)$$

The *justification state* of an argument (Baroni and Giacomin 2009) depends on the extensions it belongs to; basically, an argument is *credulously* justified (resp. *skeptically* justified) under a given semantics, if it belongs to at least one of (resp. all) the extensions under the semantics.

Extensions and Valuations Argumentation frameworks and semantics being encoded in propositional logic, computing the extensions under the semantics consists in finding the models of the formulas representing the argumentation system and the semantics. A *valuation* is a subset of the set of propositional variables $\mathbb{P} = \mathtt{ATT}_{\mathcal{A}} \cup \mathtt{IN}_{\mathcal{A}}$. The set of all valuations is $2^{\mathbb{P}}$. We use v, v_1, v_2, etc. to denote valuations. A given valuation determines the truth value of the boolean formulas of the language $\mathcal{L}_{\mathsf{Att},\mathsf{In}}$ in the usual way. The set of valuations where A is true is called *the set of models of* A or *the set of* A*-valuations* and is noted $\|A\|$.

The following proposition, adapted from (Besnard and Doutre 2004), connects extensions and valuations.

Proposition 1. *Let $\mathcal{AF} = (\mathcal{A}, R)$ be an argumentation framework and let $E \subseteq \mathcal{A}$. Consider the valuation $v_E = \{\mathsf{Att}_{a,b} : (a, b) \in R\} \cup \{\mathsf{In}_a : a \in E\}$.*

1. *E is a* stable *extension of $\mathcal{AF}$ if and only if v_E is a model of $\mathsf{Th}_{\mathcal{AF}} \wedge \mathsf{Stable}_{\mathcal{A}}$.*
2. *E is an* admissible *set of $\mathcal{AF}$ if and only if v_E is a model of $\mathsf{Th}_{\mathcal{AF}} \wedge \mathsf{Adm}_{\mathcal{A}}$.*
3. *E is an* complete *extension of $\mathcal{AF}$ if and only if v_E is a model of $\mathsf{Th}_{\mathcal{AF}} \wedge \mathsf{Complete}_{\mathcal{A}}$.*

Given a definition of a semantics σ (either stable, admissible, or complete), we denote the associated propositional formula describing the semantics by $\mathsf{Semantics}^{\sigma}$.

Corollary 1. *Let $\mathcal{AF} = (\mathcal{A}, R)$ be an argumentation framework. Let σ be a semantics. Let $C \in \mathcal{L}_{\mathsf{Att},\mathsf{In}}$ be a formula describing some property of $\mathcal{A}$. All extensions of $\mathcal{AF}$ have property C if and only if $\mathsf{Th}_{\mathcal{AF}} \wedge \mathsf{Semantics}^{\sigma}_{\mathcal{A}} \rightarrow C$ is valid.*

Example 2. *Let us consider again Example 1. $\mathcal{AF}_1$ has a single stable extension $\{a\}$, two admissible extensions $\{\}$ and $\{a\}$, and one complete extension $\{a\}$; that is:*

$$\mathsf{Th}_{\mathcal{AF}_1} \wedge \mathsf{Stable}_{\mathcal{A}_1} \rightarrow \mathsf{In}_a \wedge \neg \mathsf{In}_b$$
$$\mathsf{Th}_{\mathcal{AF}_1} \wedge \mathsf{Adm}_{\mathcal{A}_1} \rightarrow \neg \mathsf{In}_b$$
$$\mathsf{Th}_{\mathcal{AF}_1} \wedge \mathsf{Complete}_{\mathcal{A}_1} \rightarrow \mathsf{In}_a \wedge \neg \mathsf{In}_b$$

DL-PA: Dynamic Logic of Propositional Assignments

We have just seen that looking for the extensions of an argumentation framework $\mathcal{AF}$ with respect to some semantics σ amounts to looking for the models of the formulas representing $\mathcal{AF}$ and σ. We now consider a way to build these models in a logic which allows to perform operations on valuations: Dynamic Logic of Propositional Assignments DL-PA (Herzig et al. 2011; Balbiani, Herzig, and Troquard 2013). DL-PA is based on Propositional Dynamic Logic PDL (Harel 1984; Harel, Kozen, and Tiuryn 2000). Just as PDL, it has operators of sequential and nondeterministic composition of programs, test and iteration (the Kleene star), which enable reasoning about programs. The atomic programs of DL-PA are assignments of truth values to propositional variables, such as assigning true or false to p, respectively written $p{\leftarrow}\top$ and $p{\leftarrow}\bot$. The formulas of DL-PA can express how valuations are modified by programs so that after this modification stage, some property holds. In our context, they express how to build the valuations representing the extensions of $\mathcal{AF}$ w.r.t. σ. Before showing this we define syntax and semantics of DL-PA and state complexity results.

We here base our work on the star-free version of DL-PA of (Herzig et al. 2011), that we extend by the operator of converse execution of programs. We keep on calling that logic DL-PA. because the converse operator can be linearly eliminated, as we shall see.

Language The language of star-free DL-PA is defined by the following grammar:

$$\begin{array}{lll} \pi & ::= & p{\leftarrow}\top \mid p{\leftarrow}\bot \mid \varphi? \mid \pi;\pi \mid \pi \cup \pi \mid \pi^{-} \\ \varphi & ::= & p \mid \top \mid \bot \mid \neg\varphi \mid \varphi \vee \varphi \mid \langle\pi\rangle\varphi \end{array}$$

where p ranges over $\mathbb{P}$.

Key formulas are: $[\pi]\varphi$, read "after every execution of the program π formula φ holds", and $\langle\pi\rangle\varphi$, read "after some execution of the program π formula φ holds". The formula $[\pi]\varphi$ abbreviates $\neg\langle\pi\rangle\neg\varphi$.

The *atomic programs* $p{\leftarrow}\top$ and $p{\leftarrow}\bot$ respectively make p true and make p false. The operators of sequential composition (";"), nondeterministic composition ("$\cup$") and test ("(.)?") are familiar from PDL. The operator "$(.)^{-}$" is the converse operator: formula $[\pi^{-}]\varphi$ stands for "before every execution of the program π formula φ was true" and $\langle\pi^{-}\rangle\varphi$ stands for "before some execution of the program π formula φ was true".

The *length* of a formula φ, noted $|\varphi|$, is the number of symbols used to write down φ, without "$\langle$", "$\rangle$", and parentheses. For example, $|\neg(q \vee \neg r)| = 1{+}(1{+}1{+}2) = 5$ and $|\langle q{\leftarrow}\top\rangle(q \vee r)| = 3{+}3 = 6$. The length of a program π, noted $|\pi|$, is defined in the same way. For example, $|p{\leftarrow}\bot; p?| = 3{+}1{+}2 = 6$.

Conjunction ($\wedge$), implication ($\rightarrow$) and equivalence ($\leftrightarrow$) are considered with their usual meaning. We also make use the exclusive disjunction $\varphi \oplus \psi$ which abbreviates $(\varphi \wedge \neg\psi) \vee (\neg\varphi \wedge \psi)$. Furthermore, several program abbreviations are familiar from PDL. First, skip abbreviates $\top?$ ("nothing happens"). Second, for $n \geq 0$, we define inductively π^{n} and $\pi^{\leq n}$ as follows:

$$\pi^{n} = \begin{cases} \mathsf{skip} & \text{if } n = 0 \\ \pi;\pi^{n-1} & \text{if } n \geq 1 \end{cases}$$

$$\pi^{\leq n} = \begin{cases} \mathsf{skip} & \text{if } n = 0 \\ (\mathsf{skip} \cup \pi);\pi^{\leq n-1} & \text{if } n \geq 1 \end{cases}$$

$$
\begin{aligned}
\|p{\leftarrow}\top\| &= \{(v_1, v_2) \ : \ v_2 = v_1 \cup \{p\}\} \\
\|p{\leftarrow}\bot\| &= \{(v_1, v_2) \ : \ v_2 = v_1 \setminus \{p\}\} \\
\|\varphi?\| &= \{(v, v) \ : \ v \in \|\varphi\|\} \\
\|\pi; \pi'\| &= \|\pi\| \circ \|\pi'\| \\
\|\pi \cup \pi'\| &= \|\pi\| \cup \|\pi'\| \\
\|\pi^-\| &= \|\pi\|^{-1} \\
\|p\| &= \{v \ : \ p \in v\} \\
\|\top\| &= 2^{\mathbb{P}} \\
\|\bot\| &= \{\} \\
\|\neg\varphi\| &= 2^{\mathbb{P}} \setminus \|\varphi\| \\
\|\varphi \vee \psi\| &= \|\varphi\| \cup \|\psi\| \\
\|\langle\pi\rangle\varphi\| &= \{v \ : \ \text{there is } v' \text{ s.t. } (v, v') \in \|\pi\| \text{ and } v' \in \|\varphi\|\}
\end{aligned}
$$

Table 1: Interpretation of the DL-PA connectives

Finally, we introduce assignments of literals to variables by way of the following abbreviations:

$$
\begin{aligned}
p{\leftarrow}q &= (q?; p{\leftarrow}\top) \cup (\neg q?; p{\leftarrow}\bot) \\
p{\leftarrow}\neg q &= (q?; p{\leftarrow}\bot) \cup (\neg q?; p{\leftarrow}\top)
\end{aligned}
$$

The former assigns to p the truth value of q, while the latter assigns to p the truth value of $\neg q$. So $p{\leftarrow}p$ does nothing and $p{\leftarrow}\neg p$ flips the truth value of p. Note that both abbreviations have constant length (viz. 14).

Semantics Models of DL-PA are nothing but models of classical propositional logic, i.e., subsets of the set of propositional variables $\mathbb{P}$, alias valuations. We sometimes write $v(p) = 1$ when $p \in v$ and $v(p) = 0$ when $p \notin v$. DL-PA programs are interpreted by means of a (unique) *relation between valuations*. For instance, suppose $\mathbb{P} = \{p\}$ and consider the atomic program $\pi = p{\leftarrow}\top$, and the two valuations $v_1 = \{\}$ and $v_2 = \{p\}$. The execution of π relates v_1 to v_2, and v_2 to itself. In other words, π is interpreted as $\|\pi\| = \{(v_1, v_2), (v_2, v_2)\}$.

Atomic programs of the form $p{\leftarrow}\top$ and $p{\leftarrow}\bot$ are interpreted as update operations on valuations, and complex programs are interpreted just as in PDL by mutual recursion. Table 1 gives the interpretation of the DL-PA connectives.

Two formulas φ_1 and φ_2 are *formula equivalent* if $\|\varphi_1\| = \|\varphi_2\|$. Two programs π_1 and π_2 are *program equivalent* if $\|\pi_1\| = \|\pi_2\|$. In that case we write $\pi_1 \equiv \pi_2$. For example, the program equivalence $\pi; \mathsf{skip} \equiv \pi$ holds.

An *expression* is a formula or a program. When we say that two expressions are equivalent we mean program equivalence if we are talking about programs, and formula equivalence otherwise. Equivalence is preserved under replacement of a sub-expression by an equivalent expression (Balbiani, Herzig, and Troquard 2013).

Eliminating the Modal Operators DL-PA formulas being interpreted through classical propositional logic valuations, modal operators can be eliminated. In order to do this, we first eliminate the converse operator. Table 2 lists the relevant program equivalences (aka reduction axioms). Iterating their application we can eliminate the converse operator with only linear increase in program size. For example, for assignments of variables to literals we have:

$$
\begin{aligned}
(\varphi?)^- &\equiv \varphi? \\
(\pi_1; \pi_2)^- &\equiv \pi_2^-; \pi_1^- \\
(\pi_1 \cup \pi_2)^- &\equiv \pi_1^- \cup \pi_2^- \\
p{\leftarrow}\top^- &\equiv p?; (\mathsf{skip} \cup p{\leftarrow}\bot) \\
&\equiv p? \cup (p?; p{\leftarrow}\bot) \\
p{\leftarrow}\bot^- &\equiv \neg p?; (\mathsf{skip} \cup p{\leftarrow}\top) \\
&\equiv \neg p? \cup (\neg p?; p{\leftarrow}\top)
\end{aligned}
$$

Table 2: Reduction axioms for the converse operator

$$
p{\leftarrow}q^- \equiv \begin{cases} p{\leftarrow}p & \text{if } p = q \\ p{\leftrightarrow}q?; (p{\leftarrow}\top \cup p{\leftarrow}\bot) & \text{otherwise} \end{cases}
$$

$$
p{\leftarrow}\neg q^- \equiv \begin{cases} p{\leftarrow}\neg p & \text{if } p = q \\ p{\oplus}q?; (p{\leftarrow}\top \cup p{\leftarrow}\bot) & \text{otherwise} \end{cases}
$$

Proposition 2. *For every* DL-PA *formula φ there is an equivalent* DL-PA *formula φ' such that φ' is without $(.)^-$ and such that the length of φ' is linear in the length of φ.*

Next, we remind the following key result: for converse-free DL-PA, every formula is equivalent to a boolean formula (Herzig et al. 2011; Balbiani, Herzig, and Troquard 2013). With Proposition 2 we obtain the following result for our present language with converse.

Theorem 1. *For every* DL-PA *formula there is an equivalent boolean formula.*

For example, for different propositional variables r and p, the formula $\langle p{\leftarrow}\bot\rangle(p \vee r)$ is successively equivalent to $\langle p{\leftarrow}\bot\rangle p \vee \langle p{\leftarrow}\bot\rangle r$, to $\bot \vee r$, and to r.

Note that the boolean formula might be exponentially longer than the original formula.

Validity and Complexity Results A formula φ is DL-PA *valid* if it is equivalent to $\top$, i.e., if $\|\varphi\| = 2^{\mathbb{P}}$. It is DL-PA *satisfiable* if it is not a formula equivalent to $\bot$, i.e., if $\|\varphi\| \neq \{\}$. For example, the formulas $\langle p{\leftarrow}\top\rangle\top$ and $\langle p{\leftarrow}\top\rangle\varphi \leftrightarrow \neg\langle p{\leftarrow}\top\rangle\neg\varphi$ are DL-PA valid.

Due to Proposition 2, the complexity results of (Herzig et al. 2011) transfer to our extension with the converse operator: both model checking and satisfiability checking are PSPACE complete for our language.

Constructing Extensions with DL-PA

Let us first show how the extensions of an argumentation framework can be constructed by means of DL-PA programs. Remember that such programs modify valuations: our aim is to define a program which sets the truth values of the variables representing the acceptance of an argument so that after the execution of that program, the formula characterizing the semantics holds. We first present a few definitions that will help us to define that program.

Sorting Variables of $\mathcal{L}_{\mathsf{Att},\mathsf{In}}$ Formulas For every $\mathcal{L}_{\mathsf{Att},\mathsf{In}}$ formula A we consider two sets: the set of attack variables occurring in A, noted $\mathtt{ATT}(A)$, and the set of accept variables occurring in A, noted $\mathtt{IN}(A)$. For example, $\mathtt{ATT}(\neg\mathsf{Att}_{a,b} \vee \mathsf{In}_a) = \{\mathsf{Att}_{a,b}\}$ and $\mathtt{IN}(\neg\mathsf{Att}_{a,b} \vee \mathsf{In}_a) = \{\mathsf{In}_a\}$. It is the modifications of $\mathtt{ATT}(A)$ that will be minimized in order to construct the extensions, while the modifications of the set $\mathtt{IN}(A)$ will not be minimized: given the truth values of the attack variables, the semantics determines the truth values for the accept variables (or rather, the possible combinations of accept variables, because there may be several extensions).

Evaluating the Difference between Valuations The symmetric difference between two valuations $v_1, v_2 \subseteq \mathbb{P}$ is the number of variables whose truth values differ, formally defined as

$$v_1 \dot{-} v_2 = (v_1 \setminus v_2) \cup (v_2 \setminus v_1)$$

So $v_1 \dot{-} v_2$ is the set of all those p such that $v_1(p) \neq v_2(p)$. The *Hamming distance* between two valuations $v_1, v_2 \subseteq \mathbb{P}$ is the cardinality of their symmetric difference: $v_1 \dot{-} v_2$ is the *number* of all those p such that $v_1(p) \neq v_2(p)$.

Example 3. *Suppose two valuations: $\{p, q\}$ and $\{q, r, s\}$. Their symmetric difference is $\{p, r, s\}$ and their Hamming distance is* 3.

Changing Variables through DL-PA Programs Let us consider the two following DL-PA programs that can change the truth value of one or more propositional variables in the finite subset $P = \{p_1, \ldots, p_n\}$ of the set of propositional variables $\mathbb{P} = \mathtt{ATT}_{\mathcal{A}} \cup \mathtt{IN}_{\mathcal{A}}$.

$$\mathsf{vary}(P) = (p_1 \leftarrow \top \cup p_1 \leftarrow \bot); \cdots; (p_n \leftarrow \top \cup p_n \leftarrow \bot)$$
$$\mathsf{flip1}(P) = p_1 \leftarrow \neg p_1 \cup \cdots \cup p_n \leftarrow \neg p_n$$

The intuitive meaning of program $\mathsf{vary}(P)$ is "the program is composed of a sequence of n steps and at each step i, the value of variable p_i is nondeterministically set to either to true or false"; one may also say that $\mathsf{vary}(P)$ forgets the values of the variables in P. Second, program $\mathsf{flip1}(P)$ should be read as "one variable from P is randomly chosen and is nondeterministically set to either true or false". Observe that the programs $\mathsf{vary}(P)$ and $(\mathsf{flip1}(P))^{\leq n}$ are equivalent.

Note that the length of each program is linear in the cardinality of P.

The following lemma characterises the behaviour of the two programs in semantic terms.

Lemma 1. *The following hold:*

1. $(v_1, v_2) \in \|\mathsf{vary}(P)\|$ *iff* $v_1 \dot{-} v_2 \subseteq P$
2. $(v_1, v_2) \in \|\mathsf{flip1}(P)\|$ *iff* $v_1 \dot{-} v_2 = \{p_k\}$ *for some* $p_k \in P$

Given an $\mathcal{L}_{\mathsf{Att},\mathsf{In}}$ formula A, $\mathbb{P}_A$ is defined as the set of variables from $\mathbb{P}$ occurring in A. The first item of Lemma 1 hence tells us that the program $\mathsf{vary}(\mathbb{P}_A); A?$ accesses all relevant A-valuations (where 'relevant' means that only those A-valuations are accessed which keep constant the truth values of variables not occurring in A).

Example 4. *Consider the formula $A = \mathsf{In}_a \wedge \neg\mathsf{In}_b$. The set of variables of A is $\mathbb{P}_A = \{\mathsf{In}_a, \mathsf{In}_b\}$. The models of A can be built by, first, varying the truth values of the variables of the formula ($\mathsf{vary}(\mathbb{P}_A)$), and second, by testing which of the resulting valuations satisfy the formula, and by keeping them only ($A?$). $\mathsf{vary}(\mathbb{P}_A)$ is here:*

$$(\mathsf{In}_a \leftarrow \top \cup \mathsf{In}_a \leftarrow \bot); (\mathsf{In}_b \leftarrow \top \cup \mathsf{In}_b \leftarrow \bot)$$

Its execution relates each valuation for $\mathbb{P}_A$, i.e., each of $\{\}$, $\{\mathsf{In}_a\}$, $\{\mathsf{In}_b\}$, and $\{\mathsf{In}_a, \mathsf{In}_b\}$, to every other, including itself. Among the couples of valuations making up that relation, there is only one relating the model of A (that is, $\{\mathsf{In}_a\}$) to itself. So the execution of the test $A?$ only keeps this pair in the relation. So the pair $(\{\mathsf{In}_a\}, \{\mathsf{In}_a\})$ is a possible execution of the program $\mathsf{vary}(\mathbb{P}_A); A?$.

Our example illustrates that the satisfiability of a boolean formula A can be expressed in DL-PA as the existence of valuation that is accessible by the program $\mathsf{vary}(\mathbb{P}_A); A?$, i.e., by means of the formula

$$\langle \mathsf{vary}(\mathbb{P}_A); A? \rangle \top$$

The formula says that there is a way of changing the truth value of some variables of A so that A is true afterwards.

Lemma 2. *Let A be a propositional formula. A is (propositionnally) satisfiable iff $\langle \mathsf{vary}(\mathbb{P}_A); A? \rangle \top$ is DL-PA valid.*

Defining Extensions in DL-PA Let us now show how a DL-PA program can express in a concise and natural way the construction of extensions of an argumentation framework $\mathcal{AF}$ under a semantics σ. The program $\mathsf{makeExt}^{\sigma}_{\mathcal{A}}$ below constructs the valuations representing extensions w.r.t. a semantics σ, of argumentation frameworks over the set of arguments $\mathcal{A}$. Remember that the set of attack variables is $\mathtt{ATT}_{\mathcal{A}}$, that the set of accept variables is $\mathtt{IN}_{\mathcal{A}}$, and that σ is either stable, complete, or admissible acceptability semantics. We define the DL-PA program $\mathsf{makeExt}^{\sigma}_{\mathcal{A}}$ as follows:

$$\mathsf{makeExt}^{\sigma}_{\mathcal{A}} = \mathsf{vary}(\mathtt{IN}_{\mathcal{A}}); \mathsf{Semantics}^{\sigma}_{\mathcal{A}}?$$

The following result says that if v_1 completely describes the attack relation then the set of accept variables of the valuations v_2 such that $(v_1, v_2) \in \|\mathsf{makeExt}^{\sigma}_{\mathcal{A}}\|$ characterises the extensions of $\mathcal{AF}$ w.r.t. semantics σ. It is a consequence of Corollary 1 and Lemma 2.

Lemma 3. *Let $\mathcal{AF}$ be an argumentation framework. Let σ be either the stable, complete or admissible semantics. Let v_1 be a model of $\mathsf{Th}_{\mathcal{AF}}$. Then $(v_1, v_2) \in \|\mathsf{makeExt}^{\sigma}_{\mathcal{A}}\|$ iff v_2 is a model of $\mathsf{Th}_{\mathcal{AF}} \wedge \mathsf{Semantics}^{\sigma}_{\mathcal{A}}$.*

Lemma 3 entails that we can construct all the extensions of a given argumentation system w.r.t. some semantics by means of a DL-PA program.

Proposition 3. *Let $\mathcal{AF} = (\mathcal{A}, R)$ be an argumentation framework and let C be a boolean formula. The boolean formula $\mathsf{Th}_{\mathcal{AF}} \wedge \mathsf{Semantics}^{\sigma}_{\mathcal{A}} \rightarrow C$ is propositionally valid if and only if the DL-PA formula $\mathsf{Th}_{\mathcal{AF}} \rightarrow [\mathsf{makeExt}^{\sigma}_{\mathcal{A}}]C$ is valid. Moreover, the equivalence*

$$\mathsf{Th}_{\mathcal{AF}} \wedge \mathsf{Semantics}^{\sigma}_{\mathcal{A}} \leftrightarrow \langle (\mathsf{makeExt}^{\sigma}_{\mathcal{A}})^{-} \rangle \mathsf{Th}_{\mathcal{AF}}$$

is DL-PA valid.

According to Proposition 3, given a description of the attack relation, program $\mathsf{makeExt}^{\sigma}_{\mathcal{A}}$ can construct valuations where the formula describing the semantics is true, and so in a way such that only acceptance variables are changed, while the attack variables do not change. Note that the equivalence takes care of situations where there is no extension. Let the $\mathcal{L}_{\mathsf{Att},\mathsf{In}}$ formula A be a goal, i.e., a boolean formula that should be satisfied by the extensions of some $\mathcal{AF}$. By means of the program $\mathsf{makeExt}^{\sigma}_{\mathcal{A}}$ one can check what has been called *σ-consistency* in (Coste-Marquis et al. 2013): whether there exists an argumentation framework $\mathcal{AF}$ such that some or every extension w.r.t. σ satisfies A. Adopting the standard terms for characterizing a justification state, we distinguish the notions of credulous and skeptical consistency.

Definition 1 (σ-consistency). *Let $\mathcal{AF} = (\mathcal{A}, R)$ be an argumentation framework, let σ be either the stable, admissible, or complete semantics. The $\mathcal{L}_{\mathsf{Att},\mathsf{In}}$ formula A is* σ-credulously-consistent for $\mathcal{A}$ *iff* $\langle\mathsf{makeExt}^{\sigma}_{\mathcal{A}}\rangle A$ *is satisfiable; A is* σ-skeptically-consistent for $\mathcal{A}$ *iff* $[\mathsf{makeExt}^{\sigma}_{\mathcal{A}}]A$ *is satisfiable.*

Example 5. *Consider the set of arguments $\mathcal{A}_2 = \{a, b\}$ and the goal $A = \neg\mathsf{In}_a \wedge \neg\mathsf{In}_b \wedge \neg\mathsf{Att}_{a,a}$. Then $\langle\mathsf{makeExt}^{\sigma}_{\mathcal{A}}\rangle A$ is unsatisfiable; in particular, it is false in every valuation for $\mathsf{Th}_{\mathcal{AF}_2}$ of Example 1. Therefore the formula A is stable-credulous inconsistent for $\mathcal{A}_2$.*

To sum it up, we have shown how extensions can be constructed through programs modifying propositional variables. In the next section we show how to modify an argumentation framework and its extensions.

Modifying an Argumentation Framework

We start by discussing several kinds of modifications of an argumentation framework $\mathcal{AF}$ and then focus on the most involved family of operations: modifications enforcing a goal either in all extensions or in some extension of $\mathcal{AF}$.

Generally speaking, when we want to incorporate a new piece of information A into a belief base B then we want to build a new belief base that retains as much as possible the initial beliefs of B while entailing A. Neither AGM theory (Alchourrón, Gärdenfors, and Makinson 1985) nor KM (Katsuno and Mendelzon 1992) theory provide a single, concrete belief change operation: they rather constrain the set of 'reasonable' belief change operations by means of a set of postulates. Several concrete belief change operations satisfying the AGM or KM postulates have been defined in the literature. Among the most prominent are Winslett's 'possible models approach' (PMA) (Winslett 1988; 1990), Forbus's update operation (Forbus 1989), Winslett's standard semantics (WSS) (Winslett 1995), and Dalal's revision operation (Dalal 1988); see (Herzig and Rifi 1999; Lang 2007) for an overview. According to Katsuno and Mendelzon's distinction between update and revision operations (Katsuno and Mendelzon 1992), the first three are update operations, usually written $\diamond$, while Dalal's is a revision operation, usually written $*$.

Kinds of Change Several kinds of modifications of a given argumentation framework $\mathcal{AF} = (\mathcal{A}, R)$ have been distinguished (Cayrol, Bannay, and Lagasquie-Schiex 2010):

1. One may modify the set of arguments $\mathcal{A}$ by adding or removing an argument.
2. One may modify the attack relation R by adding or removing an edge between two arguments.
3. One may wish to modify the extensions of $\mathcal{AF}$.

The first kind of operation, viz. adding an argument to the set of arguments $\mathcal{A}$ or removing it, requires more linguistic resources than our language $\mathcal{L}_{\mathsf{Att},\mathsf{In}}$ provides; we will sketch a way of implementing it in DL-PA in an augmented language in the end of the paper.

Addition and removal of an attack edge between two arguments $a, b \in \mathcal{A}$ are rather simple operations: we just add or subtract (a, b) from R. In our logical representation, these operations correspond to making propositional variables true or false: the addition of (a, b) to R can be implemented by the update of $\mathsf{Th}_{\mathcal{AF}}$ by $\mathsf{Att}_{a,b}$, and the removal of (a, b) from R can be implemented by the update of $\mathsf{Th}_{\mathcal{AF}}$ by $\neg\mathsf{Att}_{a,b}$.[3] In DL-PA, the update of $\mathsf{Th}_{\mathcal{AF}}$ by $\mathsf{Att}_{a,b}$ can be implemented by the program $\mathsf{Att}_{a,b}\leftarrow\top$, and the update by $\neg\mathsf{Att}_{a,b}$ by $\mathsf{Att}_{a,b}\leftarrow\bot$. Indeed, we have:

$$\mathsf{Th}_{\mathcal{AF}} \diamond \mathsf{Att}_{a,b} = \langle \mathsf{Att}_{a,b}\leftarrow\top^{-}\rangle \mathsf{Th}_{\mathcal{AF}}$$
$$\mathsf{Th}_{\mathcal{AF}} \diamond \neg\mathsf{Att}_{a,b} = \langle \mathsf{Att}_{a,b}\leftarrow\bot^{-}\rangle \mathsf{Th}_{\mathcal{AF}}$$

where $\diamond$ is any of the above belief change operations. Once $\mathsf{Th}_{\mathcal{AF}}$ has been updated by some $\mathsf{Att}_{a,b}$ or $\neg\mathsf{Att}_{a,b}$, the extensions of the resulting framework can be obtained by conjoining the result with $\mathsf{Semantics}^{\sigma}_{\mathcal{A}}$.

Adding an argument to extensions or removing it is more involved because it has to be achieved indirectly, by changing the underlying attack relation of $\mathcal{AF}$ (or by changing the set of arguments, but as we said, we disregard this option for the time being). Moreover, when an argumentation framework has several extensions, one may wish to change the justification status of a, so that it be skeptically justified (that is, added in all the extensions), or credulously justified (added in at least one extension), or credulously justified but not skeptically justified (added in at least one extension, but removed from at least one), or even not credulously justified (removed from all extensions).

While the distinction between update and revision was irrelevant for the modification of the attack relation, it gets important when it comes to the modification of extensions: which operation should we apply? We dedicate the next section to the problem of modifying an extension.

[3] We note that the question whether this is an update or a revision does not really play a role here because we are in a simple situation: as far as the language $\mathcal{L}_{\mathsf{Att}}$ is concerned, the formula $\mathsf{Th}_{\mathcal{AF}}$ is complete (it has a unique model), and the update of complete theories by literals leads to the same result for all the belief change operations that we have mentioned, WSS, PMA, Forbus, and Dalal, be they update or revision operations.

The Modification of Extensions In order to discuss which change operation is the most appropriate, let us consider again the above argumentation framework $\mathcal{AF}_2 = (\mathcal{A}_2, R_2)$ and the stable semantics. $\mathcal{AF}_2$ has two stable extensions $E_a = \{a\}$ and $E_b = \{b\}$. We have seen that the associated boolean formula $\mathsf{Th}_{\mathcal{AF}_2} \wedge \mathsf{Stable}_{\mathcal{A}_2}$ has two $\mathcal{L}_{\mathsf{Att},\mathsf{In}}$ models:

$$v_a = \{\mathsf{Att}_{a,b}, \mathsf{Att}_{b,a}, \mathsf{In}_a\}$$
$$v_b = \{\mathsf{Att}_{a,b}, \mathsf{Att}_{b,a}, \mathsf{In}_b\}$$

Suppose we wish to modify $\mathcal{AF}_2$ such that a is in none of its stable extensions. What we have to do is to adapt the attack relation of $\mathcal{AF}_2$ in a way that is minimal and that guarantees that a does not occur in any of its extensions, while guaranteeing that a is rejected. We view minimality as minimality of the number of modifications of the attack relation; in contrast, the current extensions may be modified in a non-minimal way. This policy agrees with (Coste-Marquis et al. 2013), where the minimization of the changes on the attack relation is considered to be secondary.

What we do is to modify the models of $\mathsf{Th}_{\mathcal{AF}_2} \wedge \mathsf{Stable}_{\mathcal{A}_2}$ one by one so that In_a holds: we minimally modify the attack variables such that the result is stable. As we can see, *enforcing* a constraint is similar to update and we will hereafter commit to this reading.

To sum up, enforcing A consists in minimally updating the attack relation of an initial argumentation framework $\mathcal{AF} = (\mathcal{A}, R)$ with respect to some goal A in a way such that A holds in all of the extensions of the resulting $\mathcal{AF}' = (\mathcal{A}, R')$. Another perspective is however possible, too, where enforcing consists in minimally modifying the attack relation such that A holds in *some* of the extensions of the resulting $\mathcal{AF}' = (\mathcal{A}, R')$. This operation seems to be closer in spirit to a revision operation. So 'enforcement' can be understood in two different ways, leading to two different definitions. In both cases, there is a key difference with standard revision and update operations: in classical belief change, output is limited to one belief set, while here, several $\mathcal{AF}'$ may be produced by the enforcement operations. Let $\mathcal{AF} \diamond^{\mathsf{Cred},\sigma} A$ denote the *credulous* enforcement of property A in $\mathcal{AF}$ w.r.t. semantics σ, and let $\mathcal{AF} \diamond^{\mathsf{Skep},\sigma} A$ denote the *skeptical* enforcement of property A in $\mathcal{AF}$. We consider that both $\diamond^{\mathsf{Cred},\sigma}$ and $\diamond^{\mathsf{Skep},\sigma}$ are operations mapping an argumentation framework and an $\mathcal{L}_{\mathsf{Att},\mathsf{In}}$ formula to a set of argumentation frameworks.

In line with the definitions of classical revision and update operations, we now define some postulates that 'reasonable' operations $\diamond$ should satisfy. They are mainly inspired by (Coste-Marquis et al. 2013).

We have shown above that both attack relations and σ-consistency can be captured by DL-PA formulas. As moreover the goal A is an $\mathcal{L}_{\mathsf{Att},\mathsf{In}}$ formula, too, our postulates can be formulated in terms of DL-PA formulas.

Definition 2 (enforcement postulates). *Let $\diamond$ be an operation mapping an argumentation framework and an $\mathcal{L}_{\mathsf{Att},\mathsf{In}}$ formula to a set of argumentation frameworks. Let σ be either the stable, admissible, or complete semantics. The operation $\diamond$ is a* credulous enforcement *operation iff it satisfies the following postulates:*

E1.C *For all $\mathcal{AF}' \in \mathcal{AF} \diamond^{\sigma} A$, $\models \mathsf{Th}_{\mathcal{AF}'} \rightarrow \langle \mathsf{makeExt}^{\sigma}_{\mathcal{A}} \rangle A$.*

E2.C *If $\models \mathsf{Th}_{\mathcal{AF}} \wedge \mathsf{Semantics}^{\sigma}_{\mathcal{A}} \rightarrow \langle \mathsf{makeExt}^{\sigma}_{\mathcal{A}} \rangle A$ then $\mathcal{AF} \diamond^{\sigma} A = \{\mathcal{AF}\}$.*

E3 *If $\models A_1 \leftrightarrow A_2$ then for every $\mathcal{AF}_1 \in \mathcal{AF} \diamond^{\sigma} A_1$ there exists $\mathcal{AF}_2 \in \mathcal{AF} \diamond^{\sigma} A_2$ such that $\models \mathsf{Th}_{\mathcal{AF}_1} \leftrightarrow \mathsf{Th}_{\mathcal{AF}_2}$.*

The operation $\diamond$ is said to be a skeptical enforcement *operation iff it satisfies postulate **E3** plus the following:*

E1.S *For all $\mathcal{AF}' \in \mathcal{AF} \diamond^{\sigma} A$, $\models \mathsf{Th}_{\mathcal{AF}'} \rightarrow [\mathsf{makeExt}^{\sigma}_{\mathcal{A}}] A$.*

E2.S *If $\models \mathsf{Th}_{\mathcal{AF}} \wedge \mathsf{Semantics}^{\sigma}_{\mathcal{A}} \rightarrow [\mathsf{makeExt}^{\sigma}_{\mathcal{A}}] A$ then $\mathcal{AF} \diamond^{\sigma} A = \{\mathcal{AF}\}$.*

The postulates **E1.C** and **E1.S** say that success in required for credulous and skeptical enforcement. **E2** represents a minimal change principle: it states that if A already holds then $\mathcal{AF}$ is unchanged. Postulate **E3** is the postulate of syntax independence: enforcement should be based on the content of a goal and not on its syntax.

Additional postulates may be formulated; see (Bisquert et al. 2013; Coste-Marquis et al. 2013) for more details. A key difference is that we do not consider postulates based on the expansion operation. The main reason is that this operation is actually useless: first, if an attack has to be changed then expansion cannot be used because, as we have seen above, $\mathsf{Th}_{\mathcal{AF}}$ is complete for $\mathcal{L}_{\mathsf{Att}}$. Now consider that an argument has to be enforced in a credulous way. We face two cases: (i) either the argument is already credulously acceptable and there is no reason to change the argumentation framework, or (ii) the argument is not credulously acceptable. Then as all possible extensions are considered, some attacks must be changed so that new extensions can be constructed (and A will then hold). The same reasoning can be made for skeptical acceptance.

Let us now show how DL-PA helps us to reason about enforcement.

Expressing Extension Modification in DL-PA

The aim of this section is to show how modification programs can be defined. These programs should satisfy the enforcement postulates that we have defined. Second, they should only minimally change the attack relations of an initial argumentation framework. As previously mentioned, enforcement is close to update, and we will root our programs in the update operations that guarantee minimal change. One of the most popular is Forbus's update operation (Forbus 1989), where minimal change involves counting how many variables have been changed. Our solution is strongly connected to it.

The Hamming Distance Predicate Let us define the DL-PA formula $\mathsf{h}(A, P, \geq m)$, where A is an $\mathcal{L}_{\mathsf{Att},\mathsf{In}}$ formula, P is a set of propositional variables, and $m \geq 0$ is an integer:

$$\mathsf{h}(A, P, \geq m) = \begin{cases} \top & \text{if } m = 0 \\ \neg\langle(\mathsf{flip1}(P))^{\leq m-1}\rangle A & \text{if } m \geq 1 \end{cases}$$

We call $\mathsf{h}(A, P, \geq m)$ the *Hamming distance predicate w.r.t. the set of variables P*: it is true at a valuation v exactly when the A-valuations v' that are closest to v in the sense of the Hamming distance differ in at least m variables from

v, where the computation of the distance only considers variables from the set P, while the other variables in $\mathbb{P} \setminus P$ keep their value.

Proposition 4. *Let v a valuation, A a boolean formula, P some set of propositional variables, and $m \geq 0$. Then*

1. *$v \in \|\mathsf{h}(A, P, \geq m)\|$ iff the A-valuations that are closest to v w.r.t. P have Hamming distance at least m, i.e., iff $\mathsf{card}(v \dot{-} v') \geq m$ for every $v' \in \|A\|$ s.t. $v \dot{-} v' \subseteq P$.*
2. *$(v, v') \in \|\mathsf{h}(A, P, \geq m)?; (\mathsf{flip1}(P))^m; A?\|$ iff v' is one of the A-valuations that is closest to v w.r.t. P, i.e., iff $v' \in \|A\|$ and $\mathsf{card}(v \dot{-} v') = m$ for every $v' \in \|A\|$ s.t. $v \dot{-} v' \subseteq P$.*

It follows from the first item of Proposition 4 that when P equals $\mathbb{P}_A$ then $v \in \|\mathsf{h}(A, \mathbb{P}_A, \geq m)\|$ iff the A-valuations that are closest to v have Hamming distance at least m, i.e., iff $\mathsf{card}(v \dot{-} v') \geq m$ for every $v' \in \|A\|$. This is used in Forbus's udpate operation.

Forbus's Update Operation Forbus's update operation is based on minimization of the Hamming distance. First, the Forbus update of a valuation v by A is the set of those A-valuations whose Hamming distance to v is minimal. Second, the Forbus update of a belief base B by A collects the Forbus updates of all B-valuations by A.

The following DL-PA program performs Forbus's update operation:

$$\mathsf{forbus}(A) = \bigcup_{m \leq \mathsf{card}(\mathbb{P}_A)} \Big(\mathsf{h}(A, \mathbb{P}_A, \geq m)?; (\mathsf{flip1}(\mathbb{P}_A))^m\Big); A?$$

The program nondeterministically chooses an integer m, checks if the Hamming distance to A-valuations is at least m and flips m of the variables of A. Finally, the test A? only succeeds for A-valuations.

Proposition 5. *The formula C is true after the Forbus update of B by A if and only if $B \rightarrow [\mathsf{forbus}(A)]C$ is* DL-PA *valid.*

Argumentation Framework Update The update of argumentation frameworks has some specificities: first, we are going to modify only the attack variables while leaving the accept variables unchanged; second, the target formula is not going to be a boolean formula, but a formula saying that A will be the case *after building extensions*. Let us define the program $\mathsf{credEnf}(A)$ modifying $\mathcal{AF}$ w.r.t. some semantics σ such that the boolean formula $A \in \mathcal{L}_{\mathsf{Att},\mathsf{In}}$ becomes true in some σ-extensions:

$$\mathsf{credEnf}(A) = \bigcup_{m \leq \mathsf{card}(\mathtt{ATT}_{\mathcal{A}})} \Big(\mathsf{h}(\langle \mathsf{makeExt}^{\sigma}_{\mathcal{A}} \rangle A, \mathtt{ATT}_{\mathcal{A}}, \geq m)?; (\mathsf{flip1}(\mathtt{ATT}_{\mathcal{A}}))^m\Big); \langle \mathsf{makeExt}^{\sigma}_{\mathcal{A}} \rangle A?$$

The following program enforces a constraint in a skeptical way.

$$\mathsf{skepEnf}(A) = \bigcup_{m \leq \mathsf{card}(\mathtt{ATT}_{\mathcal{A}})} \Big(\mathsf{h}([\mathsf{makeExt}^{\sigma}_{\mathcal{A}}] A, \mathtt{ATT}_{\mathcal{A}}, \geq m)?; (\mathsf{flip1}(\mathtt{ATT}_{\mathcal{A}}))^m\Big); [\mathsf{makeExt}^{\sigma}_{\mathcal{A}}] A?$$

The length of these two programs is polynomial in the cardinality of $\mathcal{A}$. (The cardinality of the set $\mathtt{ATT}_{\mathcal{A}}$ is quadratic in that of $\mathcal{A}$ and the length of $(\mathsf{flip1}(\mathtt{ATT}_{\mathcal{A}}))^m$ is quadratic in that of $\mathcal{A}$.)

To check whether C is true in all extensions of $\mathcal{AF}$ modified by A (for $A, C \in \mathcal{L}_{\mathsf{Att},\mathsf{In}}$) can then be done by checking whether the DL-PA formula $\mathsf{Th}_{\mathcal{AF}} \rightarrow [\mathsf{skepEnf}(A)]C$ is valid. In particular we have the following proposition which states that if there is a chance to get A by modifying the attack variables then the enforcement will succeed:

Proposition 6.

$$\models [\mathsf{credEnf}(A)]\langle \mathsf{makeExt}^{\sigma}_{\mathcal{A}} \rangle A$$
$$\models [\mathsf{skepEnf}(A)][\mathsf{makeExt}^{\sigma}_{\mathcal{A}}] A$$

The second key property is that an argumentation framework is unchanged if the goal already holds.

Proposition 7. *For every goal A that is credulously justified, the credulous update program does not change anything:*

$$\models (\mathsf{Th}_{\mathcal{AF}} \wedge \langle \mathsf{makeExt}^{\sigma}_{\mathcal{A}} \rangle A \wedge C) \rightarrow [\mathsf{credEnf}(A)]C$$

For every goal A that is skeptically justified, the skeptical update program does not change anything:

$$\models (\mathsf{Th}_{\mathcal{AF}} \wedge [\mathsf{makeExt}^{\sigma}_{\mathcal{A}}] A \wedge C) \rightarrow [\mathsf{skepEnf}(A)]C$$

The modified argumentation frameworks can be extracted from the formulas $\langle \mathsf{credEnf}(A)^{-} \rangle \mathsf{Th}_{\mathcal{AF}}$ and $\langle \mathsf{skepEnf}(A)^{-} \rangle \mathsf{Th}_{\mathcal{AF}}$ representing it in DL-PA (or rather, their reduction) by forgetting the accept variables, as proposed in (Coste-Marquis et al. 2013). This operation can be implemented in our framework by the program $\mathsf{vary}(\mathtt{IN}_{\mathcal{A}})$.

Definition 3 ($\diamond^{\sigma,\mathsf{enf}}$)**.** *Let σ be either the stable, admissible, or complete semantics. Let* enf *be either the* skepEnf *or the* credEnf *program. Let $\diamond^{\sigma,\mathsf{enf}}$ be an operation mapping an argumentation framework and an $\mathcal{L}_{\mathsf{Att},\mathsf{In}}$ formula to a set of argumentation frameworks. The update of $\mathcal{AF}$ by A under σ and* enf *is*

$$\mathcal{AF} \diamond^{\sigma,\mathsf{enf}} A = \{(\mathcal{A}, R_v) \ : \ v \in \|\langle (\mathsf{enf}(A))^{-} \rangle \mathsf{Th}_{\mathcal{AF}}\|\}$$

where R_v is the attack relation extracted from v, defined as $R_v = \{(a, b) \ : \ \mathsf{Att}_{a,b} \in v\}$.

The two preceding propositions guarantee that our enforcement operations satisfy the postulates.

Theorem 2. *Operation $\diamond^{\sigma,\mathsf{credEnf}}$ satisfies **E1.C** and **E2.C**. Operation $\diamond^{\sigma,\mathsf{skepEnf}}$ satisfies **E1.S** and **E2.S**. Both operations $\diamond^{\sigma,\mathsf{credEnf}}$ and $\diamond^{\sigma,\mathsf{skepEnf}}$ satisfy **E3**.*

This result is actually not a surprise, given that our tool for enforcement is a variant of Forbus's update operation.

Example 6. *Let us take up the argumentation framework $\mathcal{AF}_2$ of Example 1. Remember that $\mathcal{AF}_2 = (\mathcal{A}_1, R_2)$, with $\mathcal{A}_1 = \{a, b\}$ and $R_2 = \{(a, b), (b, a)\}$ and that $\mathsf{Th}_{\mathcal{AF}_2} = \mathsf{Att}_{a,b} \wedge \mathsf{Att}_{b,a}$. Let us consider the stable semantics and suppose our goal is to enforce that a is always acceptable (skeptical enforcement). We disregard self-attacks for the sake of simplicity. The nondeterministic part $\bigcup_{m \leq \mathsf{card}(\mathtt{ATT}_{\mathcal{A}})}(\ldots)$ of the program $\mathsf{SkepEnf}(\mathsf{In}_{\mathsf{a}})$ changes one variable from*

$\mathsf{Th}_{\mathcal{AF}_2}$, *either* $\mathsf{Att}_{a,b}$ *or* $\mathsf{Att}_{b,a}$. *This corresponds to two candidate extensions: one where a only attacks b and one where b only attacks a. Only the former case gives valuations where a is always acceptable. Hence:*

$$\mathcal{AF} \diamond^{\mathsf{Stable,skepEnf}} \mathsf{In}_a = \{(\mathcal{A}_1, \{(a, b)\})\}$$

Going Further

We have illustrated how DL-PA offers a fruitful framework for representing argumentation framework and reasoning about them. We now sketch several ways of extending our account.

Other Argumentation Semantics Our exposition focused on the stable, admissible, and complete semantics. This can however be generalized to *every* semantics Σ whose extensions can be characterized by a propositional formula $\Sigma_{\mathcal{A}}$ built from the set of attack variables $\mathtt{ATT}_{\mathcal{A}}$ and the set of accept variables $\mathtt{IN}_{\mathcal{A}}$. In the previous sections we have given DL-PA programs modifying valuations (that represent argumentation frameworks) in a minimal way and producing (representations of) extensions. Therefore all minimization-based semantics can be handled in an elegant way, as well as all maximization-based semantics.

For instance, the preferred semantics (that captures the maximal, w.r.t. set-inclusion, admissible sets) can be handled as follows:

$$\mathsf{Semantics}^{pref}_{\mathcal{A}} =$$

$$\mathsf{Adm}_{\mathcal{A}} \wedge [\mathsf{MakeTrueSome}(\mathtt{IN}_{\mathcal{A}}); \mathsf{h}(\mathsf{Adm}_{\mathcal{A}}, \geq 1)?]\neg\mathsf{Adm}_{\mathcal{A}}$$

where $\mathsf{MakeTrueSome}(P) = (\neg p_1?; (p_1 \leftarrow \bot \cup p_1 \leftarrow \top)); \ldots; (\neg p_n?; (p_n \leftarrow \bot \cup p_n \leftarrow \top))$ makes true some of the elements of P. $[\mathsf{MakeTrueSome}(\mathtt{IN}_{\mathcal{A}})]$ evaluates all possible combinations of changes in the arguments out of the admissible set. $[\mathsf{MakeTrueSome}(\mathtt{IN}_{\mathcal{A}}); \mathsf{h}(\mathsf{Adm}_{\mathcal{A}}, \geq 1)?]\neg\mathsf{Adm}_{\mathcal{A}}$ tries to enforce all non-empty subsets of arguments currently out of the admissible set. Maximality of the admissible set is thus guaranteed. The resulting encoding is polynomial time.

Other Update Semantics The modification programs that we have defined in the present paper basically applies Forbus's update operation to the attack variables. It is possible to use other such operations, such as Winslett's Possible Models Approach (PMA) (Winslett 1988), or revision operations such as Dalal's (Dalal 1988).

Other Kinds of Change Up to now we did not cover addition and removal of some argument from an argumentation framework. Let us sketch how this could be done in a fairly straightforward way in the framework of DL-PA. First of all, we have to add a further ingredient to argumentation frameworks: let us consider triples $\mathcal{AF} = (\mathcal{A}_0, \mathcal{A}, R)$ where $\mathcal{A} \subseteq R \times R$ as before, and moreover $\mathcal{A}_0$ is a (possibly infinite) set such that $\mathcal{A} \subseteq \mathcal{A}_0$. We think of $\mathcal{A}_0$ as the background set of all possible arguments, while $\mathcal{A}$ is the set of all arguments that are currently under consideration. We have to modify the logical language $\mathcal{L}_{\mathsf{Att,In}}$ accordingly. First, we suppose that there are propositional variables $\mathsf{Att}_{a,b}$ and In_a for every a, b in the background set $\mathcal{A}_0$. Second, we add propositional variables Cons_a, one per argument $a \in \mathcal{A}_0$, where Cons_a reads "a is considered". Let us denote the resulting language by $\mathcal{L}_{\mathsf{Att,In,Cons}}$. Then the theory of $\mathcal{AF} = (\mathcal{A}_0, \mathcal{A}, R)$ is the boolean formula

$$\mathsf{Th}_{\mathcal{AF}} = \left(\bigwedge_{(a,b)\in R} \mathsf{Att}_{a,b}\right) \wedge \left(\bigwedge_{(a,b)\notin R} \neg\mathsf{Att}_{a,b}\right) \wedge \left(\bigwedge_{a\in\mathcal{A}} \mathsf{Cons}_a\right)$$

So $\mathsf{Th}_{\mathcal{AF}}$ does not say anything about the arguments that are currently not under consideration: the models of $\mathsf{Th}_{\mathcal{AF}}$ have arbitrary truth values for $\mathsf{Att}_{a,b}$, $\mathsf{Att}_{b,a}$, In_a, and Cons_a as soon as $a \notin \mathcal{A}$.

The semantic definitions have to be adapted, too, and should only quantify over arguments in $\mathcal{A}$, and not over those in $\mathcal{A}_0$. For stable semantics we get:

$$\mathsf{Stable}_{\mathcal{A}} = \bigwedge_{a\in\mathcal{A}} \left(\mathsf{Cons}_a \rightarrow \left(\mathsf{In}_a \leftrightarrow \neg \bigvee_{b\in\mathcal{A}} (\mathsf{In}_b \wedge \mathsf{Att}_{b,a})\right)\right)$$

In this setting, the mere addition or deletion of an argument a can be achieved straightforwardly, viz. by changing the status of a from 'disregarded' to 'considered' by means of the assignments $\mathsf{Cons}_a \leftarrow \top$ and $\mathsf{Cons}_a \leftarrow \bot$. Subsequently, the attack relation can be modified as sketched above: one has to first delete all the $\mathsf{Att}_{a,b}$ and $\mathsf{Att}_{b,a}$ such that $b \in \mathcal{A}$, and then add the attack relation as desired.

Conclusion

The main result of this paper is the encoding of argumentation frameworks and their dynamics in DL-PA. More precisely, our contribution is threefold.

First, as long as argument acceptability can be expressed in propositional logic, finding acceptable arguments and enforcing acceptability can be done in DL-PA. Other logical frameworks allow capturing and computing argument acceptability (see (Charwat et al. 2013) for an overview), but few of them allow capturing and computing acceptability change as well.

Second, as DL-PA formulas can be rewritten as propositional logic formulas, the result of the modification of an argumentation framework is described by a propositional formula from the models of which one may retrieve the modified argumentation frameworks. Our proposal is hence more 'operational' than those of (Bisquert et al. 2013; Coste-Marquis et al. 2013) because we use a formal logic encompassing the representation of change operations. Moreover, we consider not only credulous acceptability changes, as most of the current approaches do (Baumann 2012), but skeptical acceptability change as well.

Third, our framework takes advantage of the complexity results for DL-PA: both model checking and satisfiability checking are in PSPACE. A closer look at the formulas expressing the modifications shows that the alternation of quantifications is bounded, which typically leads to complexity bounds at the second level of the polynomial hierarchy.

The proposed DL-PA encodings may be related to QBF encodings for argumentation (Arieli and Caminada 2013). As QBF has the same complexity as star-free DL-PA, all we do in DL-PA must be polynomially encodable into QBF.

However, the availability of assignment programs makes a difference: update programs such as $\mathsf{forbus}(A)$ and extension construction programs such as $\mathsf{makeExt}^{\sigma}_{\mathcal{A}}$ capture things in a more general, flexible, and natural way than a QBF encoding.

To conclude, the richness of our framework makes it expandable to other kinds of changes, other update semantics, and other argumentation semantics beyond those that are detailed in the present paper. We plan to investigate this research avenue in future work.

Abstract

The study of extension-based semantics within the seminal abstract argumentation model of Dung has largely focused on definitional, algorithmic and complexity issues. In contrast, matters relating to comparisons of representational limits, in particular, the extent to which given collections of extensions are expressible within the formalism, have been under-developed. As such, little is known concerning conditions under which a candidate set of subsets of arguments are "realistic" in the sense that they correspond to the extensions of some argumentation framework AF for a semantics of interest. In this paper we present a formal basis for examining extension-based semantics in terms of the sets of extensions that these may express within a single AF. We provide a number of characterization theorems which guarantee the existence of AFs whose set of extensions satisfy specific conditions and derive preliminary complexity results for decision problems that require such characterizations.

1 Introduction

The last 15 years have seen an enormous effort to design, compare, and implement different semantics for Dung's abstract argumentation frameworks (Dung 1995), AFs for short. As a result of this extensive study argumentation is now a significant topic within AI research (Bench-Capon and Dunne 2007; Rahwan and Simari 2009). Surprisingly, systematic comparison of AF capabilities respecting *multiple* extensions, and thus their power in modelling multiple viewpoints within a single framework has, so far, been neglected. Nevertheless, an understanding of which extensions can, in principle, coexist when a framework is evaluated with respect to a semantics of interest not only clarifies the "strength" of that semantics but also is a crucial issue in several applications.

In this work, we address this issue by studying the *signatures* of argumentation semantics. A semantics σ maps each argumentation framework F to a set of extensions (i.e. a set of sets of arguments). The signature of σ is defined by

$$\Sigma_\sigma = \{\sigma(F) \mid F \text{ is an AF}\},$$

and gives the collection of all possible sets of extensions an AF can possess under semantics σ. We shall focus on several important semantics namely naive, preferred, semi-stable, stage, stable, and complete semantics (Dung 1995; Verheij 1996; Caminada, Carnielli, and Dunne 2012) and aim at finding simple criteria to decide whether a set $\mathbb{S}$ is contained in Σ_σ. For instance, we will show that each $\mathbb{S} \in \Sigma_{pref}$ satisfies the condition that for each pair of distinct sets A and B from $\mathbb{S}$ there is at least one $a \in A$ and $b \in B$ such that a, b do not occur together in any set in $\mathbb{S}$. Thus, for instance, $\mathbb{S} = \{\{a, b\}, \{c, d\}, \{a, c\}, \{b, d\}\}$ is part of the signature Σ_{pref} while neither $\mathbb{S} \cup \{\{a, d\}\}$ nor $\mathbb{S} \cup \{\{b, c\}\}$ are. This fact can be exploited in a search procedure for enumerating preferred extensions: assume for a given AF F, the three extensions from $\mathbb{S}$ have already been calculated as preferred extensions of F. The procedure can now restrict the search space to find further extensions of F (if they exist) to sets with at least one argument different from a, b, c, and d.

The problem we study here is also essential in many other aspects.

First, our results are important for constructing AFs. Indeed, knowing whether a set $\mathbb{S}$ is contained in Σ_σ is a necessary condition which should be checked before actually looking for an AF F which *realizes* $\mathbb{S}$ under σ, i.e. $\sigma(F) = \mathbb{S}$. This is of high importance when dynamic aspects of argumentation are considered (Falappa et al. 2011). As an example, suppose a framework F possesses as its σ-extensions a set $\mathbb{S}$ and one asks for an adaptation of the framework F such that its σ-extensions are given by $\mathbb{S} \cup \{E\}$, i.e. one extension is to be added. The addition of E to $\mathbb{S}$ may, for instance, be desired by some agent on the grounds that E contains some subset of arguments which it wishes to be collectively accepted by other agents: no extension in $\mathbb{S}$, however, provides support for the subset of interest to be considered justifiable. Furthermore the agent wishing to add E is reluctant to jeopardize the chance of this happening if the modified AF is such that some existing element of $\mathbb{S}$ ceases to be an extension: such an outcome being likely to prejudice other agents against agreeing to changes which admit E. Before considering the adapted framework's structure, it is obviously crucial to know whether an appropriate framework exists at all, i.e. whether $S \cup \{E\} \in \Sigma_\sigma$. In a recent paper on revision of AFs (Coste-Marquis et al. 2013), the authors circumvent this issue by allowing revision to result in a set of AFs such that

the union of their extensions yields the desired outcome. Our results provide exact conditions under which their approach admits a single AF as an outcome of a given revision.

Second, our work adds to the comparison of semantics (see, e.g., (Baroni and Giacomin 2007)) by means of different properties. So far such properties have largely focused on aspects of *single* extensions $S \in \mathbb{S}$ rather than on *sets* of such. An obvious exception being incomparability (the sets in $\mathbb{S}$ are not proper subsets of each other; this property is also known as I-maximality); as we will see, however, all of the standard semantics impose additional (yet distinct) requirements on $\mathbb{S}$ in order for containment in the signature to hold. Furthermore, our results add to the growing body of work considering *generic* treatments of argumentation semantics, that is with respect to shared properties rather than from the perspective of distinguishing features. Previous such examinations of abstract argumentation semantics include the "principle-based evaluation" methods proposed by Baroni and Giacomin (2007) and the concept of "rationality postulates" from (Caminada and Amgoud 2007). For example, we show that most semantics σ are closed under intersection of extensions (more formally, for all AFs F_1, F_2, there exists an AF F such that $\sigma(F) = \sigma(F_1) \cap \sigma(F_2)$, whenever $\sigma(F_1) \cap \sigma(F_2) \neq \emptyset$).

Related work includes studies on enforcing (Baumann 2012; Baumann and Brewka 2010) certain outcomes, where the task is to modify AFs in such a way that desired arguments become acceptable. However, the issue of multiple extensions is not covered. In fact, the work which is closest to our investigations are studies of intertranslatability issues (Dvořák and Spanring 2012; Dvořák and Woltran 2011), where signatures of semantics are put in relation to each other. More precisely, if there is an exact translation such that θ-extensions of the transformed AF coincide with the σ-extensions of the original AF, then θ is at least as expressive as σ, that is $\Sigma_\sigma \subseteq \Sigma_\theta$ in our terms. These results, however, tell us little about the *contents* of Σ_σ and Σ_θ.

To summarize, the main contributions of our work are:

• We first identify necessary conditions any set of extensions under a given semantics σ satisfies, i.e. we identify sets of extensions Σ^+_σ with $\Sigma_\sigma \subseteq \Sigma^+_\sigma$. This not only informs the exact characteristics for the signature of σ, but also determines those sets of extensions that are impossible to be jointly expressed with one AF.

• Then, we provide sufficient conditions for a set of extensions to be realizable under a given semantics σ. For any such set $\mathbb{S}$, we present constructions of canonical frameworks having $\mathbb{S}$ as their σ-extensions. In other words we identify sets of extensions Σ^-_σ with $\Sigma^-_\sigma \subseteq \Sigma_\sigma$. For all semantics σ under consideration (with the exception of complete extensions) our results hold with $\Sigma^+_\sigma = \Sigma^-_\sigma$. We, thus, obtain exact characterizations of the signatures Σ_σ.

• We apply our results to study the aforementioned property of closure under intersection (of extension-sets). Moreover, we identify limits of disagreement the different semantics face. While the capabilities of semantics differ in cases involving expressing more than two extensions, it turns out that the maximal number of extensions (over n arguments) that can be captured is equal for many semantics.

• One particular application of our results is the problem of recasting, i.e. to decide if the σ-extensions of a given AF can be expressed via another semantics θ. We give some preliminary complexity results of the recasting problem, which go up to Π^P_2-completeness. In contrast, we show that the problem of checking if $\mathbb{S} \in \Sigma_\sigma$ for a given $\mathbb{S}$ is decidable in polynomial time for all exactly characterized semantics.

2 Preliminaries

We assume a countably infinite domain $\mathfrak{A}$ of arguments. An *argumentation framework* (AF) is a pair $F = (A, R)$ where $A \subseteq \mathfrak{A}$ is non-empty and finite, and $R \subseteq A \times A$ is the attack relation. The collection of all AFs is given as $AF_{\mathfrak{A}}$. We write $a \mapsto_R b$ for $(a, b) \in R$ and $S \mapsto_R a$ (resp. $a \mapsto_R S$) if $\exists s \in S$ such that $s \mapsto_R a$ (resp. $a \mapsto_R s$). We drop subscript R in $\mapsto_R$ if there is no ambiguity. For $S \subseteq A$, the *range* of S (wrt. R), denoted S^+_R, is the set $S \cup \{b \mid S \mapsto_R b\}$.

Given $F = (A, R)$, an argument $a \in A$ is *defended* (in F) by a set $S \subseteq A$ if for each $b \in A$, such that $b \mapsto_R a$, also $S \mapsto_R b$. A set T of arguments is defended (in F) by S if each $a \in T$ is defended by S (in F). The following result is in the spirit of Dung's fundamental lemma and is used later.

Lemma 1. *Given an AF $F = (A, R)$ and two sets of arguments $S, T \subseteq A$. If S defends itself in F and T defends itself in F, then $S \cup T$ defends itself in F.*

Given an AF $F = (A, R)$, a set $S \subseteq A$ is *conflict-free* (in F), if there are no arguments $a, b \in S$, such that $(a, b) \in R$. We denote the set of all conflict-free sets in F as $cf(F)$. $S \in cf(F)$ is called *admissible* (in F) if S defends itself. We denote the set of admissible sets in F as $adm(F)$.

The semantics we focus in this work are the naive, stable, preferred, complete, stage, and semi-stable extensions. Given $F = (A, R)$ they are defined as subsets of $cf(F)$:

- $S \in naive(F)$, if there is no $T \in cf(F)$ with $T \supset S$
- $S \in stb(F)$, if $S \mapsto a$ for all $a \in A \setminus S$
- $S \in pref(F)$, if $S \in adm(F)$ and $\nexists T \in adm(F)$ s.t. $T \supset S$
- $S \in com(F)$, if $S \in adm(F)$ and $a \in S$ for all $a \in A$ defended by S
- $S \in stage(F)$, if $\nexists T \in cf(F)$ with $T^+_R \supset S^+_R$
- $S \in sem(F)$, if $S \in adm(F)$ and $\nexists T \in adm(F)$ s.t. $T^+_R \supset S^+_R$

The objects of our interest are the *signatures* of a semantics.

Definition 1. The signature Σ_σ of a semantics σ is defined as

$$\Sigma_\sigma = \{\sigma(F) \mid F \in AF_{\mathfrak{A}}\}.$$

For characterizing the signatures of the semantics of our interest we will make frequent use of the following concepts.

Definition 2. Given $\mathbb{S} \subseteq 2^{\mathfrak{A}}$, $Arg_{\mathbb{S}}$ denotes $\bigcup_{S \in \mathbb{S}} S$ and $Pairs_{\mathbb{S}}$ denotes $\{(a, b) \mid \exists S \in \mathbb{S} : \{a, b\} \subseteq S\}$. $\mathbb{S}$ is called an *extension-set* (over $\mathfrak{A}$) if $Arg_{\mathbb{S}}$ is finite. While $|\mathbb{S}|$ denotes the number of extensions in $\mathbb{S}$, $\|\mathbb{S}\|$ stands for $|Arg_{\mathbb{S}}|$.

Observe that for any $a \in Arg_{\mathbb{S}}$, $(a, a) \in Pairs_{\mathbb{S}}$ holds for all extension-sets $\mathbb{S}$; also note that for all considered semantics σ each element $\mathbb{S} \in \Sigma_\sigma$ is an extension-set.

3 Properties of Argumentation Semantics

In this section, we provide necessary conditions for an extension-set $\mathbb{S}$ to be in the signature Σ_σ. To this end, we have to find common properties for $\sigma(F)$ which hold for any AF F. We do so by abstracting away from the syntactical structure of a given framework.

Some properties are rather easy to see: *cf*(F) satisfies the property that for any $S \in$ *cf*(F), also $S' \in$ *cf*(F) for any $S' \subseteq S$. Likewise, for all $\sigma \in \{naive, stb, stage, pref, sem\}$ it obviously holds that $\sigma(F)$ is incomparable for any AF. We define these two properties formally.

Definition 3. Let $\mathbb{S} \subseteq 2^{\mathfrak{A}}$. The *downward-closure*, *dcl*$(\mathbb{S})$, of $\mathbb{S}$ is given by $\{S' \subseteq S \mid S \in \mathbb{S}\}$. We call $\mathbb{S}$ *downward-closed* if $\mathbb{S} =$ *dcl*$(\mathbb{S})$ and *incomparable* if for each $S, S' \in \mathbb{S}$, $S \subseteq S'$ implies $S = S'$.

However, all considered semantics σ enjoy additional properties. Just consider the incomparable extension-set $\mathbb{S} = \{\{a, b\}, \{a, c\}, \{b, c\}\}$. Now suppose there exists an AF F with $\sigma(F) = \mathbb{S}$. Then F must not contain attacks between a and b, a and c, and respectively b and c. But then $\sigma(F)$ typically contains $\{a, b, c\}$.

Stable, Stage, Naive and Conflict-Free Sets

There are several ways to define the required property which excludes sets like $\mathbb{S}$ from above. To characterize stable, stage and naive extensions, we start with a rather strong restriction making use of the concept of *Pairs*$_\mathbb{S}$ (in Section 6, we will discuss an alternative yet equivalent definition in terms of a ternary operator on $\mathbb{S}$). For the other semantics, we will use a strictly weaker criterion.

Definition 4. An extension-set $\mathbb{S} \subseteq 2^{\mathfrak{A}}$ is *tight* if for all $S \in \mathbb{S}$ and $a \in$ *Arg*$_\mathbb{S}$ it holds that if $S \cup \{a\} \notin \mathbb{S}$ then there exists an $s \in S$ such that $(a, s) \notin$ *Pairs*$_\mathbb{S}$.

For incomparable $\mathbb{S}$, the definition of $\mathbb{S}$ being tight reduces to check whether for all $S \in \mathbb{S}$ and $a \in$ *Arg*$_\mathbb{S} \setminus S$ there is an $s \in S$ such that $(a, s) \notin$ *Pairs*$_\mathbb{S}$. The idea behind the notion of being tight is that if an argument a does not occur in some extension S there must be a reason for that. The most simple reason one can think of is that there is a conflict between a and some $s \in S$, i.e. a and s do not occur jointly in any extension-set of $\mathbb{S}$ or, in other words, $(a, s) \notin$ *Pairs*$_\mathbb{S}$. Indeed, the set $\mathbb{S} = \{\{a, b\}, \{a, c\}, \{b, c\}\}$ from above is not tight, since there is no reason to, for instance, exclude c from extension $\{a, b\}$ ((a, c) and (b, c) are both contained in *Pairs*$_\mathbb{S}$). On the other hand, the set $\{\{a, b\}, \{a, c\}, \{b, d\}, \{c, d\}\}$ is easily checked to be tight.

Before stating our first results, we examine certain properties of tight sets which we exploit later.

Lemma 2. *For a tight extension-set* $\mathbb{S} \subseteq 2^{\mathfrak{A}}$ *it holds that*

1. *the* $\subseteq$*-maximal elements in* $\mathbb{S}$ *form a tight set, and*
2. *if* $\mathbb{S}$ *is incomparable then each* $\mathbb{S}' \subseteq \mathbb{S}$ *is tight.*

Proof. Consider some tight extension-set $\mathbb{S}$. (1) For each $S \in \mathbb{S}$ and $a \in$ *Arg*$_\mathbb{S}$ it holds that $S \cup \{a\} \notin \mathbb{S}$ if $S \cup \{a\} \notin \mathbb{S}'$, where $\mathbb{S}'$ is the set of $\subseteq$-maximal elements in $\mathbb{S}$. Hence, as *Pairs*$_\mathbb{S} =$ *Pairs*$_{\mathbb{S}'}$ and $\mathbb{S}' \subseteq \mathbb{S}$, $\mathbb{S}'$ is tight too. (2) Let $\mathbb{S}$ be incomparable, and consider some $\mathbb{S}' \subseteq \mathbb{S}$. Then

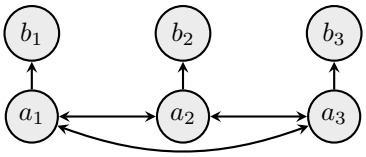

Figure 1: Argumentation framework F used in Example 1.

Pairs$_{\mathbb{S}'} \subseteq$ *Pairs*$_\mathbb{S}$ and, as $\mathbb{S}$ is incomparable, $S \cup \{a\} \notin \mathbb{S}$ iff $S \cup \{a\} \notin \mathbb{S}'$ for all $S \in \mathbb{S}$, $a \in$ *Arg*$_\mathbb{S}$. Thus $\mathbb{S}'$ is tight. □

Proposition 1. *For each* AF $F = (A, R)$*,*

1. *cf*(F) *is non-empty, downward-closed and tight;*
2. *naive*(F) *is non-empty, incomparable and its downward-closure is tight;*
3. *stage*(F) *is non-empty, incomparable and tight;*
4. *stb*(F) *is incomparable and tight.*

Proof. The properties of being non-empty and incomparable are clear. Likewise, it is easy to see that *cf*$(F) =$ *dcl*(*cf*(F)), i.e. *cf*(F) is downward-closed. To show that *cf*(F) is tight, let $S \in$ *cf*(F) and $a \in$ *Arg*$_{cf(F)}$, such that $S \cup \{a\} \notin$ *cf*(F). It follows that $S \neq \emptyset$ (otherwise, $\{a\} \notin$ *cf*(F) and since we know *cf*$(F) =$ *dcl*(*cf*(F)), this would yield $a \notin$ *Arg*$_{cf(F)}$). Moreover there exists an argument $s \in S$ such that $s \mapsto a$ or $a \mapsto s$. Then $\{a, s\} \notin$ *cf*(F) and since *cf*$(F) =$ *dcl*(*cf*(F)), $\{a, s\} \not\subseteq T$ for any $T \in$ *cf*(F). It follows that $(a, s) \notin$ *Pairs*$_{cf(F)}$. Since this applies to all S, a with $S \in$ *cf*(F) and $a \notin S$, tightness of *cf*(F) follows. Next, observe that *dcl*(*naive*(F)) = *cf*(F), by definition of the semantics. Thus *dcl*(*naive*(F)) is tight, and by Lemma 2, *naive*(F) is tight. With the same lemma, we get that every $\mathbb{S} \subseteq$ *naive*(F) is tight. By the well-known fact that *stb*$(F) \subseteq$ *stage*$(F) \subseteq$ *naive*(F), the result follows. □

Example 1. For the AF F in Figure 1, we have $\mathbb{S} =$ *stb*$(F) =$ *stage*$(F) = \{\{a_1, b_2, b_3\}, \{a_2, b_1, b_3\}, \{a_3, b_1, b_2\}\}$ and *naive*$(F) = \mathbb{S} \cup \{\{b_1, b_2, b_3\}\}$. $\mathbb{S}$ is indeed tight. Take, for instance, $E = \{a_1, b_2, b_3\}$; then for each argument t not in E (i.e. b_1, a_2, a_3) there is an argument $s \in E$ such $(s, t) \notin$ *Pairs*$_\mathbb{S}$. In this particular case a_1 plays this role for each t. The other two extensions behave in a symmetric way. However, *dcl*$(\mathbb{S})$ is not tight. In fact, $\{b_2, b_3\} \in$ *dcl*$(\mathbb{S})$ and now for b_1, $\{b_1, b_2, b_3\} \notin$ *dcl*$(\mathbb{S})$ but (b_1, b_2) and (b_1, b_3) are contained in *Pairs*$_{dcl(\mathbb{S})} =$ *Pairs*$_\mathbb{S}$. Proposition 1 now gives evidence that an AF G with *naive*$(G) = \mathbb{S}$ cannot exist.

Preferred, Semi-Stable and Admissible Sets

The following property checks whether each pair of extensions in an extension-set $\mathbb{S}$ has at least one mutual conflict in case its union is not contained in $\mathbb{S}$.

Definition 5. A set $\mathbb{S} \subseteq 2^{\mathfrak{A}}$ is called *adm-closed* if for each $A, B \in \mathbb{S}$ the following holds: if $(a, b) \in$ *Pairs*$_\mathbb{S}$ for each $a, b \in A \cup B$, then also $A \cup B \in \mathbb{S}$.

Note that for $a, b \in A$ (likewise $a, b \in B$), $(a, b) \in$ *Pairs*$_\mathbb{S}$ holds by definition. Thus the property of adm-closed is determined by arguments $a \in A \setminus B$, $b \in B \setminus A$, for $A, B \in \mathbb{S}$.

Lemma 3. *Every tight extension-set is also adm-closed.*

Proof. Consider some tight extension-set $\mathbb{S}$ and let $A, B \in \mathbb{S}$. We need to show that in case $(a, b) \in \mathit{Pairs}_{\mathbb{S}}$ for each $a, b \in A \cup B$, then also $A \cup B \in \mathbb{S}$. Let $B = \{b_1, \ldots, b_n\}$. As $\mathbb{S}$ is tight and $(a, b_1) \in \mathit{Pairs}_{\mathbb{S}}$ for all $a \in A$, $A \cup \{b_1\} = A_1 \in \mathbb{S}$ must hold. We can do this for each $b_i \in B$ and get $A_{n-1} \cup \{b_n\} = (A \cup B) \in \mathbb{S}$. □

Observe that for incomparable $\mathbb{S}$ the property of being adm-closed reduces to check for each $A, B \in \mathbb{S}$ $(A \neq B)$, whether there exist $a, b \in A \cup B$ such that $(a, b) \notin \mathit{Pairs}_{\mathbb{S}}$.

We can give results analogous to those of Lemma 2.

Lemma 4. *For an adm-closed extension-set $\mathbb{S} \subseteq 2^{\mathfrak{A}}$,*

1. *the $\subseteq$-maximal elements in $\mathbb{S}$ form an adm-closed set,*
2. *if $\mathbb{S}$ is incomparable then each $\mathbb{S}' \subseteq \mathbb{S}$ is adm-closed, and*
3. *$\mathbb{S} \cup \{\emptyset\}$ is adm-closed.*

Proof. (1) basically follows from the fact that $\mathit{Pairs}_{\mathbb{S}} = \mathit{Pairs}_{\mathbb{S}'}$ where $\mathbb{S}'$ is the set of $\subseteq$-maximal elements in $\mathbb{S}$. For (2) recall that for incomparable $\mathbb{S}$, adm-closed reduces to check for each $A, B \in \mathbb{S}$ with $A \neq B$, whether there exist $a, b \in A \cup B$ such that $(a, b) \notin \mathit{Pairs}_{\mathbb{S}}$. It is easy to see that this property still holds for $\mathbb{S}' \subseteq \mathbb{S}$ (since then, $\mathit{Pairs}'_{\mathbb{S}} \subseteq \mathit{Pairs}_{\mathbb{S}}$). (3) holds, since $S \cup \emptyset \in \mathbb{S}$ for each $S \in \mathbb{S}$ ensures that $\mathbb{S} \cup \{\emptyset\}$ is adm-closed by definition. □

The following proposition finally shows the role the property of being adm-closed plays in terms of admissible, preferred and semi-stable semantics.

Proposition 2. *For each* AF $F = (A, R)$,

1. *$\mathit{adm}(F)$ is adm-closed and contains $\emptyset$;*
2. *$\mathit{pref}(F)$ is non-empty, incomparable and adm-closed;*
3. *$\mathit{sem}(F)$ is non-empty, incomparable and adm-closed.*

Proof. ad 1) By definition, $\emptyset$ is always admissible. We show that $\mathit{adm}(F)$ is adm-closed. Towards a contradiction, assume $B, C \in \mathit{adm}(F)$ such that for all $b, c \in B \cup C$, $(b, c) \in \mathit{Pairs}_{\mathit{adm}(F)}$, but $B \cup C \notin \mathit{adm}(F)$. From Lemma 1 we know that $B \cup C$ defends itself in F. So for $B \cup C \notin \mathit{adm}(F)$ there must be a conflict in $B \cup C$, i.e. there is an attack $(b, c) \in R$ such that $\{b, c\} \subseteq B \cup C$. But then, for all $D \in \mathit{adm}(F)$, $\{b, c\} \not\subseteq D$. Hence, $(b, c) \notin \mathit{Pairs}_{\mathit{adm}(F)}$, a contradiction.

ad 2+3) By definition, both semantics $\sigma \in \{\mathit{pref}, \mathit{sem}\}$ yield at least one extension and for any $S, S' \in \sigma(F)$, $S \subseteq S'$ implies $S = S'$. By Lemma 4 and definition of preferred extensions, the fact that $\mathit{pref}(F)$ is adm-closed follows from the already shown property of $\mathit{adm}(F)$ being adm-closed. Since $\mathit{sem}(F) \subseteq \mathit{pref}(F)$ holds for all AFs F, Lemma 4 immediately shows that $\mathit{sem}(F)$ is adm-closed, as well. □

Example 2. Consider the framework F in Figure 2 and let $A = \{a, b\}$, $B = \{a, c, e\}$, $C = \{b, d, e\}$, and $\mathbb{S} = \{A, B, C\}$. We have $\mathit{pref}(F) = \mathit{sem}(F) = \mathbb{S}$. $\mathbb{S}$ is adm-closed, since for each pair of extensions, there exists a pair of arguments not contained in $\mathit{Pairs}_{\mathbb{S}}$: $b, c \in A \cup B$ and $(b, c) \notin \mathit{Pairs}_{\mathbb{S}}$; $a, d \in A \cup C$ and $(a, d) \notin \mathit{Pairs}_{\mathbb{S}}$; $c, d \in B \cup C$ and $(c, d) \notin \mathit{Pairs}_{\mathbb{S}}$. However, we also observe

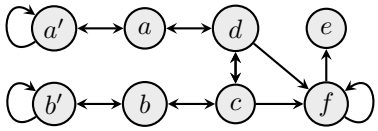

Figure 2: Argumentation framework F used in Example 2.

that $\mathbb{S}$ is not tight, since $A \cup \{e\} \notin \mathbb{S}$ but both (a, e) and (b, e) are contained in $\mathit{Pairs}_{\mathbb{S}}$. This shows that the reverse of Lemma 3 does not hold.

Complete Sets

Finally, we turn to the complete semantics. Compared to being adm-closed, we need a further relaxation.

Definition 6. Given an extension-set $\mathbb{S} \subseteq 2^{\mathfrak{A}}$ and $E \subseteq \mathfrak{A}$. we define the completion-sets $\mathbb{C}_{\mathbb{S}}(E)$ of E in $\mathbb{S}$ as the set of $\subseteq$-minimal sets $S \in \mathbb{S}$ with $E \subseteq S$.

In words, completion sets just give the "next" (in terms of supersets of A) elements contained in $\mathbb{S}$.

Definition 7. A set $\mathbb{S} \subseteq 2^{\mathfrak{A}}$ is called *com-closed* if for each $\mathbb{T} \subseteq \mathbb{S}$ the following holds: if $(a, b) \in \mathit{Pairs}_{\mathbb{S}}$ for each $a, b \in \mathit{Arg}_{\mathbb{T}} = \bigcup_{T \in \mathbb{T}} T$, then there exists a unique completion-set $S \in \mathbb{C}_{\mathbb{S}}(\mathit{Arg}_{\mathbb{T}})$. For a com-closed extension-set $\mathbb{S} \subseteq 2^{\mathfrak{A}}$ and $E \subseteq \mathfrak{A}$, we denote the unique element of $\mathbb{C}_{\mathbb{S}}(E)$ by $C_{\mathbb{S}}(E)$.

Lemma 5. *Each adm-closed extension-set is com-closed.*

Proof. Consider an adm-closed extension-set $\mathbb{S}$ and $\mathbb{T} \subseteq \mathbb{S}$. Then $(a, b) \in \mathit{Pairs}_{\mathbb{S}}$ for each $a, b \in \mathit{Arg}_{\mathbb{T}}$ implies $\mathit{Arg}_{\mathbb{T}} \in \mathbb{S}$, i.e. $\mathbb{C}_{\mathbb{S}}(\mathit{Arg}_{\mathbb{T}}) = \{\mathit{Arg}_{\mathbb{T}}\}$. □

In case of incomparable sets, the notions of adm-closed and com-closed coincide. In anticipation of the following result, this coincidence reflects the fact that all preferred extensions are complete.

Proposition 3. *For each* AF F, *$\mathit{com}(F)$ is a non-empty, com-closed extension-set with $(\bigcap_{S \in \mathit{com}(F)} S) \in \mathit{com}(F)$.*

Proof. First note that there is always at least one complete extension, namely the grounded extension. Moreover the grounded extension is the unique $\subseteq$-minimal complete extension and hence $(\bigcap_{S \in \mathit{com}(F)} S) \in \mathit{com}(F)$. Finally consider a set of complete extensions $\mathbb{E} \subseteq \mathit{com}(F)$ such that $(a, b) \in \mathit{Pairs}_{\mathit{com}(F)}$ for each $a, b \in \mathit{Arg}_{\mathbb{E}}$. By Lemma 1, $\mathit{Arg}_{\mathbb{E}}$ is an admissible set and thus can be extended to a unique complete extension $E' \supseteq \mathit{Arg}_{\mathbb{E}}$ by iteratively adding all defended arguments. Therefore $\mathit{com}(F)$ is com-closed. □

Example 3. Consider the AF $F = (\{a, a', b, b', c\}, \{(x, x'), (x', x), (x', x'), (x', c) \mid x \in \{a, b\}\})$. We have $\mathit{com}(F) = \{\emptyset, \{a\}, \{b\}, \{a, b, c\}\}$, which is com-closed, in particular, as $\mathbb{C}_{\mathit{com}(F)}(\{a\} \cup \{b\}) = \{\{a, b, c\}\}$. Observe that since $(a, b) \in \mathit{Pairs}_{\mathit{com}(F)}$, but $\{a, b\} \notin \mathit{com}(F)$, $\mathit{com}(F)$ is not adm-closed. This also shows that the reverse direction of Lemma 5 does not hold.

4 Realizability

In the previous section we have given necessary characteristics for the extension-sets $\mathbb{S} \in \Sigma_\sigma$, where $\sigma \in \{cf, adm, naive, stb, stage, pref, sem, com\}$. Except for the complete semantics, we will now show that these characteristics are also sufficient.

To this end, we need the concept of *realizability*: an extension-set $\mathbb{S} \subseteq 2^{\mathfrak{A}}$ is σ-realizable if there is an AF $F \in AF_{\mathfrak{A}}$, such that $\sigma(F) = \mathbb{S}$. We start with the following concept of a canonical argumentation framework, which will underlie all subsequent results on realizability.

Definition 8. Given an extension-set $\mathbb{S}$, we define the canonical argumentation framework for $\mathbb{S}$ as

$$F^{cf}_{\mathbb{S}} = \big(Arg_{\mathbb{S}}, (Arg_{\mathbb{S}} \times Arg_{\mathbb{S}}) \setminus Pairs_{\mathbb{S}}\big).$$

The idea behind the framework is simple: we draw a relation between two arguments iff they do *not* occur jointly in any set $S \in \mathbb{S}$. Thus, for any $\mathbb{S}$, $F^{cf}_{\mathbb{S}}$ is symmetric and has no self-attacking arguments (recall that for each $a \in Arg_{\mathbb{S}}$, $(a, a) \in Pairs_{\mathbb{S}}$). As an example, consider $\mathbb{T} = \{\{a_1, b_2, b_3\}, \{a_2, b_1, b_3\}, \{a_3, b_1, b_2\}, \{b_1, b_2, b_3\}\}$. $F^{cf}_{\mathbb{T}}$ has the same structure as the AF from Figure 1, but with all attacks being symmetric. We obtain $stb(F^{cf}_{\mathbb{T}}) = naive(F^{cf}_{\mathbb{T}}) = \mathbb{T}$. When we consider $\mathbb{S} = \{\{a_1, b_2, b_3\}, \{a_2, b_1, b_3\}, \{a_3, b_1, b_2\}\}$, i.e. $\mathbb{S} = \mathbb{T} \setminus \{\{b_1, b_2, b_3\}\}$, we obtain the same framework $F^{cf}_{\mathbb{S}} = F^{cf}_{\mathbb{T}}$, since $Pairs_{\mathbb{S}} = Pairs_{\mathbb{T}}$. In terms of naive semantics, this is not problematic, since $\mathbb{S}$ (as discussed in Example 1) cannot be realized via naive semantics at all. However, this observation readily suggests that realizing $\mathbb{S}$ with, say, stable semantics, requires additional concepts.

Stable, Stage, Naive and Conflict-Free Sets

Proposition 4. *(1) For each downward-closed and tight extension-set $\mathbb{S} \neq \emptyset$, $cf(F^{cf}_{\mathbb{S}}) = \mathbb{S}$. (2) For each incomparable extension-set $\mathbb{S} \neq \emptyset$, where $dcl(\mathbb{S})$ is tight, $naive(F^{cf}_{\mathbb{S}}) = \mathbb{S}$.*

Proof. (1) Let $F^{cf}_{\mathbb{S}} = (Arg_{\mathbb{S}}, R_{\mathbb{S}})$. $cf(F^{cf}_{\mathbb{S}}) \subseteq \mathbb{S}$: Observe that for each $E \in cf(F^{cf}_{\mathbb{S}})$, $(a, b) \in Pairs_{\mathbb{S}}$ for all $a, b \in E$ by construction of $R_{\mathbb{S}}$. Now suppose there exists $E' \in cf(F^{cf}_{\mathbb{S}})$ such that $E' \notin \mathbb{S}$. Wlog let E' be $\subseteq$-minimal with this property. Then $E' = S \cup \{c\}$ for some $S \in \mathbb{S}$. As $\mathbb{S}$ is tight there is an $s \in S$ such that $(s, c) \notin Pairs_{\mathbb{S}}$, a contradiction to the above observation. $cf(F^{cf}_{\mathbb{S}}) \supseteq \mathbb{S}$: Follows immediately by the fact that $\forall (a, b) \in Pairs_{\mathbb{S}} : (a, b) \notin R_{\mathbb{S}}$.

(2) First, note that $F^{cf}_{dcl(\mathbb{S})} = F^{cf}_{\mathbb{S}}$, since $Arg_{dcl(\mathbb{S})} = Arg_{\mathbb{S}}$ and $Pairs_{dcl(\mathbb{S})} = Pairs_{\mathbb{S}}$. $cf(F^{cf}_{\mathbb{S}}) = dcl(\mathbb{S})$ follows from (1). By construction of $dcl(\mathbb{S})$, the $\subseteq$-maximal sets in $dcl(\mathbb{S})$ are given by $\mathbb{S}$ and as naive sets are just $\subseteq$-maximal conflict-free, $naive(F^{cf}_{\mathbb{S}}) = \mathbb{S}$ follows. □

We proceed with stable and stage semantics. Stable semantics are the only semantics that can realize $\mathbb{S} = \emptyset$. Note that $\mathbb{S} = \emptyset$ is easily *stb*-realizable, for instance with the framework $(\{a\}, \{(a, a)\})$. In Proposition 1 the only difference between stable and stage semantics was the case $\mathbb{S} = \emptyset$.

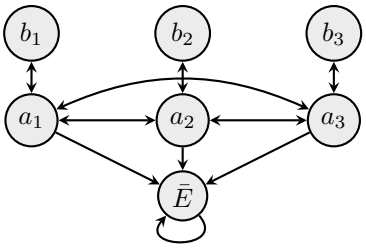

Figure 3: Excluding $\{b_1, b_2, b_3\}$ from $stb(F^{cf}_{\mathbb{S}})$.

The next result shows that this indeed is the only difference between the signatures for stable and stage semantics.

The idea of the construction below is to suitably extend the canonical framework from Definition 8 such that undesired sets are excluded. Coming back to our example with $\mathbb{S} = \{\{a_1, b_2, b_3\}, \{a_2, b_1, b_3\}, \{a_3, b_1, b_2\}\}$, recall that $F^{cf}_{\mathbb{S}}$ had one such undesired naive (and stable) extension, $E = \{b_1, b_2, b_3\}$. To get rid of it we add a new argument which is attacked by all other sets from $\mathbb{S}$ but not by E, see Figure 3 for illustration. The next definition generalizes this idea which is due to (Dvořák and Spanring 2012).

Definition 9. Given an extension-set $\mathbb{S}$ and its canonical framework $F^{cf}_{\mathbb{S}} = (A^{cf}_{\mathbb{S}}, R^{cf}_{\mathbb{S}})$, let $\mathbb{X} = stb(F^{cf}_{\mathbb{S}}) \setminus \mathbb{S}$. We define $F^{st}_{\mathbb{S}} = (A^{cf}_{\mathbb{S}} \cup \{\bar{E} \mid E \in \mathbb{X}\}, R^{cf}_{\mathbb{S}} \cup \{(\bar{E}, \bar{E}), (a, \bar{E}) \mid E \in \mathbb{X}, a \in Arg_{\mathbb{S}} \setminus E\})$.

Proposition 5. *For each non-empty, incomparable and tight extension-set $\mathbb{S}$, $stb(F^{st}_{\mathbb{S}}) = stage(F^{st}_{\mathbb{S}}) = \mathbb{S}$.*

Proof. Since $\mathbb{S}$ is non-empty, showing existence of an AF F with $stb(F) = \mathbb{S}$ is sufficient (for each F with $stb(F) \neq \emptyset$, $stb(F) = stage(F)$ holds).

Moreover, for each incomparable and tight extension-set $\mathbb{S}$, it holds that $\mathbb{S} \subseteq stb(F^{cf}_{\mathbb{S}})$: Towards a contradiction, let $S \in \mathbb{S}$ such that $S \notin stb(F^{cf}_{\mathbb{S}})$. By construction of $F^{cf}_{\mathbb{S}}$, $S \in cf(F^{cf}_{\mathbb{S}})$. Thus $\exists a \in Arg_{\mathbb{S}} : S \not\mapsto a$. But then by construction, $(a, s) \in Pairs_{\mathbb{S}}$, for all $s \in S$; this contradicts $\mathbb{S}$ being tight.

Now let $\mathbb{X} = stb(F^{cf}_{\mathbb{S}}) \setminus \mathbb{S}$ and consider $F^{st}_{\mathbb{S}}$. We show that $stb(F^{st}_{\mathbb{S}}) = \mathbb{S}$. $stb(F^{st}_{\mathbb{S}}) \subseteq \mathbb{S}$: Let $E \in stb(F^{st}_{\mathbb{S}})$. Then also $E \in stb(F^{cf}_{\mathbb{S}}) = \mathbb{X} \cup \mathbb{S}$. But if $E \in \mathbb{X}$, by Definition 9, $E \not\mapsto \bar{E}$ and also $\bar{E} \notin E$, thus $E \notin stb(F^{st}_{\mathbb{S}})$. Hence, $E \in \mathbb{S}$. $stb(F^{st}_{\mathbb{S}}) \supseteq \mathbb{S}$: Let $E \in \mathbb{S}$. We already know that $E \in stb(F^{cf}_{\mathbb{S}})$. Now consider $F^{st}_{\mathbb{S}}$. E still attacks all arguments in $Arg_{\mathbb{S}} \setminus E$. Now consider an arbitrary argument $\bar{E}'$ for $E' \in \mathbb{X}$. $\bar{E}'$ is attacked by all arguments $a \in Arg_{\mathbb{S}} \setminus E'$ and as E and E' are both stable in $F^{cf}_{\mathbb{S}}$ (and thus incomparable) at least one of these arguments must be contained in E. Hence $E \in stb(F^{st}_{\mathbb{S}})$. □

Preferred, Semi-Stable and Admissible Sets

Towards a suitable canonical AF for admissibility-based semantics we introduce the following technical concept.

Definition 10. Given an extension-set $\mathbb{S}$, the *defense-formula* $\mathcal{D}^{\mathbb{S}}_a$ of an argument $a \in Arg_{\mathbb{S}}$ in $\mathbb{S}$ is defined as $\bigvee_{S \in \mathbb{S} \text{ s.t. } a \in S} \bigwedge_{s \in S \setminus \{a\}} s$. $\mathcal{D}^{\mathbb{S}}_a$ given as (a logically equivalent) CNF is called *CNF-defense-formula* $\mathcal{CD}^{\mathbb{S}}_a$ of a in $\mathbb{S}$.

Intuitively, $\mathcal{D}^{\mathbb{S}}_a$ describes the conditions for the argument a being in an extension. Each disjunct represents a set of arguments which jointly allows a to "join" an extension, i.e. represents a collection of arguments defending a. Further note that $\mathcal{D}^{\mathbb{S}}_a = \top$ if and only if $\{a\} \in \mathbb{S}$.

Example 4. Consider $\mathbb{T} = \{\emptyset, \{a\}, \{b, c\}, \{a, c, d\}\}$. Then $\mathcal{D}^{\mathbb{T}}_a = \top, \mathcal{D}^{\mathbb{T}}_b = c, \mathcal{D}^{\mathbb{T}}_c = b \vee (a \wedge d)$ and $\mathcal{D}^{\mathbb{T}}_d = a \wedge c$. The corresponding CNF-defense-formulas[1] are $\mathcal{CD}^{\mathbb{T}}_a = \{\}$, $\mathcal{CD}^{\mathbb{T}}_b = \{\{c\}\}$, $\mathcal{CD}^{\mathbb{T}}_c = \{\{a, b\}, \{b, d\}\}$, and $\mathcal{CD}^{\mathbb{T}}_d = \{\{a\}, \{c\}\}$.

Lemma 6. *Given an extension-set $\mathbb{S}$ and an argument $a \in Arg_{\mathbb{S}}$, then for each $S \subseteq Arg_{\mathbb{S}}$ with $a \in S$: $(S \setminus \{a\})$ is a model of $\mathcal{D}^{\mathbb{S}}_a$ (resp. $\mathcal{CD}^{\mathbb{S}}_a$) iff there exists an $S' \subseteq S$ with $a \in S'$ such that $S' \in \mathbb{S}$.*

Proof. The if-direction follows straight forwardly by definition of $\mathcal{D}^{\mathbb{S}}_a$, since the conjunction of the elements of $S' \setminus \{a\}$ forms a term of $\mathcal{D}^{\mathbb{S}}_a$ for each $S' \in \mathbb{S}$ with $a \in S'$.

To show the only-if-direction consider some $S \subseteq Arg_{\mathbb{S}}$ with $a \in S$ where $S \setminus \{a\}$ is a model of $\mathcal{D}^{\mathbb{S}}_a$. If $\mathcal{D}^{\mathbb{S}}_a = \top$ then it holds that $\{a\} \in \mathbb{S}$. For $S \setminus \{a\}$ to be a model of $\mathcal{D}^{\mathbb{S}}_a \neq \top$, there must be some term $\tau \in \mathcal{D}^{\mathbb{S}}_a$, whose elements form a subset of $S \setminus \{a\}$. Consider such a term $\tau \in \mathcal{D}^{\mathbb{S}}_a$. Then by construction of $\mathcal{D}^{\mathbb{S}}_a$ there is some $S' \in \mathbb{S}$ with $a \in S'$, where $S' \setminus \{a\}$ coincides with the elements of τ. So $S' \subseteq S$. □

We make use of the defense formulas in the following construction.

Definition 11. Given an extension-set $\mathbb{S}$, the *canonical defense-argumentation-framework* $F^{def}_{\mathbb{S}} = (A^{def}_{\mathbb{S}}, R^{def}_{\mathbb{S}})$ extends the canonical AF $F^{cf}_{\mathbb{S}} = (Arg_{\mathbb{S}}, R^{cf}_{\mathbb{S}})$ as follows:

$$A^{def}_{\mathbb{S}} = Arg_{\mathbb{S}} \cup \bigcup_{a \in Arg_{\mathbb{S}}} \{\alpha_{a\gamma} \mid \gamma \in \mathcal{CD}^{\mathbb{S}}_a\}, \text{ and}$$

$$R^{def}_{\mathbb{S}} = R^{cf}_{\mathbb{S}} \cup \bigcup_{a \in Arg_{\mathbb{S}}} \{(b, \alpha_{a\gamma}), (\alpha_{a\gamma}, \alpha_{a\gamma}), (\alpha_{a\gamma}, a) | \gamma \in \mathcal{CD}^{\mathbb{S}}_a, b \in \gamma\}.$$

$F^{def}_{\mathbb{S}}$ consists of all arguments given in the extension-set plus a certain amount of additional arguments. Each $\alpha_{a\gamma}$ attacks argument a and is attacked by all arguments occurring as literals in clause γ of the CNF-defense-formula of a. So in $F^{def}_{\mathbb{S}}$ for a to be defended from $\alpha_{a\gamma}$ it takes at least one argument of these occurring as atoms in clause γ of $\mathcal{CD}^{\mathbb{S}}_a$.

Example 5. Again consider extension-set $\mathbb{T} = \{\emptyset, \{a\}, \{b, c\}, \{a, c, d\}\}$. We have given the CNF-defense-formulas in Example 4. $F^{def}_{\mathbb{T}}$ is given by the AF in Figure 4. Considering, for instance, argument c, where $\mathcal{CD}^{\mathbb{T}}_c = \{\{a, b\}, \{b, d\}\}$, one can see that in $F^{def}_{\mathbb{T}}$ it takes a or b in order to defend c from $\alpha_{c\{a,b\}}$, and b or d in order to defend c from $\alpha_{c\{b,d\}}$.

Proposition 6. *For each adm-closed extension-set $\mathbb{S}$ where $\emptyset \in \mathbb{S}$, $adm(F^{def}_{\mathbb{S}}) = \mathbb{S}$.*

[1] In what follows, we write CNF formulas in clause form.

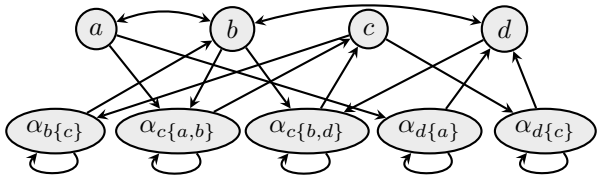

Figure 4: AF $F^{def}_{\mathbb{T}}$ used in Example 5.

Proof. $\mathbb{S} \subseteq adm(F^{def}_{\mathbb{S}})$: Let $S \in \mathbb{S}$. If $S = \emptyset$, the assertion trivially holds. If $S = \{a\}$, then $\mathcal{CD}^{\mathbb{S}}_a$ is the empty set of clauses. By definition of $R^{def}_{\mathbb{S}}$, a is then defended in $F^{def}_{\mathbb{S}}$ and thus $S \in adm(F^{def}_{\mathbb{S}})$. Thus let $S \in \mathbb{S}$ contain at least two arguments. By construction, S is conflict-free in $F^{def}_{\mathbb{S}}$. It remains to show that each $s \in S$ is defended by S in $F^{def}_{\mathbb{S}}$. Let $s \in S$. We know from Lemma 6 that $S \setminus \{s\}$ is a model of $\mathcal{CD}^{\mathbb{S}}_s$. Hence, each clause $\gamma \in \mathcal{CD}^{\mathbb{S}}_s$ contains at least one variable $t_\gamma \in S \setminus \{s\}$. Thus, by construction of $R^{def}_{\mathbb{S}}$, $(S \setminus \{s\}) \mapsto \alpha_{s\gamma}$ for each $\gamma \in \mathcal{CD}^{\mathbb{S}}_s$, i.e. S defends s in $F^{def}_{\mathbb{S}}$.

$adm(F^{def}_{\mathbb{S}}) \subseteq \mathbb{S}$: Let $S \in adm(F^{def}_{\mathbb{S}})$. For $S = \emptyset$, $S \in \mathbb{S}$ by definition. If $S = \{a\}$, then $a \mapsto b$ whenever some argument b attacks a. Hence, $\mathcal{CD}^{\mathbb{S}}_a = \{\}$, i.e. $\mathcal{D}^{\mathbb{S}}_a = \top$ must hold, therefore $S \in \mathbb{S}$. Now assume S contains at least two arguments. As S is conflict-free in $F^{def}_{\mathbb{S}}$, the construction of $R^{def}_{\mathbb{S}}$ guarantees that for all $a, b \in S$, $(a, b) \in Pairs_{\mathbb{S}}$. Let $s \in S$ with $\{s\} \notin adm(F^{def}_{\mathbb{S}})$. Then we have $\alpha_{s\gamma} \mapsto s$ for each $\gamma \in \mathcal{CD}^{\mathbb{S}}_s$. Since s is defended by S, for each $\gamma \in \mathcal{CD}^{\mathbb{S}}_s$, $\exists t_\gamma \in (S \setminus \{s\}) : t_\gamma \mapsto \alpha_{s\gamma}$. By definition of $F^{def}_{\mathbb{S}}$, thus t_γ occurs in the clause γ. It follows that $T = \{t_\gamma \mid \gamma \in \mathcal{CD}^{\mathbb{S}}_s\}$ is a model of $\mathcal{CD}^{\mathbb{S}}_s$ and $\mathcal{D}^{\mathbb{S}}_s$. Then by Lemma 6 there is some $S'_s \subseteq T \cup \{s\}$ (note that also $S'_s \subseteq S$ as $s \in S$ and for each $t_\gamma \in T$ also $t_\gamma \in S$) with $s \in S'_s$ such that $S'_s \in \mathbb{S}$. Recall also that in case $\{s\} \in adm(F^{def}_{\mathbb{S}})$, we know that $\{s\} \in \mathbb{S}$ (say $S'_s = \{s\}$). Now since $(a, b) \in Pairs_{\mathbb{S}}$ for all $a, b \in S$ and since $\mathbb{S}$ is adm-closed, it must hold that $S'_{s_1} \cup S'_{s_2} \in \mathbb{S}$ for any $s_1, s_2 \in S$. Hence $S = \left(\bigcup_{s_i \in S} S'_{s_i}\right) \in \mathbb{S}$. □

The construction also works for further semantics.

Proposition 7. *For each non-empty, incomparable and adm-closed extension-set $\mathbb{S}$ there exist F, F' with $pref(F) = \mathbb{S}$ and $sem(F') = \mathbb{S}$.*

Proof. By Proposition 6 and Lemma 4.3, $adm(F^{def}_{\mathbb{S}}) = \mathbb{S} \cup \{\emptyset\}$. Since $\mathbb{S}$ is incomparable, $pref(F^{def}_{\mathbb{S}}) = \mathbb{S}$. Moreover, as shown by Dvořák and Woltran (2011), for each AF F there is an AF F' such that $pref(F) = sem(F')$. □

Each extension-set $\mathbb{S}$ realizable under the admissible semantics, can also be realized under the complete semantics: extend $F^{def}_{\mathbb{S}}$ for each $a \in Arg_{\mathbb{S}}$ by a self-attacking argument with an attack from and to a. As Example 3 already suggests, the complete semantics is however capable of realizing more diverse extension-sets. However, the property of being com-closed (cf. Definition 7) so far only gives an approximation of the sets which can realized.

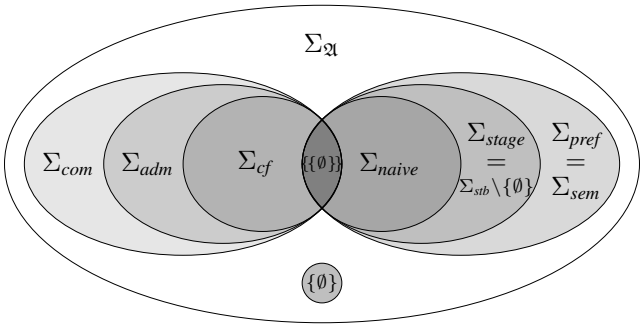

Figure 5: Relations between signatures.

Example 6. Let $\mathbb{S} = \{\emptyset, \{a\}, \{b\}, \{c\}, \{a, b, c\}, \{a, d, e\}, \{b, d, f\}, \{x, c\}, \{x, d\}\}$. $\mathbb{S}$ is com-closed and and satisfies $(\bigcap_{S \in \mathbb{S}} S) = \emptyset \in \mathbb{S}$. We argue that $\mathbb{S}$ is not *com*-realizable. Towards a contradiction consider an AF F such that $com(F) = \mathbb{S}$. First as $\{x, c\}, \{x, d\} \in \mathbb{S}$ and no superset of $\{x, c, d\}$ is in $\mathbb{S}$, there must be a conflict between c and d. In case $(c, d) \in R$ and $(d, c) \notin R$, (x, d) is not admissible (as $(x, c) \in Pairs_{\mathbb{S}}$). Similar for $(d, c) \in R$ and $(c, d) \notin R$. Thus $(c, d), (d, c) \in R$. Now consider $\{a, b\}$ which must be admissible as $\{a\}, \{b\}$ are admissible and $(a, b) \in Pairs_{\mathbb{S}}$. But as $\{a, b\} \notin \mathbb{S}$ it has to defend argument c ($C_{\mathbb{S}}(\{a, b\}) = \{a, b, c\}$). But we have $(d, c) \in R$ and $(a, d), (b, d) \in Pairs_{\mathbb{S}}$. Hence $\{a, b\}$ cannot defend c.

5 Signatures & Limits of Disagreement

We now state our main result, i.e. exact characterizations of the signatures for the semantics dealt with in this paper.

Theorem 1. *The signatures for the considered semantics are given by the following collections of extension-sets.*

$$\Sigma_{cf} = \{\mathbb{S} \neq \emptyset \mid \mathbb{S} \text{ is downward-closed and tight}\}$$
$$\Sigma_{naive} = \{\mathbb{S} \neq \emptyset \mid \mathbb{S} \text{ is incomparable and } dcl(\mathbb{S}) \text{ is tight}\}$$
$$\Sigma_{stb} = \{\mathbb{S} \mid \mathbb{S} \text{ is incomparable and tight}\}$$
$$\Sigma_{stage} = \{\mathbb{S} \neq \emptyset \mid \mathbb{S} \text{ is incomparable and tight}\}$$
$$\Sigma_{adm} = \{\mathbb{S} \neq \emptyset \mid \mathbb{S} \text{ is adm-closed and contains } \emptyset\}$$
$$\Sigma_{pref} = \Sigma_{sem} = \{\mathbb{S} \neq \emptyset \mid \mathbb{S} \text{ is incomparable and adm-closed}\}$$

All relations of the theorem are immediate from results in the previous section and the corresponding characteristics from Propositions 1 and 2. Moreover, $\Sigma_{com} \subset \{\mathbb{S} \neq \emptyset \mid \mathbb{S} \text{ is com-closed and } (\bigcap_{S \in \mathbb{S}} S) \in \mathbb{S}\}$, cf. Proposition 3.

By inspecting the respective properties, we can now immediately put the signatures of different semantics in relation to each other. For illustration see Figure 5, where $\Sigma_{\mathfrak{A}}$ just denotes the set of all extensions-sets over $\mathfrak{A}$, and the singleton $\{\emptyset\}$, i.e. the extension-set containing no extension, belongs to Σ_{stb}.

Theorem 2. *The following relations hold*

$$\Sigma_{naive} \subset \Sigma_{stage} \subset \Sigma_{sem} = \Sigma_{pref}, \qquad \Sigma_{stb} = \Sigma_{stage} \cup \{\emptyset\}$$
$$\Sigma_{cf} \subset \Sigma_{adm} \subset \Sigma_{com}$$
$$\{dcl(\mathbb{S}) \mid \mathbb{S} \in \Sigma_{naive}\} = \Sigma_{cf}, \quad \Sigma_{adm} \supset \{\mathbb{S} \cup \{\emptyset\} \mid \mathbb{S} \in \Sigma_{pref}\}$$

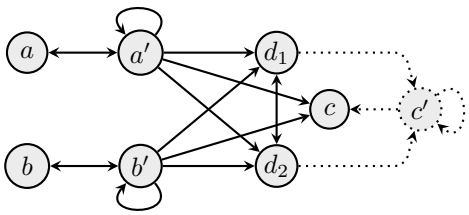

Figure 6: AFs F_1,F_2 with $(com(F_1) \cap com(F_2)) \notin \Sigma_{com}$.

Proof. In what follows, we make implicit use of the results from Theorem 1. First, by Lemma 2.1, $\Sigma_{naive} \subseteq \Sigma_{stage}$; $\Sigma_{naive} \neq \Sigma_{stage}$ is witnessed by Example 1. Relations $\Sigma_{stage} \subseteq \Sigma_{sem}$ and $\Sigma_{cf} \subseteq \Sigma_{adm}$ follow from Lemma 3. $\Sigma_{stage} \neq \Sigma_{sem}$ is by Example 2. $\Sigma_{cf} \neq \Sigma_{adm}$ is seen by extension-set $\{\emptyset, \{a, b\}\}$ which is adm-closed but not downward-closed. The fact that *adm*-realizability implies *com*-realizability and Example 3 show $\Sigma_{adm} \subset \Sigma_{com}$. The relations in the last line follow from the definition of $dcl(\cdot)$ and Lemma 4.3 respectively. □

With our results on signatures at hand, we now provide some interesting implications. The first result examines the question whether the intersection of two extension-sets under a given semantics σ, can always be realized.

Theorem 3. *For each $\sigma \in \{cf, naive, stb, stage, pref, sem, adm\}$ it holds that for any AFs F_1, F_2 there exists an AF F such that $\sigma(F) = \sigma(F_1) \cap \sigma(F_2)$ if $\sigma(F_1) \cap \sigma(F_2) \neq \emptyset$.*[2]

Proof. (Sketch.) We have to show that $\sigma(F_1) \cap \sigma(F_2)$ satisfies the properties according to the signature of the particular semantics. Existence of F is then a consequence of Theorem 1. The result for *stb*, *stage*, *pref*, *sem* follows from Lemma 2.2 and Lemma 4.2. The argument for *adm* is as follows (*cf* and *naive* are handled in a similar way). Assume $\mathbb{S} = adm(F_1) \cap adm(F_2)$ is not adm-closed, i.e. there are $A, B \in \mathbb{S}$ such that for all $a, b \in (A \cup B)$, $(a, b) \in Pairs_{\mathbb{S}}$, but $(A \cup B) \notin \mathbb{S}$. Then there is $i \in \{1, 2\}$, such that $A, B \in adm(F_i)$ but $(A \cup B) \notin adm(F_i)$. But then, $adm(F_i)$ is not adm-closed, a contradiction to Proposition 2. □

The complete semantics turns out to be the only semantics not closed under this form of intersection. Consider $\mathbb{S} = \{\emptyset, \{a\}, \{b\}, \{a, b, c, d_1\}, \{a, b, c, d_2\}\}$, $\mathbb{S}_1 = \mathbb{S} \cup \{\{a, b\}\}$, and $\mathbb{S}_2 = \mathbb{S} \cup \{\{a, b, c\}\}$. $\mathbb{S}_1$ and $\mathbb{S}_2$ are realizable under the complete semantics. Corresponding AFs are depicted in Figure 6: $\mathbb{S}_1$ are the complete extensions of the entire AF, and $\mathbb{S}_2$ the ones of the AF without the dotted part. However, $\mathbb{S} = \mathbb{S}_1 \cap \mathbb{S}_2$ is not com-closed and therefore, by Proposition 3, no AF F exists such that $com(F) = \mathbb{S}$.

Our next results concern limits in expressing multiple extensions. Our first result is positive in a sense that as long as two (maximal) sets of arguments are involved, all semantics are capable to deliver such extensions. Recall that three sets (e.g. $\mathbb{S} = \{\{a, b\}, \{a, c\}, \{b, c\}\}$) are already problematic.

Proposition 8. *For any incomparable extension-set $\mathbb{S} \neq \emptyset$ with $|\mathbb{S}| \leq 2$, $\mathbb{S} \in \Sigma_\sigma$ for $\sigma \in \{naive, stb, stage, pref, sem\}$.*

[2] $\sigma(F_1) \cap \sigma(F_2) \neq \emptyset$ is not a necessary condition for $\sigma = stb$.

Proof. By Theorem 2, it suffices to show the claim for naive semantics. By Theorem 1, we need to show that $dcl(\mathbb{S})$ is tight, which trivially holds for $|\mathbb{S}| = 1$. For $\mathbb{S} = \{S_1, S_2\}$, let $S \in dcl(\mathbb{S})$ and $a \in Arg_{\mathbb{S}}$ such that $S \cup \{a\} \notin dcl(\mathbb{S})$. Wlog. assume $S \subseteq S_1$. Then, $a \in S_2 \setminus S_1$ and $S \not\subseteq S_2$, i.e. there is some $s \in S \setminus S_2$. Since $|\mathbb{S}| = 2$, $(a, s) \notin Pairs_{\mathbb{S}}$. □

How many extensions can maximally be achieved by an AF under a semantics σ? Such results ease checking $\mathbb{S} \in \Sigma_\sigma$ whenever the cardinality of $\mathbb{S}$ exceeds a certain number.

Research in this direction has recently been initiated by Baumann and Strass (2014). They proposed a function giving the maximal number of stable extensions an AF with n arguments can have. In accordance to realizability, we are interested in the number of extensions as a function of a fixed amount of arguments occurring in any extension.

While our results on signatures give insights about the extent of structural diversity a semantics can express, the maximal number of extensions gives, to some degree, an answer to how much quantitative disagreement a semantics can express.

Definition 12. Given a semantics σ, we define the diversity-function $\Delta_\sigma(n) = \max_{F \in AF_{\mathfrak{A}}, \|\sigma(F)\|=n} |\sigma(F)|$.

It is easy to see that $\Delta_\sigma(n) = 2^n$ for $\sigma \in \{cf, adm, com\}$. For the other semantics, we first give a technical lemma.

Lemma 7. *For any* AF F*, there is a symmetric* AF F^{sym} *with* $\|pref(F)\| = \|pref(F^{sym})\|$ *and* $|pref(F)| \leq |pref(F^{sym})|$.

Proof (Sketch). Transform $F = (A, R)$ by (1) removing all arguments $a \notin Arg_{pref(F)}$ together with adjacent attacks, and (2) adding (b, a) to R if $(a, b) \in R$. Obviously conflict-freeness and defense is preserved, i.e. any set admissible in F is admissible in F^{sym}. Moreover, as only attacks to and from arguments not occurring in any preferred extension of F are removed, any conflict between two $E_1, E_2 \in pref(F)$ survives the translation, therefore there must be two different $E_1', E_2' \in pref(F^{sym})$ with $E_1 \subseteq E_1'$ and $E_2 \subseteq E_2'$. Hence $|pref(F)| \leq |pref(F^{sym})|$. As $Arg_{pref(F^{sym})}$ coincides with the arguments of F^{sym} (by symmetry of F^{sym}), it follows that $\|pref(F)\| = \|pref(F^{sym})\|$. □

Using the recent results by Baumann and Strass (2014), Lemma 7 and Theorem 1 allow to specify the function Δ_σ for all incomparable semantics σ.

Theorem 4. *For* $\sigma \in \{naive, stb, stage, pref, sem\}$*, we have*

$$\Delta_\sigma(n) = \begin{cases} 1 & n = 1 \\ 3^s & n \geq 2 \wedge n = 3s \\ 4 \cdot 3^{s-1} & n \geq 2 \wedge n = 3s + 1 \\ 2 \cdot 3^s & n \geq 2 \wedge n = 3s + 2. \end{cases}$$

Proof. Consider a semantics $\sigma \in \{naive, stb, stage, pref, sem\}$ and an AF F having maximal diversity, i.e. $|\sigma(F)| = \Delta_\sigma(\|\sigma(F)\|)$. Since $\Sigma_\sigma \subseteq \Sigma_{pref}$, we can find an AF F' with $pref(F') = \sigma(F)$. By Lemma 7 we can find a symmetric $F^{sym}{=}(A^{sym}, R^{sym})$ such that $\|pref(F^{sym})\| = \|\sigma(F)\|$ and $|pref(F^{sym})| = |\sigma(F)|$ (as we assume F maximally diverse). In this symmetric AF it holds that $pref(F^{sym}) = \sigma(F^{sym})$. As $\|\sigma(F^{sym})\| = |A^{sym}|$ we can generalize the result of (Baumann and Strass 2014) for $\Delta_{stb}(n)$ to all semantics σ. □

6 Complexity

In this section, we first consider the problem of checking membership in a signature for semantics σ, i.e. given an extension-set $\mathbb{S}$, does $\mathbb{S} \in \Sigma_\sigma$ hold? For most of the semantics, it is not hard to see that this can be done in polynomial time in the size of $\mathbb{S}$. The only exception is the naive semantics, since the characterization in Theorem 1 makes use of $dcl(\mathbb{S})$ which is not polynomially bounded in the size of $\mathbb{S}$.

We provide an alternative characterization based on the ternary majority operator maj_3: given $S_1, S_2, S_3 \subseteq \mathfrak{A}$, $maj_3(S_1, S_2, S_3) = (S_1 \cap S_2) \cup (S_2 \cap S_3) \cup (S_1 \cap S_3)$.

Proposition 9. *For an incomparable extension-set* $\mathbb{S}$ *it holds that* $dcl(\mathbb{S})$ *is tight iff for all* $S_1, S_2, S_3 \in \mathbb{S}$ *there is an* $S \in \mathbb{S}$*, such that* $maj_3(S_1, S_2, S_3) \subseteq S$.

Proof. Suppose for all $S_1, S_2, S_3 \in \mathbb{S}$ there is some $S \in \mathbb{S}$ such that $maj_3(S_1, S_2, S_3) \subseteq S$. Towards a contradiction assume that the downward-closure of $\mathbb{S}$ is not tight, i.e. there exist $S' \in dcl(\mathbb{S})$ and $a \in Arg_{\mathbb{S}} = Arg_{dcl(\mathbb{S})}$, such that $(S' \cup \{a\}) \notin dcl(\mathbb{S})$ and for all $s \in S'$, $(a, s) \in Pairs_{\mathbb{S}} = Pairs_{dcl(\mathbb{S})}$. Assume $|S'| = 1$, i.e. $S' = \{s\}$. As $(a, s) \in Pairs_{\mathbb{S}}$ by assumption, $\{a, s\} \in dcl(\mathbb{S})$, a contradiction to $S' \cup \{a\} \notin dcl(\mathbb{S})$. Hence $|S'| > 1$, i.e. $S' = \{s_1, \ldots, s_n\}$ with $n > 1$. By assumption, $\{s_1, \ldots, s_n, a\} \notin \mathbb{S}$, but $(a, s_i) \in Pairs_{\mathbb{S}}$ for each $s_i \in S'$. Hence, for each $s_i \in S'$ there is some $S_i \in \mathbb{S}$ with $\{a, s_i\} \subseteq S_i$ for $i = 1 \ldots n$. Moreover $maj_3(S_i, S_j, S') \supseteq \{s_i, s_j, a\}$ for each $i, j \in \{1, \ldots, n\}$ since $s_i \in S' \cap S_i$, $s_j \in S' \cap S_j$, and $a \in S_i \cap S_j$. Therefore there is some $S_{ij} \in \mathbb{S}$ with $S_{ij} \supseteq \{s_i, s_j, a\}$. Now for some $k \in \{1, \ldots, n\}$, we get $S_{ijk} = maj_3(S_{ij}, S_k, S') \supseteq \{s_i, s_j, s_k, a\}$ and $S_{ijk} \in \mathbb{S}$. Following this procedure for all $1 \ldots n$ yields a $T \in \mathbb{S}$ with $T \supseteq \{s_1, \ldots, s_n, a\}$, a contradiction to $S' \cup \{a\} \notin dcl(\mathbb{S})$.

On the other hand consider some extension-set $\mathbb{S}$ where $dcl(\mathbb{S})$ is tight and assume, towards a contradiction, sets $S_1, S_2, S_3 \in \mathbb{S}$ such that $maj_3(S_1, S_2, S_3) \not\subseteq S$, for all $S \in \mathbb{S}$. Now, consider the maximal $S' \subset maj_3(S_1, S_2, S_3)$ with $S' \in dcl(\mathbb{S})$, i.e. $\exists a \in maj_3(S_1, S_2, S_3) \setminus S'$ such that $S' \cup \{a\} \notin dcl(\mathbb{S})$. As $S' \cup \{a\} \subseteq maj_3(S_1, S_2, S_3)$, all $s \in (S' \cup \{a\})$ are also contained in $((S_1 \cap S_2) \cup (S_2 \cap S_3) \cup (S_1 \cap S_3))$. Thus for each $s \in S'$ there is some $S_i \in \{S_1, S_2, S_3\}$ with $\{s, a\} \subseteq S_i$. Hence, $(s, a) \in Pairs_{\mathbb{S}}$, so that $dcl(\mathbb{S})$ is not tight, a contradiction. □

Testing the majority criterion is done in polynomial time by looping over all triples (S_1, S_2, S_3) stemming from $\mathbb{S}$. We obtain the following theorem.

Theorem 5. *For semantics* $\sigma \in \{cf, naive, stb, stage, adm, pref, sem\}$*, given* $\mathbb{S}$*, testing* $\mathbb{S} \in \Sigma_\sigma$ *is in polynomial time.*

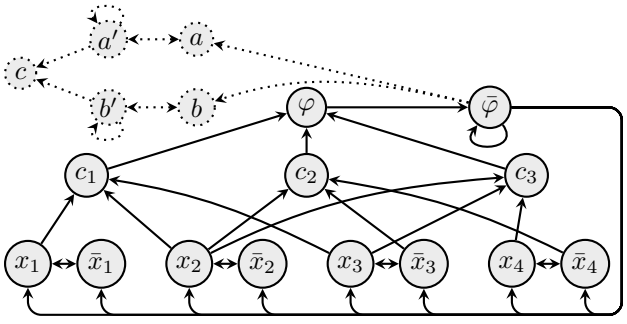
Next we exploit our results to give a preliminary complexity analysis in terms of the problem of *recasting*: given an AF $F_1 \in AF_{\mathfrak{A}}$ and two semantics σ_1, σ_2, decide whether there exists an $F_2 \in AF_{\mathfrak{A}}$, such that $\sigma_1(F_1) = \sigma_2(F_2)$. By the very nature of signatures, this is equivalent to test $\sigma_1(F_1) \in \Sigma_{\sigma_2}$. Table 1 summarizes our results. An entry for row σ_1 and column σ_2 gives the complexity of deciding whether $\sigma_1(F) \in \Sigma_{\sigma_2}$. $\mathcal{C}$-h abbreviates hardness for class $\mathcal{C}$; $\mathcal{C}$-c abbreviates completeness for class $\mathcal{C}$; "trivial" means

Table 1: Complexity of the recasting problem.

	cf	*adm*	*com*
cf	-	trivial	trivial
adm	coNP-c	-	trivial
com	coNP-c	coNP-c	-

	naive	*stb*	*stage*	*pref*	*sem*
naive	-	trivial	trivial	trivial	trivial
stb	coNP-h	-	NP-c	NP-c	NP-c
stage	coNP-h	trivial	-	trivial	trivial
pref	coNP-h	Π_2^P-c	Π_2^P-c	-	trivial
sem	coNP-h	Π_2^P-c	Π_2^P-c	trivial	-

that each instance is a "Yes"-instance. For both tables, these "trivial" entries are immediate from Theorem 2.



Theorem 6. *The complexity results depicted in Table 1 hold.*

Proof. (Sketch.) Due to the space constraints, we exemplify only one of the coNP-membership arguments for the upper table and provide a non-deterministic algorithm disproving, given an AF F, $com(F) \in \Sigma_{adm}$. Here, we check (i) $\emptyset \notin com(F)$ or (ii) $com(F)$ is not *adm*-closed. Clearly (i) can be done in polynomial time. For (ii) notice that if $com(F)$ is not *adm*-closed then there exist sets $A, B \in com(F)$ such that $A \cup B \in cf(F)$ but $A \cup B \notin com(F)$. But then there exists a set C with $A \cup B \subset C \in com(F)$. So to disprove $com(F)$ being *adm*-closed we guess sets A, B, C and test whether $A, B, C \in com(F)$, $A \cup B \subset C$ but $A \cup B \notin com(F)$.

For coNP-hardness, we first give the result for $\sigma_1 \in \{adm, com\}$ and $\sigma_2 = cf$. We use a standard reduction from CNF formulas $\varphi(X) = \bigwedge_{c \in C} c$ with each clause $c \in C$ a disjunction of literals from X to $F_\varphi = (A_\varphi, R_\varphi)$ given as

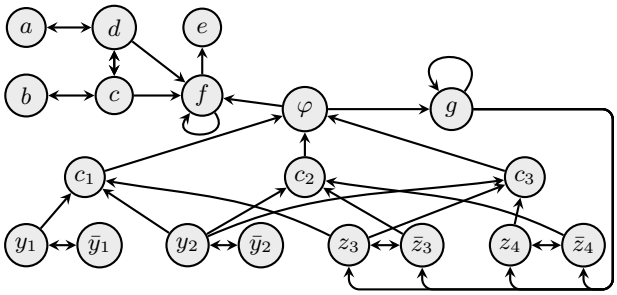
$$A_\varphi = \{\varphi, \bar{\varphi}\} \cup C \cup X \cup \bar{X}$$
$$R_\varphi = \{(c, \varphi) \mid c \in C\} \cup \{(x, \bar{x}), (\bar{x}, x) \mid x \in X\} \cup \{(x, c) \mid x \text{ occurs in } c\} \cup \{(\bar{x}, c) \mid \neg x \text{ occurs in } c\} \cup \{(\varphi, \bar{\varphi}), (\bar{\varphi}, \bar{\varphi})\} \cup \{(\bar{\varphi}, x), (\bar{\varphi}, \bar{x}) \mid x \in X\}.$$

We illustrate the framework F_φ (ignore the dashed part for the moment) for the CNF-formula $\varphi = (x_1 \vee x_2 \vee x_3) \wedge (x_2 \vee \neg x_3 \vee \neg x_4) \wedge (x_2 \vee x_3 \vee x_4)$.

It holds that φ is satisfiable iff there is an $S \neq \emptyset$ in $\sigma_1(F_\varphi)$ iff there is an $S \in \sigma_1(F_\varphi)$ with $\varphi \in S$ (Dimopoulos and Torres 1996). Now if $adm(F_\varphi) = com(F_\varphi) = \{\emptyset\}$ then $\sigma_1(F_\varphi)$ is clearly *cf*-realizable. On the other hand $\{\varphi\} \notin adm(F)$ (and thus $\{\varphi\} \notin com(F)$). So if there is an $S \in \sigma_1(F_\varphi)$ with $\varphi \in S$ then $\sigma_1(F_\varphi)$ is not downward closed and thus not *cf*-realizable. Thus we obtain that φ is satisfiable iff $\sigma_1(F_\varphi)$ is not *cf*-realizable.

The result for $\sigma_1 = com$ and $\sigma_2 = adm$ can be shown via an extension of above reduction to $F'_\varphi = (A'_\varphi, R'_\varphi)$ with $A'_\varphi = A_\varphi \cup \{a, a', b, b', c\}$ and $R'_\varphi = R_\varphi \cup \{(a, a'), (a', a), (a', a'), (a', c), (b, b'), (b', b), (b', b'), (b', c), (\bar{\varphi}, a), (\bar{\varphi}, b)\}$. The AF F'_φ for the example CNF is illustrated in the above figure including the dashed part.

We turn to second table and use $\Sigma_{stb} = \Sigma_{stage} \cup \{\emptyset\}$, $\Sigma_{stage} \subset \Sigma_{sem} = \Sigma_{pref}$ from our main theorems. Thus, $stb(F) \in \Sigma_\sigma$ ($\sigma \in \{stage, pref, sem\}$) iff $stb(F) \neq \emptyset$. Deciding whether an AF has a stable extension is known to be NP-complete.



Next, we consider the coNP-hardness of recasting to *naive* semantics. Again, we extend F_φ from above and define $F^*_\varphi = (A^*_\varphi, R^*_\varphi)$ using an additional gadget (see Figure 1) via $A^*_\varphi = A_\varphi \cup \{a_1, a_2, a_3, b_1, b_2, b_3\}$ and $R^*_\varphi = \big(R_\varphi \setminus \{(\bar{\varphi}, \bar{\varphi})\}\big) \cup \{(\bar{\varphi}, a_i), (\bar{\varphi}, b_i) \mid 1 \leq i \leq 3\} \cup \{(\bar{\varphi}, \varphi)\} \cup \{(a_i, a_j), (a_i, b_i) \mid 1 \leq i, j \leq 3, i \neq j\}$. It is known that φ is satisfiable iff $\{\bar{\varphi}\} \cup C$ is not the unique preferred extension of F^*_φ (Dunne 2009) (the additional part in the AF does not affect the claim). As $\{\bar{\varphi}\} \cup C$ is also a stable extension this result extends to *stb*, *sem* and *stage* semantics. Let $\sigma \in \{stb, pref, sem, stage\}$. If φ is unsatisfiable then $\{\bar{\varphi}\} \cup C$ is the only $S \in \sigma(F^*_\varphi)$. Otherwise, for each model M of φ, there exist $S_1, S_2, S_3 \in \sigma(F^*_\varphi)$, such that $maj_3(S_1, S_2, S_3) = M \cup \overline{X \setminus M} \cup \{\varphi, b_1, b_2, b_3\}$ is a maximal conflict-free set but not admissible and thus not in $\sigma(F^*_\varphi)$. By Proposition 9 and Theorem 1, $\sigma(F^*_\varphi) \notin \Sigma_{naive}$. Hence φ is satisfiable iff $\sigma(F^*_\varphi)$ is not *naive*-realizable.

Finally, we consider the Π_2^P-entries, i.e. $\sigma_1 \in \{pref, sem\}$, $\sigma_2 \in \{stb, stage\}$. Since $\sigma_1(F) \neq \emptyset$ for any AF F, and $\Sigma_{stb} = \Sigma_{stage} \cup \{\emptyset\}$, we can stick to $\sigma_2 = stb$. Membership is by an algorithm that, given an $F = (A, R)$, disproves $\sigma_1(F) \in \Sigma_{stb}$, that is it looks for counter examples (violating tightness) from $\sigma_1(F)$ as follows: guess sets $S \subseteq A$, $\{A_s \subseteq A \mid s \in S\}$ and $a \in A \setminus B$; check $S \in \sigma_1(F)$ and $S \cup \{a\} \notin \sigma_1(F)$, and for all $s \in B$ check $A_s \in \sigma_1(F)$ and $\{a, s\} \subseteq A_s$ (for all checks, an NP-oracle is sufficient (Dunne and Bench-Capon 2002; Dvořák and Woltran 2010)). For sets passing all the checks we have that S and a contradict tightness as $S \cup \{a\} \notin \sigma_1(F)$ but for each $s \in S$, $(a, s) \in Pairs_{\sigma_1(F)}$. By Theorem 1, $\sigma_1(F) \notin \Sigma_{stb}$.

We show Π_2^P-hardness for $\sigma_1 = pref$ (*pref* semantics can be efficiently reduced to *sem* semantics (Dvořák and Woltran 2011), the result for $\sigma_1 = sem$ thus follows): Given QBF $\Phi = \forall Y \exists Z \varphi(Y, Z)$, where φ is a CNF $\bigwedge_{c \in C} c$ with each c a disjunction of literals from $X = Y \cup Z$, let $F_\Phi = (A_\Phi, R_\Phi)$ with $A_\Phi = \{\varphi, g\} \cup C \cup X \cup \bar{X} \cup \{a, b, c, d, e, f\}$ and

$$R_\Phi = \{(c, \varphi) \mid c \in C\} \cup \{(x, \bar{x}), (\bar{x}, x) \mid x \in X\} \cup \{(x, c) \mid x \text{ occurs in } c\} \cup \{(\bar{x}, c) \mid \neg x \text{ occurs in } c\} \cup \{(\varphi, g), (g, g)\} \cup \{(g, z), (g, \bar{z}) \mid z \in Z\} \cup \{(a, d), (d, a), (b, c), (c, b), (c, d), (d, c), (c, f), (d, f), (f, e), (f, f), (\varphi, f)\}$$

We illustrate F_Φ for the QBF $\Phi = \forall y_1, y_2 \exists z_3, z_4 \big((y_1 \vee y_2 \vee z_3) \wedge (y_2 \vee \neg z_3 \vee \neg z_4) \wedge (y_2 \vee z_3 \vee z_4)\big)$.

F_Φ links the reduction from (Dunne and Bench-Capon 2002) with an AF similar to Figure 2. It holds that $\mathit{pref}(F_\Phi) \in \Sigma_{\mathit{stb}}$ iff φ is contained in all $E \in \mathit{pref}(F_\Phi)$. □

7 Discussion

In this work, we initiated a study on the characteristics the sets of extensions w.r.t. a given semantics satisfy. For the semantics naive, stable, stage, preferred, and semi-stable we have an exact picture fully describing their signatures. These results also tell about the limits of global disagreement (a notion introduced in (Booth et al. 2012)) that can be modelled within AFs, e.g. our results show that preferred and semi-stable semantics are able to express more disagreement than stage semantics: $\Sigma_{\mathit{stage}} \subset \Sigma_{\mathit{pref}} = \Sigma_{\mathit{sem}}$.

Besides an exact characterization of the signature of complete semantics, future work includes an investigation of other important semantics, in particular resolution-based grounded (Baroni, Dunne, and Giacomin 2011) and cf2-semantics (Baroni, Giacomin, and Guida 2005), and an according extension of our complexity analysis. On the one hand, exact bounds for the recasting problem involving naive extensions is still missing. On the other hand, the question of how complexity may be affected when $\mathbb{S}$ is specified through some other concise form, e.g. a propositional formula whose models are exactly $S \in \mathbb{S}$ is of some interest and the subject of current investigation. We also want to explore how our results allow for pruning the search space in algorithms for abstract argumentation. Finally, since we have viewed semantics here only in an extension-based way, it would also be of high interest to extend our studies to labelling-based semantics (Caminada and Gabbay 2009).

The Parameterized Complexity of Reasoning Problems Beyond NP

Ronald de Haan* and **Stefan Szeider***

dehaan@kr.tuwien.ac.at stefan@szeider.net

Abstract

Today's propositional satisfiability (SAT) solvers are extremely powerful and can be used as an efficient back-end for solving NP-complete problems. However, many fundamental problems in knowledge representation and reasoning are located at the second level of the Polynomial Hierarchy or even higher, and hence polynomial-time transformations to SAT are not possible, unless the hierarchy collapses. Recent research shows that in certain cases one can break through these complexity barriers by fixed-parameter tractable (fpt) reductions which exploit structural aspects of problem instances in terms of problem parameters.

In this paper we develop a general theoretical framework that supports the classification of parameterized problems on whether they admit such an fpt-reduction to SAT or not. We instantiate our theory by classifying the complexities of several case study problems, with respect to various natural parameters. These case studies include the consistency problem for disjunctive answer set programming and a robust version of constraint satisfaction.

1 Introduction

Over the last two decades, propositional satisfiability (SAT) has become one of the most successful and widely applied techniques for the solution of NP-complete problems. Today's SAT-solvers are extremely efficient and robust, instances with hundreds of thousands of variables and clauses can be solved routinely. In fact, due to the success of SAT, NP-complete problems have lost their scariness, as in many cases one can efficiently encode NP-complete problems to SAT and solve them by means of a SAT-solver (Gomes et al., 2008; Biere et al., 2009; Sakallah and Marques-Silva, 2011; Malik and Zhang, 2009). However, many important computational problems, most prominently in knowledge representation and reasoning, are located above the first level of the Polynomial Hierarchy (PH) and thus considered "harder" than SAT. Hence we cannot hope for polynomial-time reductions from these problems to SAT, as such transformations would cause the (unexpected) collapse of the PH.

Realistic problem instances are not random and often contain some kind of "hidden structure." Recent research succeeded to exploit such hidden structure to break the complexity barriers between levels of the PH, for problems that arise in disjunctive answer set programming (Fichte and Szeider, 2013) and abductive reasoning (Pfandler, Rümmele, and Szeider, 2013). The idea is to exploit problem structure in terms of a problem *parameter*, and to develop reductions to SAT that can be computed efficiently as long as the problem parameter is reasonably small. The theory of *parameterized complexity* (Downey and Fellows, 1999; Flum and Grohe, 2006; Niedermeier, 2006) provides exactly the right type of reduction suitable for this purpose, called *fixed-parameter tractable reductions*, or *fpt-reductions* for short. Now, for a suitable choice of the parameter, one can aim at developing fpt-reductions from the hard problem under consideration to SAT.

Such positive results go significantly beyond the state-of-the-art of current research in parameterized complexity. By shifting the scope from fixed-parameter tractability to fpt-reducibility (to SAT), parameters can be less restrictive and hence larger classes of inputs can be processed efficiently. Therefore, the potential for positive tractability results is greatly enlarged. In fact, there are some known reductions that, in retrospect, can be seen as fpt-reductions to SAT. A prominent example is Bounded Model Checking (Biere et al., 1999), which can be seen as an fpt-reduction from the model checking problem for linear temporal logic (LTL), which is PSPACE-complete, to SAT, where the parameter is an upper bound on the size of a counterexample. Bounded Model Checking is widely used for hardware and software verification at industrial scale (Biere, 2009).

New Contributions The aim of this paper is to establish a general theoretical framework that supports the classification of hard problems on whether they admit an fpt-reduction to SAT or not. The main contribution is the development of a new hardness theory that can be used to provide evidence that certain problems do not admit an fpt-reduction to SAT, similar to NP-hardness which provides evidence against polynomial-time tractability (Garey and Johnson, 1979) and W[1]-hardness which provides evidence against fixed-parameter tractability (Downey and Fellows, 1999).

At the center of our theory are two hierarchies of parameterized complexity classes: the $*$-k hierarchy and the k-$*$ hierarchy. We define the complexity classes in terms of weighted variants of the quantified Boolean satisfiability problem with

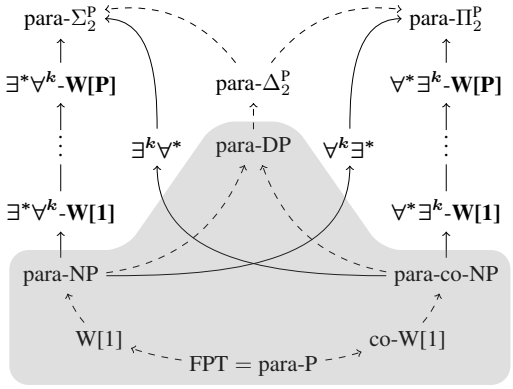

Figure 1: The parameterized complexity classes of the $*$-k and k-$*$ hierarchies (bold) in relation to existing classes. Arrows indicate inclusion relations. Dashed arrows indicate previously known relations. The classes highlighted in gray allow fpt-reductions to SAT; the other classes are unlikely to allow this.

one quantifier alternation, which is canonical for the second level of the PH. For the classes in the k-$*$ hierarchy, the (Hamming) weight of the assignment to the variables in the first quantifier block is bounded by the parameter k, the weight of the second quantifier block is unrestricted ("$*$"). For the classes in the $*$-k hierarchy it is the other way around, the weight in the second block restricted by k and the first block is unrestricted. Both hierarchies span various degrees of hardness between the classes para-NP and para-co-NP at the bottom and para-Σ_2^P at the top (para-C contains all parameterized problems that, after fpt-time preprocessing, ultimately belong to complexity class C (Flum and Grohe, 2003)). Figure 1 illustrates the relationship between the various parameterized complexity classes under consideration.

To illustrate the usefulness of our theory, we consider as a running example the fundamental problem of *answer set programming* which asks whether a disjuncive logic program has a stable model. This problem is Σ_2^P-complete (Eiter and Gottlob, 1995), and exhibits completeness or hardness for various of our complexity classes; see Table 1 for an overview. As a second case study, we will classify the complexity of a robust version of constraint satisfaction (Abramsky, Gottlob, and Kolaitis, 2013). In addition we were able to identify many other natural problems that populate our new complexity classes. We refer to a technical report corresponding to this paper which contains full proofs of all results, contains a compendium of problems, and is available on arXiv (http://arxiv.org/abs/1312.1672).

2 Preliminaries

2.1 Parameterized Complexity Theory

We introduce some core notions from parameterized complexity theory. For an in-depth treatment we refer to other sources (Downey and Fellows, 1999; Flum and Grohe, 2006; Niedermeier, 2006). A *parameterized problem* L is a subset of $\Sigma^* \times \mathbb{N}$ for some finite alphabet Σ. For an instance $(I, k) \in \Sigma^* \times \mathbb{N}$, we call I the *main part* and k the *parameter*. The following generalization of polynomial time computability is commonly regarded as the tractability notion of parameterized complexity theory. A parameterized problem L is *fixed-parameter tractable* if there exists a computable function f and a constant c such that there exists an algorithm that decides whether $(I, k) \in L$ in time $O(f(k)\|I\|^c)$, where $\|I\|$ denotes the size of I. Such an algorithm is called an *fpt-algorithm*, and this amount of time is called *fpt-time*. FPT is the class of all fixed-parameter tractable decision problems. If the parameter is constant, then fpt-algorithms run in polynomial time where the order of the polynomial is independent of the parameter. This provides a good scalability in the parameter in contrast to running times of the form $\|I\|^k$, which are also polynomial for fixed k, but are already impractical for, say, $k > 3$.

Parameterized complexity also offers a hardness theory, similar to the theory of NP-hardness, that allows researchers to give strong theoretical evidence that some parameterized problems are not fixed-parameter tractable. This theory is based on the *Weft hierarchy* of complexity classes FPT $\subseteq$ W[1] $\subseteq$ W[2] $\subseteq \cdots \subseteq$ W[SAT] $\subseteq$ W[P], where all inclusions are believed to be strict. For a hardness theory, a notion of reduction is needed. Let $L \subseteq \Sigma^* \times \mathbb{N}$ and $L' \subseteq (\Sigma')^* \times \mathbb{N}$ be two parameterized problems. An *fpt-reduction* from L to L' is a mapping $R : \Sigma^* \times \mathbb{N} \to (\Sigma')^* \times \mathbb{N}$ from instances of L to instances of L' such that there exist some computable function $g : \mathbb{N} \to \mathbb{N}$ such that for all $(I, k) \in \Sigma^* \times \mathbb{N}$: (i) (I, k) is a yes-instance of L if and only if $(I', k') = R(I, k)$ is a yes-instance of L', (ii) $k' \leq g(k)$, and (iii) R is computable in fpt-time. We write $L \leq_{\text{fpt}} L'$ if there is an fpt-reduction from L to L'.

The parameterized complexity classes W[t], $t \geq 1$, W[SAT] and W[P] are based on the satisfiability problems of Boolean circuits and formulas. We consider *Boolean circuits* with a single output gate. We call input nodes *variables*. We distinguish between *small* gates, with fan-in ≤ 2, and *large gates*, with fan-in > 2. The *depth* of a circuit is the length of a longest path from any variable to the output gate. The *weft* of a circuit is the largest number of large gates on any path from a variable to the output gate. We let Nodes(C) denote the set of all nodes of a circuit C. A *Boolean formula* can be considered as a Boolean circuit where all gates have fan-out ≤ 1. We adopt the usual notions of truth assignments and satisfiability of a Boolean circuit. We say that a truth assignment for a Boolean circuit has *weight* k if it sets exactly k of the variables of the circuit to true. We denote the class of Boolean circuits with depth u and weft t by $\Gamma_{t,u}$. We denote the class of all Boolean circuits by Γ, and the class of all Boolean formulas by Φ. For any class $\mathcal{C}$ of Boolean circuits, we define the following parameterized problem.

p-WSAT[$\mathcal{C}$] *Instance:* A Boolean circuit $C \in \mathcal{C}$, and an integer k. *Parameter:* k. *Question:* Does there exist an assignment of weight k that satisfies C?

We denote closure under fpt-reductions by $[\ \cdot\ ]^{\text{fpt}}$. The classes W[t] are defined by letting W[t] $= [\ \{\, p\text{-WSAT}[\Gamma_{t,u}] : u \geq 1 \,\}\ ]^{\text{fpt}}$ for all $t \geq 1$. The classes W[SAT] and W[P] are defined by letting W[SAT] $= [\ p\text{-WSAT}[\Phi]\ ]^{\text{fpt}}$ and W[P] $= [\ p\text{-WSAT}[\Gamma]\ ]^{\text{fpt}}$.

Parameterized complexity theory also offers complexity classes for problems that lie higher in the polynomial hierarchy. Let K be a classical complexity class, e.g., NP. The parameterized complexity class para-K is then defined as the class of all parameterized problems $L \subseteq \Sigma^* \times \mathbb{N}$, for some finite alphabet Σ, for which there exist an alphabet Π, a computable function $f : \mathbb{N} \to \Pi^*$, and a problem $P \subseteq \Sigma^* \times \Pi^*$ such that $P \in K$ and for all instances $(x, k) \in \Sigma^* \times \mathbb{N}$ of L we have that $(x, k) \in L$ if and only if $(x, f(k)) \in P$. Intuitively, the class para-C consists of all problems that are in C after a precomputation that only involves the parameter (Flum and Grohe, 2003). The class para-NP can also be defined via nondeterministic fpt-algorithms.

2.2 The Polynomial Hierarchy

There are many natural decision problems that are not contained in the classical complexity classes P and NP. The *Polynomial Hierarchy* (Meyer and Stockmeyer, 1972; Stockmeyer, 1976; Wrathall, 1976; Papadimitriou, 1994) contains a hierarchy of increasing complexity classes Σ_i^{P}, for all $i \geq 0$. We give a characterization of these classes based on the satisfiability problem of various classes of quantified Boolean formulas. A *quantified Boolean formula* is a formula of the form $Q_1 X_1 Q_2 X_2 \dots Q_m X_m \psi$, where each Q_i is either $\forall$ or $\exists$, the X_i are disjoint sets of propositional variables, and ψ is a Boolean formula over the variables in $\bigcup_{i=1}^{m} X_i$. The quantifier-free part of such formulas is called the *matrix* of the formula. Truth of such formulas is defined in the usual way. Let $\gamma = \{x_1 \mapsto d_1, \dots, x_n \mapsto d_n\}$ be a function that maps some variables of a formula φ to other variables or to truth values. We let $\varphi[\gamma]$ denote the application of such a substitution γ to the formula φ. We also write $\varphi[x_1 \mapsto d_1, \dots, x_n \mapsto d_n]$ to denote $\varphi[\gamma]$. For each $i \geq 1$ we define the following decision problem.

QSAT_i
Instance: A quantified Boolean formula $\varphi = \exists X_1 \forall X_2 \exists X_3 \dots Q_i X_i \psi$, where Q_i is a universal quantifier if i is even and an existential quantifier if i is odd.
Question: Is φ true?

Input formulas to the problem QSAT_i are called Σ_i^{P}-formulas. For each nonnegative integer $i \leq 0$, the complexity class Σ_i^{P} can be characterized as the closure of the problem QSAT_i under polynomial-time reductions (Stockmeyer, 1976; Wrathall, 1976). The Σ_i^{P}-hardness of QSAT_i holds already when the matrix of the input formula is restricted to 3CNF for odd i, and restricted to 3DNF for even i. Note that the class Σ_0^{P} coincides with P, and the class Σ_1^{P} coincides with NP. For each $i \geq 1$, the class Π_i^{P} is defined as co-Σ_i^{P}.

2.3 Fpt-reductions to SAT

Every problem in NP $\cup$ co-NP can be solved with one call to a SAT solver, and every problem in DP $= \{ L_1 \cap L_2 : L_1 \in$ NP, $L_2 \in$ co-NP $\}$ can be solved with two calls to a SAT solver. The Boolean Hierarchy (Cai and Hemachandra, 1986) contains all problems that can be solved with a constant number of calls to a SAT solver. On the other hand, (under complexity theoretic assumptions) there are problems in Δ_2^{P} that cannot be solved efficiently with a constant number of calls to a SAT solver. Hence, in particular, by showing that a parameterized problem is in para-NP or para-co-NP (see Section 2.1) we establish that the problem admits an fpt-reduction to SAT (see Figure 1 and Table 1).

In addition, we could consider the class of parameterized problems that can be solved by an fpt-algorithm that makes $f(k)$ many calls to a SAT solver, for some function f. This notion opens another possibility to obtain (parameterized) tractability results for problems beyond NP (cf. De Haan and Szeider, 2014).

2.4 Answer Set Programming

We will use the logic programming setting of answer set programming (ASP) (cf. Marek and Truszczynski, 1999; Brewka, Eiter, and Truszczynski, 2011) as a running example in the remainder of the paper. A *disjunctive logic program* (or simply: a *program*) P is a finite set of rules of the form $r = (a_1 \vee \dots \vee a_k \leftarrow b_1, \dots, b_m, \mathit{not}\ c_1, \dots, \mathit{not}\ c_n)$, for $k, m, n \geq 0$, where all a_i, b_j and c_l are atoms. A rule is called *disjunctive* if $k > 1$, and it is called *normal* if $k \leq 1$ (note that we only call rules with strictly more than one disjunct in the head disjunctive). A rule is called *negation-free* if $n = 0$. A program is called normal if all its rules are normal, and called negation-free if all its rules are negation-free. We let $\mathrm{At}(P)$ denote the set of all atoms occurring in P. By *literals* we mean atoms a or their negations $\mathit{not}\ a$. With $\mathrm{NF}(r)$ we denote the rule $(a_1 \vee \dots \vee a_k \leftarrow b_1, \dots, b_m)$. The *(GL) reduct* of a program P with respect to a set M of atoms, denoted P^M, is the program obtained from P by: (i) removing rules with $\mathit{not}\ a$ in the body, for each $a \in M$, and (ii) removing literals $\mathit{not}\ a$ from all other rules (Gelfond and Lifschitz, 1991). An *answer set* A of a program P is a subset-minimal model of the reduct P^A. The following decision problem is concerned with the question of whether a given program has an answer set.

ASP-CONSISTENCY
Instance: A disjunctive logic program P.
Question: Does P have an answer set?

Many implementations of answer set programming already employ SAT solving techniques, e.g., Cmodels (Giunchiglia, Lierler, and Maratea, 2006), ASSAT (Lin and Zhao, 2004), and Clasp (Gebser et al., 2007). Work has also been done on translations from ASP to SAT, both for classes of programs that allow reasoning within NP or co-NP (Ben-Eliyahu and Dechter, 1994; Fages, 1994; Lin and Zhao, 2004; Janhunen et al., 2006) and for classes of programs for which reasoning is beyond NP and co-NP (Janhunen et al., 2006; Lee and Lifschitz, 2003; Lifschitz and Razborov, 2006). We hope that our work provides new means for a theoretical study of these and related approaches to ASP.

3 Parameterizations for ASP

ASP-CONSISTENCY is Σ_2^{P}-complete in general, and can therefore (under complexity theoretic assumptions) not be reduced to SAT in polynomial time. With the aim of identifying fpt-reductions from ASP-CONSISTENCY to SAT, we consider several parameterizations.

Parameter	Complexity
normality-bd size	para-NP-complete (Fichte and Szeider, 2013)
# contingent atoms	para-co-NP-complete (Prop 1)
# contingent rules	$\exists^k\forall^*$-complete (Thms 7 and 8)
# disjunctive rules	$\exists^*\forall^k$-W[1]-hard (Thm 14)
max atom occurrence	para-Σ_2^{P}-complete (Cor 16)

Table 1: Complexity results for different parameterizations of ASP-CONSISTENCY.

Fichte and Szeider (2013) identified one parameterization of ASP-CONSISTENCY under which the problem is contained in para-NP. This parameterization is based on the notion of backdoors to normality for disjunctive logic programs. A set X of atoms is a *normality-backdoor* for a program P if deleting the atoms $x \in X$ and their negations $not\ x$ from the rules of P results in a normal program. ASP-CONSISTENCY is contained in para-NP, when parameterized by the size of a smallest normality-backdoor of the input program.

Two other parameterizations that we consider are related to atoms that must be part of any answer set of a program P. We identify a subset $\mathrm{Comp}(P)$ of *compulsory atoms*, that any answer set must include. Given a program P, we let $\mathrm{Comp}(P)$ be the smallest set such that: (i) if $(w \leftarrow not\ w)$ is a rule of P, then $w \in \mathrm{Comp}(P)$; and (ii) if $(b \leftarrow a_1, \ldots, a_n)$ is a rule of P, and $a_1, \ldots, a_n \in \mathrm{Comp}(P)$, then $b \in \mathrm{Comp}(P)$. We then let the set $\mathrm{Cont}(P)$ of *contingent atoms* be those atoms that occur in P but are not in $\mathrm{Comp}(P)$. We call a rule *contingent* if it contains contingent atoms in the head. (In fact, we could use any polynomial time computable algorithm A that computes for every program P a set $\mathrm{Comp}_A(P)$ of atoms that must be included in any answer set of P.)

The following are candidates for additional parameters that could result in fpt-reductions to SAT: (i) the number of disjunctive rules in the program (i.e., the number of rules with strictly more than one disjunct in the head); (ii) the number of contingent atoms in the program; and (iii) the number of contingent rules in the program. We will often denote the parameterized problems based on ASP-CONSISTENCY and these parameters (i) ASP-CONSISTENCY(#disj.rules), (ii) ASP-CONSISTENCY(#cont.atoms) and (iii) ASP-CONSISTENCY(#cont.rules), respectively.

The question that we would like to answer is which (if any) of these parameterizations allows an fpt-reduction to SAT. Tools from classical complexity theory seem unfit to distinguish these parameters from each other and from the parameterization by Fichte and Szeider: if the parameter values are given as part of the input, the problem remains Σ_2^{P}-complete in all cases; if we bound the parameter values by a constant, then in all cases the complexity of the problem decreases to the first-level of the PH (a proof of this can be found in the technical report). However, some of the parameterizations allow an fpt-reduction to SAT, whereas others seemingly do not.

Also the existing tools from parameterized complexity theory are unfit to distinguish between these different parameterizations of ASP-CONSISTENCY. Practically all existing parameterized complexity classes that can be used to show that an fpt-reduction is unlikely to exist (such as the classes of the W-hierarchy) are located below para-NP. Therefore, these classes do not allow us to differentiate between problems that are in para-NP and problems that are not.

However, using the parameterized complexity classes developed in this paper we will be able to make the distinction between parameterizations that allow an fpt-reduction to SAT and parameterizations that seem not to allow this. Furthermore, our theory relates the latter ones in such a way that an fpt-reduction to SAT for any of them gives us an fpt-reduction to SAT for all of them. As can be seen in Table 1, ASP-CONSISTENCY(#cont.atoms) can be fpt-reduced to SAT, whereas we have evidence that this is not possible for ASP-CONSISTENCY(#disj.rules) and ASP-CONSISTENCY(#cont.rules).

We will use ASP-CONSISTENCY together with the various parameterizations discussed above as a running example, which allows us to demonstrate the developed theoretical tools. We begin with showing a positive result for ASP-CONSISTENCY(#cont.atoms).

Proposition 1. ASP-CONSISTENCY(#cont.atoms) *is* para-co-NP-*complete.*

Proof. Hardness for para-co-NP follows from the reduction of Eiter and Gottlob (1995, Theorem 3). We show membership in para-co-NP. Let P be a program that contains k many contingent atoms. We sketch an fpt-reduction to SAT for the problem whether P has no answer set. There are 2^k candidate sets that could be an answer set, namely $N \cup \mathrm{Comp}(P)$ for each $N \subseteq \mathrm{Cont}(P)$. For each such set $M_N = N \cup \mathrm{Comp}(P)$ it can be checked in deterministic polynomial time whether M_N is a model of P^{M_N}, and it can be checked by an NP-algorithm whether M_N is not a minimal model of P^{M_N}. Therefore, by the NP-completeness of SAT, for each $N \subseteq \mathrm{Cont}(P)$, there exists a propositional formula φ_N that is satisfiable if and only if M_N is not a minimal model of P^{M_N}. All together, the statement that for no $N \subseteq \mathrm{Cont}(P)$ the set $N \cup \mathrm{Comp}(P)$ is an answer set holds true if and only if the disjunction $\bigvee_{N \subseteq \mathrm{Cont}(P)} \varphi_N$ is satisfiable. □

4 The Hierarchies $*$-k and k-$*$

We are going to define two hierarchies of parameterized complexity classes that will act as intractability classes in our hardness theory. All classes will be based on weighted variants of the satisfiability problem QSAT_2. An instance of the problem QSAT_2 has both an existential quantifier and a universal quantifier block. Therefore, there are several ways of restricting the weight of assignments. Restricting the weight of assignments to the existential quantifier block will result in the k-$*$ hierarchy, and restricting the weight of assignments to the universal quantifier block will result in the $*$-k hierarchy. The two hierarchies are based on the following two parameterized decision problems. Let $\mathcal{C}$ be a class of Boolean circuits. The problem $\exists^k\forall^*$-$\mathrm{WSAT}(\mathcal{C})$ provides the foundation for the k-$*$ hierarchy.

$\exists^k\forall^*$-WSAT($\mathcal{C}$)
Instance: A Boolean circuit $C \in \mathcal{C}$ over two disjoint sets X and Y of variables, and an integer k.
Parameter: k.
Question: Does there exist a truth assignment α to X with weight k such that for all truth assignments β to Y the assignment $\alpha \cup \beta$ satisfies C?

Similarly, the problem $\exists^*\forall^k$-WSAT($\mathcal{C}$) provides the foundation for the $*$-k hierarchy.

$\exists^*\forall^k$-WSAT($\mathcal{C}$)
Instance: A Boolean circuit $C \in \mathcal{C}$ over two disjoint sets X and Y of variables, and an integer k.
Parameter: k.
Question: Does there exist a truth assignment α to X such that for all truth assignments β to Y with weight k the assignment $\alpha \cup \beta$ satisfies C?

For convenience, instances to these two problems consisting of a circuit C over sets X and Y of variables and an integer k, we will denote by $(\exists X.\forall Y.C, k)$. We now define the following parameterized complexity classes, that together form the k-$*$ hierarchy. We let $\exists^k\forall^*$-W[t] $= [\, \{\, \exists^k\forall^*\text{-WSAT}(\Gamma_{t,u}) : u \geq 1 \,\} \,]^{\text{fpt}}$, we let $\exists^k\forall^*$-W[SAT] $= [\, \exists^k\forall^*\text{-WSAT}(\Phi) \,]^{\text{fpt}}$, and we let $\exists^k\forall^*$-W[P] $= [\, \exists^k\forall^*\text{-WSAT}(\Gamma) \,]^{\text{fpt}}$.

We define the classes of the $*$-k hierarchy similarly. We let $\exists^*\forall^k$-W[t] $= [\, \{\, \exists^*\forall^k\text{-WSAT}(\Gamma_{t,u}) : u \geq 1 \,\} \,]^{\text{fpt}}$, we let $\exists^*\forall^k$-W[SAT] $= [\, \exists^*\forall^k\text{-WSAT}(\Phi) \,]^{\text{fpt}}$, and we let $\exists^*\forall^k$-W[P] $= [\, \exists^*\forall^k\text{-WSAT}(\Gamma) \,]^{\text{fpt}}$. Note that these definitions are analogous to those of the parameterized complexity classes of the W-hierarchy (Downey and Fellows, 1999).

We can define dual classes for each of the parameterized complexity classes in the k-$*$ and $*$-k hierarchies. These co-classes are based on problems complementary to the problems $\exists^k\forall^*$-WSAT and $\exists^*\forall^k$-WSAT, i.e., these problems have as yes-instances exactly the no-instances of $\exists^k\forall^*$-WSAT and $\exists^*\forall^k$-WSAT, respectively. Equivalently, these complementary problems can be considered as variants of $\exists^k\forall^*$-WSAT and $\exists^*\forall^k$-WSAT where the existential and universal quantifiers are swapped, and are therefore denoted with $\forall^k\exists^*$-WSAT and $\forall^*\exists^k$-WSAT. We use a similar notation for the dual complexity classes, e.g., we denote co-$\exists^*\forall^k$-W[t] by $\forall^*\exists^k$-W[t].

5 The Class $\exists^k\forall^*$

In this section, we consider the k-$*$ hierarchy. It turns out that this hierarchy collapses entirely into a single parameterized complexity class. This class we will denote by $\exists^k\forall^*$. As we will see, the class $\exists^k\forall^*$ turns out to be quite robust. We start this section with showing that that the k-$*$ hierarchy collapses. We discuss how this class is related to existing parameterized complexity classes, and we show how it can be used to show the intractability of a variant of the answer set existence problem whose complexity the existing theory cannot classify properly.

5.1 Collapse of the k-$*$ hierarchy

Theorem 2 (Collapse of the k-$*$ hierarchy). $\exists^k\forall^*$-W[1] $= \exists^k\forall^*$-W[2] $= \ldots = \exists^k\forall^*$-W[SAT] $= \exists^k\forall^*$-W[P].

Proof. Since by definition $\exists^k\forall^*$-W[1] $\subseteq \exists^k\forall^*$-W[2] $\subseteq \ldots \subseteq \exists^k\forall^*$-W[P], it suffices to show that $\exists^k\forall^*$-W[P] $\subseteq \exists^k\forall^*$-W[1]. We show this by giving an fpt-reduction from $\exists^k\forall^*$-WSAT(Γ) to $\exists^k\forall^*$-WSAT(3DNF). Since 3DNF $\subseteq \Gamma_{1,3}$, this suffices. We remark that this reduction is based on the standard Tseitin transformation that transforms arbitrary Boolean formulas into 3CNF by means of additional variables.

Let (φ, k) be an instance of $\exists^k\forall^*$-WSAT(Γ) with $\varphi = \exists X.\forall Y.C$. Assume without loss of generality that C contains only binary conjunctions and negations. Let o denote the output gate of C. We construct an instance (φ', k) of $\exists^k\forall^*$-WSAT(3DNF) as follows. The formula φ' will be over the set of variables $X \cup Y \cup Z$, where $Z = \{\, z_r : r \in \text{Nodes}(C) \,\}$. For each $r \in \text{Nodes}(C)$, we define a subformula χ_r. We distinguish three cases. If $r = r_1 \wedge r_2$, then we let $\chi_r = (z_r \wedge \neg z_{r_1}) \vee (z_r \wedge \neg z_{r_2}) \vee (z_{r_1} \wedge z_{r_2} \wedge \neg z_r)$. If $r = \neg r_1$, then we let $\chi_r = (z_r \wedge z_{r_1}) \vee (\neg z_r \wedge \neg z_{r_1})$. If $r = w$, for some $w \in X \cup Y$, then we let $\chi_r = (z_r \wedge \neg w) \vee (\neg z_r \wedge w)$. Now we define $\varphi' = \exists X.\forall Y \cup Z.\psi$, where $\psi = \bigvee_{r \in \text{Nodes}(C)} \chi_r \vee z_o$. It is straightforward to verify that this reduction is correct. □

As mentioned above, in order to simplify notation, we will use $\exists^k\forall^*$ to denote the class $\exists^k\forall^*$-W[1] $= \ldots = \exists^k\forall^*$-W[P]. Also, we will denote $\exists^k\forall^*$-WSAT(Γ) by $\exists^k\forall^*$-WSAT. We make some observations about the relation of $\exists^k\forall^*$ to existing parameterized complexity classes. It is straightforward to see that $\exists^k\forall^* \subseteq$ para-Σ_2^{P}. In polynomial time, any formula $\exists X.\forall Y.\psi$ can be transformed into a Σ_2^{P}-formula that is true if and only if for some assignment α of weight k to the variables X the formula $\forall Y.\psi[\alpha]$ is true. Trivially, para-co-NP $\subseteq \exists^k\forall^*$. To summarize, we obtain the following inclusions: para-co-NP $\subseteq \exists^k\forall^* \subseteq \Sigma_2^{\text{P}}$, and para-NP $\subseteq \forall^k\exists^* \subseteq \Pi_2^{\text{P}}$. This immediately leads to the following result.

Proposition 3. *If* $\exists^k\forall^* \subseteq$ para-NP*, then* NP $=$ co-NP.

A natural question to ask is whether para-NP $\subseteq \exists^k\forall^*$. The following result indicates that this is unlikely.

Proposition 4. *If* para-NP $\subseteq \exists^k\forall^*$*, then* NP $=$ co-NP.

Proof (sketch). Let SAT be the language of satisfiable propositional formulas, and UNSAT the language of unsatisfiable propositional formulas. The parameterized problem $P = \{\, (\varphi, 1) : \varphi \in \text{SAT} \,\}$ is in para-NP. Since the parameter value is constant for all instances of P, an fpt-reduction from P to $\exists^k\forall^*$-WSAT can be transformed into an polynomial time reduction from SAT to UNSAT. □

This implies that $\exists^k\forall^*$ is very likely to be a strict subset of para-Σ_2^{P}.

Corollary 5. *If* $\exists^k\forall^* =$ para-Σ_2^{P}*, then* NP $=$ co-NP.

The following result shows another way in which the class $\exists^k\forall^*$ relates to the existing complexity class co-NP. Let P be a parameterized decision problem, and let $c \geq 1$ be an integer. We say that the *c-th slice of P*, denoted P_c, is the (unparameterized) decision problem $\{\, x : (x, c) \in P \,\}$.

Proposition 6. *Let P be a parameterized problem complete for $\exists^k\forall^*$, and let $c \geq 1$ be an integer. Then P_c is in* co-NP*. Moreover, there exists some integer $d \geq 1$ such that $P_1 \cup \cdots \cup P_d$ is* co-NP*-complete.*

A proof of this statement can be found in the technical report.

5.2 Answer set programming and completeness for the k-$*$ hierarchy

Now that we defined this new intractability class $\exists^k\forall^*$ and that we have some basic results about it in place, we are able to prove the intractability of a variant of our running example problem. In fact, we show that one variant of our running example is complete for the class $\exists^k\forall^*$.

Theorem 7. ASP-CONSISTENCY(#cont.rules) *is $\exists^k\forall^*$-hard.*

Proof. We give an fpt-reduction from $\exists^k\forall^*$-WSAT(3DNF). This reduction is a parameterized version of a reduction of Eiter and Gottlob (1995, Theorem 3). Let (φ, k) be an instance of $\exists^k\forall^*$-WSAT(3DNF), where $\varphi = \exists X.\forall Y.\psi$, $X = \{x_1, \ldots, x_n\}$, $Y = \{y_1, \ldots, y_m\}$, $\psi = \delta_1 \vee \cdots \vee \delta_u$, and $\delta_\ell = l^\ell_1 \wedge l^\ell_2 \wedge l^\ell_3$ for each $1 \leq \ell \leq u$. We construct a disjunctive program P. We consider the sets X and Y of variables as atoms. In addition, we introduce fresh atoms $v_1, \ldots, v_n$, $z_1, \ldots, z_m$, w, and x^j_i for all $1 \leq j \leq k$, $1 \leq i \leq n$. We let P consist of the following rules:

$$
\begin{array}{lll}
x^j_1 \vee \cdots \vee x^j_n \leftarrow & \text{for } 1 \leq j \leq k; & (1)\\
\leftarrow x^j_i, x^{j'}_i & \text{for } 1 \leq i \leq n, 1 \leq j < j' \leq k; & (2)\\
y_i \vee z_i \leftarrow, \quad w \leftarrow y_i, z_i & \text{for } 1 \leq i \leq m; & (3)\\
y_i \leftarrow w, \quad z_i \leftarrow w & \text{for } 1 \leq i \leq m; & (4)\\
x_i \leftarrow w, \quad v_i \leftarrow w & \text{for } 1 \leq i \leq n; & (5)\\
x_i \leftarrow x^j_i & \text{for } 1 \leq i \leq n, 1 \leq j \leq k; & (6)\\
v_i \leftarrow not\ x^1_i, \ldots, not\ x^k_i & \text{for } 1 \leq i \leq n; & (7)\\
w \leftarrow \sigma(l^\ell_1), \sigma(l^\ell_2), \sigma(l^\ell_3) & \text{for } 1 \leq \ell \leq u; & (8)\\
w \leftarrow not\ w. & & (9)
\end{array}
$$

Here we let $\sigma(x_i) = x_i$ and $\sigma(\neg x_i) = v_i$ for each $1 \leq i \leq n$; and we let $\sigma(y_j) = y_j$ and $\sigma(\neg y_j) = z_j$ for each $1 \leq j \leq m$. Intuitively, v_i corresponds to $\neg x_i$, and z_j corresponds to $\neg y_j$. The main difference with the reduction of Eiter and Gottlob is that we use the rules in (1), (2), (6) and (7) to let the variables x_i and v_i represent an assignment of weight k to the variables in X. The rules in (5) ensure that the atoms v_i and x_i are compulsory. It is straightforward to verify that $\text{Comp}(P) = \{w\} \cup \{\, x_i, v_i : 1 \leq i \leq n \,\} \cup \{\, y_i, z_i : 1 \leq i \leq m \,\}$. Notice that P has exactly k contingent rules, namely the rules in (1). A full proof that $(\varphi, k) \in \exists^k\forall^*$-WSAT if and only if P has an answer set can be found in the technical report. □

Theorem 8. ASP-CONSISTENCY(#cont.rules) *is in $\exists^k\forall^*$.*

Proof. We show membership in $\exists^k\forall^*$ by reducing ASP-CONSISTENCY(#cont.rules) to $\exists^k\forall^*$-WSAT. Let P be a program, where $r_1, \ldots, r_k$ are the contingent rules of P and where $\text{At}(P) = \{d_1, \ldots, d_n\}$. We construct a quantified Boolean formula $\varphi = \exists X.\forall Y \cup Z \cup W.\psi$ such that $(\varphi, k) \in \exists^k\forall^*$-WSAT if and only if P has an answer set.

In order to do so, we firstly construct a Boolean formula $\psi_P(z_1, \ldots, z_n, z'_1, \ldots, z'_n)$ (or, for short: ψ_P) over variables $z_1, \ldots, z_n, z'_1, \ldots, z'_n$ such that for any $M \subseteq \text{At}(P)$ and any $M' \subseteq \text{At}(P)$ holds that M is a model of $P^{M'}$ if and only if $\psi_P[\alpha_M \cup \alpha_{M'}]$ evaluates to true, where $\alpha_M : \{z_1, \ldots, z_n\} \to \{0, 1\}$ is defined by letting $\alpha_M(z_i) = 1$ if and only if $d_i \in M$, and $\alpha_{M'} : \{z'_1, \ldots, z'_n\} \to \{0, 1\}$ is defined by letting $\alpha_{M'}(z'_i) = 1$ if and only if $d_i \in M'$, for all $1 \leq i \leq n$. We define $\psi_P = \bigwedge_{r \in P}(\psi^1_r \vee \psi^2_r)$, where $\psi^1_r = (z'_{i^3_1} \vee \cdots \vee z'_{i^3_c})$ and $\psi^2_r = ((z_{i^1_1} \vee \cdots \vee z_{i^1_a}) \leftarrow (z_{i^2_1} \wedge \cdots \wedge z_{i^2_b}))$ for $r = (d_{i^1_1} \vee \cdots \vee d_{i^1_a} \leftarrow d_{i^2_1}, \ldots, d_{i^2_b}, not\ d_{i^3_1}, \ldots, not\ d_{i^3_c})$. It is easy to verify that ψ_P satisfies the required property.

We now introduce the set X of existentially quantified variables of φ. For each contingent rule r_i of P we let $a^i_1, \ldots, a^i_{\ell_i}$ denote the atoms that occur in the head of r_i. For each r_i, we introduce variables $x^i_0, x^i_1, \ldots, x^i_{\ell_i}$, i.e., $X = \{\, x^i_j : 1 \leq i \leq k, 0 \leq j \leq \ell_i \,\}$. Furthermore, for each atom d_i, we add universally quantified variables y_i, z_i and w_i, i.e., $Y = \{\, y_i : 1 \leq i \leq n \,\}$, $Z = \{\, z_i : 1 \leq i \leq n \,\}$, and $W = \{\, w_i : 1 \leq i \leq n \,\}$.

We then construct ψ as follows:

$$
\begin{array}{rl}
\psi = & \psi_X \wedge \left(\psi^1_Y \vee \psi_W \vee \psi_{\text{min}}\right) \wedge \left(\psi^1_Y \vee \psi^2_Y\right);\\
\psi_X = & \displaystyle\bigwedge_{1 \leq i \leq k} \left(\bigvee_{0 \leq j \leq \ell_i} x^i_j \wedge \bigwedge_{0 \leq j < j' \leq \ell_i} (\neg x^i_j \vee \neg x^i_{j'}) \right);\\
\psi^1_Y = & \displaystyle\bigvee_{\substack{1 \leq i \leq k\\ 1 \leq j \leq \ell_i}} \psi^{i,j}_y \vee \bigvee_{d_i \in \text{Cont}(P)} \psi^{d_i}_y \vee \bigvee_{d_i \in \text{Comp}(P)} \neg y_i;\\
\psi^{d_m}_y = & (y_m \wedge \neg x^{i_1}_{j_1} \wedge \cdots \wedge \neg x^{i_u}_{j_u})\\
& \text{if } \{\, x^i_j : 1 \leq i \leq k, 1 \leq j \leq \ell_i, a^i_j = d_m \,\} =\\
& \{a^{i_1}_{j_1}, \ldots, a^{i_u}_{j_u}\}, \text{ and}\\
\psi^{d_m}_y = & \bot\\
& \text{if } \{\, x^i_j : 1 \leq i \leq k, 1 \leq j \leq \ell_i, a^i_j = d_m \,\} = \emptyset;\\
\psi^{i,j}_y = & (x^i_j \wedge \neg y_m) \qquad \text{where } a^i_j = d_m;\\
\psi^2_Y = & \psi_P(y_1, \ldots, y_n, y_1, \ldots, y_n);\\
\psi_W = & \displaystyle\bigvee_{1 \leq i \leq n} (w_i \leftrightarrow (y_i \leftrightarrow z_i));\\
\psi_{\text{min}} = & \psi^1_{\text{min}} \vee \psi^2_{\text{min}} \vee \psi^3_{\text{min}};\\
\psi^1_{\text{min}} = & \displaystyle\bigvee_{1 \leq i \leq n} (z_i \wedge \neg y_i);\\
\psi^2_{\text{min}} = & (\neg w_1 \wedge \cdots \wedge \neg w_m); \text{ and}\\
\psi^3_{\text{min}} = & \neg\psi_P(z_1, \ldots, z_n, y_1, \ldots, y_n).
\end{array}
$$

The idea behind this construction is the following. The variables in X represent guessing at most one atom in the head of each contingent rule to be true. Such a guess represents a possible answer set $M \subseteq \text{At}(P)$ (a proof of this can be found in the technical report). The formula ψ_X ensures that for each $1 \leq i \leq k$, exactly one x^i_j is set to true. The formula ψ^1_Y filters out every assignment in which the variables Y are not set corresponding to M. The formula ψ^2_Y filters out every assignment corresponding to a candidate $M \subseteq \text{At}(P)$ such that $M \not\models P$. The formula ψ_W filters out every assignment such that w_i is not set to the value $(y_i \text{ XOR } z_i)$. The formula ψ^1_{min} filters out every assignment where the variables Z correspond to a set M' such that $M' \not\subseteq M$. The formula ψ^2_{min} filters out every assignment where the variables Z correspond to the set M, by referring to the variables w_i. The formula ψ^3_{min}, finally, ensures that in every remaining assignment, the

variables Z do not correspond to a set $M' \subseteq M$ such that $M' \models P$. A full proof that P has an answer set if and only if $(\varphi, k) \in \exists^k\forall^*$-WSAT can be found in the technical report. □

Corollary 9. ASP-CONSISTENCY(#cont.rules) *is* $\exists^k\forall^*$-*complete.*

6 The $*$-k Hierarchy

We now turn our attention to the $*$-k hierarchy. Unlike in the k-$*$ hierarchy, in the canonical quantified Boolean satisfiability problems of the $*$-k hierarchy, we cannot add auxiliary variables to the second quantifier block whose truth assignment is not restricted. Therefore, because of similarity to the W-hierarchy, we believe that the classes of the $*$-k hierarchy are distinct. We will mainly focus on the first level of the $*$-k hierarchy. We begin with proving some basic properties. The main result in this section is a normalization result for $\forall^*\exists^k$-W[1].

Proposition 10. *If* para-co-NP $\subseteq \exists^*\forall^k$-W[P]*, then* NP $=$ co-NP.

Proof (sketch). With an argument similar to the one in the proof of Proposition 4, a polynomial-time reduction from UNSAT to SAT can be constructed. An additional technical observation needed for this case is that SAT is in NP also when the input is a Boolean circuit. □

Next, we show that the problem $\exists^*\forall^k$-WSAT is already $\exists^*\forall^k$-W[1]-hard when the input circuits are restricted to formulas in c-DNF, for any constant $c \geq 2$. In order to make our life easier, we switch our perspective to the co-problem $\forall^*\exists^k$-WSAT when stating and proving the following results. Note that the proofs of the following results make heavy use of the original normalization proof for the class W[1] by Downey and Fellows (1995; 1999).

Lemma 11. *For any* $u \geq 1$, $\forall^*\exists^k$-WSAT$(\Gamma_{1,u}) \leq_{\text{fpt}} \forall^*\exists^k$-WSAT$(s$-CNF$)$*, where* $s = 2^u + 1$.

Proof (sketch). The reduction is completely analogous to the reduction used in the proof of Downey and Fellows (1995, Lemma 2.1), where the presence of universally quantified variables is handled in four steps. In Steps 1 and 2, in which only the form of the circuit is modified, no changes are needed. In Step 3, universally quantified variables can be handled exactly as existentially quantified variables. Step 4 can be performed with only a slight modification, the only difference being that universally quantified variables appearing in the input circuit will also appear in the resulting clauses that verify whether a given product-of-sums or sum-of-products is satisfied. It is straightforward to verify that this reduction with the mentioned modifications works for our purposes. □

Theorem 12. $\forall^*\exists^k$-WSAT(2CNF) *is* $\forall^*\exists^k$-W[1]*-complete.*

Proof (sketch). Clearly $\forall^*\exists^k$-WSAT(2CNF) is in $\forall^*\exists^k$-W[1], since a 2CNF formula can be considered as a constant-depth circuit of weft 1. To show that $\forall^*\exists^k$-WSAT(2CNF) is $\forall^*\exists^k$-W[1]-hard, we give an fpt-reduction from $\forall^*\exists^k$-WSAT$(\Gamma_{1,u})$ to $\forall^*\exists^k$-WSAT(2CNF), for arbitrary $u \geq 1$. By Lemma 11, we know that we can reduce $\forall^*\exists^k$-WSAT$(\Gamma_{1,u})$ to $\forall^*\exists^k$-WSAT$(s$-CNF$)$, for $s = 2^u + 1$. We continue the reduction in multiple steps. In each step, we let C denote the circuit resulting from the previous step, and we let Y denote the universally quantified and X the existentially quantified input variables of C, and we let k denote the parameter value. We only briefly describe the last two steps, since these are completely analogous to constructions in the work of Downey and Fellows (1999).

Step 1: contracting the universally quantified variables. This step transforms C into a CNF formula C' such that each clause contains at most one variable in Y such that (C, k) is a yes-instance if and only if (C', k) is a yes-instance. We introduce new universally quantified variables Y' containing a variable y'_A for each set A of literals over Y of size at least 1 and at most s. Now, it is straightforward to construct a set D of polynomially many ternary clauses over Y and Y' such that the following property holds. An assignment α to $Y \cup Y'$ satisfies D if and only if for each subset $A = \{l_1, \ldots, l_b\}$ of literals over Y it holds that $\alpha(l_1) = \alpha(l_2) = \ldots = \alpha(l_b) = 1$ if and only if $\alpha(y'_A) = 1$. Note that we do not directly add the set D of clauses to the formula C'.

We introduce $k - 1$ many new existentially quantified variables $x^\star_1, \ldots, x^\star_{k-1}$. We add binary clauses to C' that enforce that the variables $x^\star_1, \ldots, x^\star_{k-1}$ all get the same truth assignment. Also, we add binary clauses to C' that enforce that each $x \in X$ is set to false if $x^\star_1$ is set to true.

We introduce $|D|$ many existentially quantified variables, including a variable x''_d for each clause $d \in D$. For each $d \in D$, we add the following clauses to C'. Let $d = (l_1, l_2, l_3)$, where each l_i is a literal over $Y \cup Y'$. We add the clauses $(\neg x''_d \vee \neg l_1)$, $(\neg x''_d \vee \neg l_2)$ and $(\neg x''_d \vee \neg l_3)$, enforcing that the clause d cannot be satisfied if x''_d is set to true.

We then modify the clauses of C as follows. Let $c = (l^x_1, \ldots, l^x_{s_1}, l^y_1, \ldots, l^y_{s_2})$ be a clause of C, where $l^x_1, \ldots, l^x_{s_1}$ are literals over X, and $l^y_1, \ldots, l^y_{s_2}$ are literals over Y. We replace c by the clause $(l^x_1, \ldots, l^x_{s_1}, x^\star_1, y'_B)$, where $B = \{l^y_1, \ldots, l^y_{s_2}\}$. Clauses c of C that contain no literals over the variables Y remain unchanged.

The idea of this reduction is the following. If $x^\star_1$ is set to true, then exactly one of the variables x''_d must be set to true, which can only result in an satisfying assignment if the clause $d \in D$ is not satisfied. Therefore, if an assignment α to the variables $Y \cup Y'$ does not satisfy D, there is a satisfying assignment of weight k that sets both $x^\star_1$ and x''_d to true, for some $d \in D$ that is not satisfied by α. Otherwise, we know that the value α assigns to variables y'_A corresponds to the value α assigns to $\bigwedge_{a \in A} a$, for $A \subseteq \text{Lit}(Y)$. Then any satisfying assignments of weight k for C is also a satisfying assignments of weight k for C'.

Step 2: making C antimonotone in X. This step transforms C into a circuit C' that has only negative occurrences of existentially quantified variables, and transforms k into k' depending only on k, such that (C, k) is a yes-instance if and only if (C', k') is a yes-instance. The reduction is completely analogous to the reduction in the proof of Downey and Fellows (1999, Theorem 10.6).

Step 3: contracting the existentially quantified variables. This step transforms C into a circuit C' in CNF

that contains only clauses with two variables in X and no variables in Y and clauses with one variable in X and one variable in Y, and transforms k into k' depending only on k, such that (C, k) is a yes-instance if and only if (C', k') is a yes-instance. The reduction is completely analogous to the reduction in the proof of Downey and Fellows (1999, Theorem 10.7). □

Corollary 13. *For any fixed integer $r \geq 2$, the problem $\exists^*\forall^k$-WSAT(r-DNF) is $\exists^*\forall^k$-W[1]-complete.*

6.1 Answer set programming and hardness for the $*$-k hierarchy

We now turn to another variant of our running example problem.

Theorem 14. ASP-CONSISTENCY(#disj.rules) *is $\exists^*\forall^k$-W[1]-hard.*

Proof. We give an fpt-reduction from $\exists^*\forall^k$-WSAT(3DNF), which we know to be $\exists^*\forall^k$-W[1]-hard from Corollary 13. This is, like the reduction in the proof of Theorem 7 above, a parameterized version of a reduction of Eiter and Gottlob (1995, Theorem 3). Let (φ, k) be an instance of $\exists^*\forall^k$-WSAT(3DNF), where $\varphi = \exists X.\forall Y.\psi$, $X = \{x_1, \ldots, x_n\}$, $Y = \{y_1, \ldots, y_m\}$, $\psi = \delta_1 \vee \cdots \vee \delta_u$, and $\delta_\ell = l^\ell_1 \wedge l^\ell_2 \wedge l^\ell_3$ for each $1 \leq \ell \leq u$. By step 2 in the proof of Theorem 12, we may assume without loss of generality that all universally quantified variables $y_1, \ldots, y_m$ occur only positively in ψ. We construct a disjunctive program P. We consider the variables X and Y as atoms. In addition, we introduce fresh atoms $v_1, \ldots, v_n, w$, and y^j_i for all $1 \leq j \leq k$, $1 \leq i \leq m$. We let P consist of the following rules:

$$x_i \leftarrow \mathit{not}\ v_i \qquad \text{for } 1 \leq i \leq n; \quad (10)$$
$$v_i \leftarrow \mathit{not}\ x_i \qquad \text{for } 1 \leq i \leq n; \quad (11)$$
$$y^j_1 \vee \cdots \vee y^j_m \leftarrow \qquad \text{for } 1 \leq j \leq k; \quad (12)$$
$$y_i \leftarrow y^j_i \qquad \text{for } 1 \leq i \leq m, 1 \leq j \leq k; \quad (13)$$
$$y^j_i \leftarrow w \qquad \text{for } 1 \leq i \leq m, 1 \leq j \leq k; \quad (14)$$
$$w \leftarrow y^j_i, y^{j'}_i \qquad \text{for } 1 \leq i \leq m, 1 \leq j < j' \leq k; \quad (15)$$
$$w \leftarrow \sigma(l^\ell_1), \sigma(l^\ell_2), \sigma(l^\ell_3) \qquad \text{for } 1 \leq \ell \leq u; \quad (16)$$
$$w \leftarrow \mathit{not}\ w. \quad (17)$$

Here we let $\sigma(\neg x_i) = v_i$ for each $1 \leq i \leq n$; we let $\sigma(x_i) = x_i$ for each $1 \leq i \leq n$; and we let $\sigma(y_i) = y_i$ for each $1 \leq i \leq m$. Intuitively, v_i corresponds to $\neg x_i$. The main difference with the reduction of Eiter and Gottlob is that we use the rules in (12)–(15) to let the variables y_i represent an assignment of weight k to the variables in Y. Note that P has k disjunctive rules, namely the rules (12). A full proof that $(\varphi, k) \in \exists^*\forall^k$-WSAT if and only if P has an answer set can be found in the technical report. □

This hardness result holds even for the case where each atom occurs only a constant number of times in the input program. In order to show this, we consider the following polynomial-time transformation on disjunctive logic programs. Let P be an arbitrary program, and let x be an atom of P that occurs $\ell \geq 3$ many times. We introduce new atoms x_j for all $1 \leq j \leq \ell$. We replace each occurrence of x in P by a unique atom x_j. Then, to P, we add the rules $(x_{j+1} \leftarrow x_j)$, for all $1 \leq j < \ell$, and the rule $(x_1 \leftarrow x_\ell)$. We call the resulting program P'. It is straightforward to verify that P has an answer set if and only if P' has an answer set.

Proposition 15. ASP-CONSISTENCY(#disj.rules) *is $\exists^*\forall^k$-W[1]-hard, even when each atom occurs at most 3 times.*

Proof. The transformation described above can be repeatedly applied to ensure that each atom occurs at most 3 times. Since this transformation does not introduce new disjunctive rules, the result follows by Theorem 14. □

Repeated application of the described transformation also gives us the following result.

Corollary 16. ASP-CONSISTENCY(max.atom.occ.) *is* para-Σ^{P}_2*-complete.*

7 Robust Constraint Satisfaction

Next, we consider another application of our hardness theory to a reasoning problem that originates in the domain of knowledge representation. We consider the class of robust constraint satisfaction problems, introduced recently by Gottlob (2012) and Abramsky, Gottlob, and Kolaitis (2013). These problems are concerned with the question of whether every partial assignment of a particular size can be extended to a full solution, in the setting of constraint satisfaction problems. As we will see, a natural parameterized variant of this class of problems is complete for the class $\forall^k\exists^*$.

A *CSP instance* N is a triple (X, D, C), where X is a finite set of *variables*, the *domain* D is a finite set of *values*, and C is a finite set of *constraints*. Each constraint $c \in C$ is a pair (S, R), where $S = \mathrm{Var}(c)$, the *constraint scope*, is a finite sequence of distinct variables from X, and R, the *constraint relation*, is a relation over D whose arity matches the length of S, i.e., $R \subseteq D^r$ where r is the length of S.

Let $N = (X, D, C)$ be a CSP instance. A *partial instantiation* of N is a mapping $\alpha : X' \to D$ defined on some subset $X' \subseteq X$. We say that α *satisfies* a constraint $c = ((x_1, \ldots, x_r), R) \in C$ if $\mathrm{Var}(c) \subseteq X'$ and $(\alpha(x_1), \ldots, \alpha(x_r)) \in R$. If α satisfies all constraints of N then it is a *solution* of N. We say that α *violates* a constraint $c = ((x_1, \ldots, x_r), R) \in C$ if there is no extension β of α defined on $X' \cup \mathrm{Var}(c)$ such that $(\beta(x_1), \ldots, \beta(x_r)) \in R$.

Let k be a nonnegative integer. We say that a CSP instance $N = (X, D, C)$ is *k-robustly satisfiable* if for each instantiation $\alpha : X' \to D$ defined on some subset $X' \subseteq X$ of k many variables (i.e., $|X'| = k$) that does not violate any constraint in C, it holds that α can be extended to a solution for the CSP instance (X, D, C). Now consider the following parameterized problem.

ROBUST-CSP-SAT
Instance: A CSP instance (X, D, C), and a nonnegative integer k.
Parameter: k.
Question: Is (X, D, C) k-robustly satisfiable?

We show that this problem is complete for $\forall^k\exists^*$.

Theorem 17. ROBUST-CSP-SAT *is in $\forall^k\exists^*$.*

Proof. We give an fpt-reduction from ROBUST-CSP-SAT to $\forall^k\exists^*$-WSAT. Let (X, D, C, k) be an instance of ROBUST-CSP-SAT, where (X, D, C) is a CSP instance, $X = \{x_1, \ldots, x_n\}$, $D = \{d_1, \ldots, d_m\}$, and k is an integer. We

construct an instance (φ, k) of $\forall^k\exists^*$-WSAT. For the formula φ, we use propositional variables $Z = \{ z^i_j : 1 \leq i \leq n, 1 \leq j \leq m \}$ and $Y = \{ y^i_j : 1 \leq i \leq n, 1 \leq j \leq m \}$. Intuitively, the variables z^i_j will represent an arbitrary assignment α that assigns values to k variables in X. Any variable z^i_j represents that variable x_i gets assigned value d_j. The variables y^i_j will represent the solution β that extends the arbitrary assignment α. Similarly, any variable y^i_j represents that variable x_i gets assigned value d_j. We then let $\varphi = \forall Z.\exists Y.\psi$ with $\psi = (\psi^Z_{\text{proper}} \wedge \neg\psi^Z_{\text{violate}}) \rightarrow (\psi^{Y,Z}_{\text{corr}} \wedge \psi^Y_{\text{proper}} \wedge \bigwedge_{c \in C} \psi^Y_c)$. We will describe the subformulas of φ below, as well as the intuition behind them. We start with the formula ψ^Z_{proper}. This formula represents whether for each variable x_i at most one value is chosen for the assignment α. We let $\psi^Z_{\text{proper}} = \bigwedge_{1 \leq i \leq n} \bigwedge_{1 \leq j < j' \leq m} (\neg z^i_j \vee \neg z^i_{j'})$. Next, we consider the formula ψ^Z_{violate}. This subformula encodes whether the assignment α violates some constraint $c \in C$. We let $\psi^Z_{\text{violate}} = \bigvee_{c=(S,R) \in C} \bigwedge_{\overline{d} \in R} \bigvee_{z \in \Psi^{\overline{d},c}}$, where we define the set $\Psi^{\overline{d},c} \subseteq Z$ as follows. Let $c = ((x_{i_1}, \ldots, x_{i_r}), R) \in C$ and $\overline{d} = (d_{j_1}, \ldots, d_{j_r}) \in R$. Then we let $\Psi^{\overline{d},c} = \{ z^{i_\ell}_j : 1 \leq \ell \leq r, j \neq j_\ell \}$. Intuitively, the set $\Psi^{\overline{d},c}$ contains the variables z^i_j that represent those variable assignments in α that prevent that β satisfies c by assigning $\text{Var}(c)$ to $\overline{d}$. Then, the formula ψ^Y_{proper} ensures that for each variable x_i exactly one value d_j is chosen in β. We define: $\psi^Y_{\text{proper}} = \bigwedge_{1 \leq i \leq n} [\bigvee_{1 \leq j \leq m} y^i_j \wedge \bigwedge_{1 \leq j < j' \leq m} (\neg y^i_j \vee \neg y^i_{j'})]$. Next, the formula $\psi^{Y,Z}_{\text{corr}}$ ensures that β is indeed an extension of α. We define: $\psi^{Y,Z}_{\text{corr}} = \bigwedge_{1 \leq i \leq n} \bigwedge_{1 \leq j \leq m} (z^i_j \rightarrow y^i_j)$. Finally, for each $c \in C$, the formula ψ^Y_c represents whether β satisfies the constraint c. Let $c = ((x_{i_1}, \ldots, x_{i_r}), R) \in C$. We define $\psi^Y_c = \bigvee_{(d_{j_1}, \ldots, d_{j_r}) \in R} \bigwedge_{1 \leq \ell \leq r} y^{i_\ell}_{j_\ell}$. A full proof that $(X, D, C, k) \in$ ROBUST-CSP-SAT if and only if $(\varphi, k) \in \forall^k\exists^*$-WSAT can be found in the technical report. □

In order to prove $\forall^k\exists^*$-hardness, we need the following technical lemma.

Lemma 18. *Let (φ, k) be an instance of $\exists^k\forall^*$-WSAT with $\varphi = \exists X.\forall Y.\psi$. In polynomial time, we can construct an equivalent instance (φ', k) of $\exists^k\forall^*$-WSAT with $\varphi' = \exists X.\forall Y'.\psi'$, such that for any assignment $\alpha : X \rightarrow \{0,1\}$ that has weight $m \neq k$, it holds that $\forall Y'.\psi'[\alpha]$ is true.*

Proof (sketch). We introduce a set Z of additional universally quantified variables, and use these to verify whether k many existentially quantified variables are set to true. We do so by constructing a propositional formula χ containing variables in X and Z that is satisfiable if and only if exactly k many variables in X are set to true. We let $\chi' = (\exists Z.\chi) \rightarrow \psi$. We then know that $\forall Y.\chi'[\alpha]$ is true for all truth assignments $\alpha : X \rightarrow \{0,1\}$ of weight $m \neq k$. Moreover, the formula $\forall Y.\chi'$ is equivalent to the formula $\forall Y \cup Z.(\neg\chi) \vee \psi$. □

Theorem 19. ROBUST-CSP-SAT *is $\forall^k\exists^*$-hard, even when the domain size $|D|$ is restricted to* 2.

Proof. We give an fpt-reduction from $\forall^k\exists^*$-WSAT(3CNF) to ROBUST-CSP-SAT. Let (φ, k) be an instance of $\forall^k\exists^*$-WSAT(3CNF), with $\varphi = \forall X.\exists Y.\psi$, and $\psi = c_1 \wedge \cdots \wedge c_u$. By Lemma 18, we may assume without loss of generality that for any assignment $\alpha : X \rightarrow \{0,1\}$ of weight $m \neq k$, we have that $\exists Y.\psi[\alpha]$ is false. We construct an instance (Z, D, C, k) of ROBUST-CSP-SAT as follows. We define the set Z of variables by $Z = X \cup Y'$, where $Y' = \{ y^i : y \in Y, 1 \leq i \leq 2k+1 \}$, and we let $D = \{0,1\}$. We will define the set C of constraints below, by representing them as a set of clauses whose length is bounded by $f(k)$, for some fixed function f.

The intuition behind the construction of C is the following. We replace each variable $y \in Y$, by $2k+1$ copies y^i of it. Assigning a variable $y \in Y$ to a value $b \in \{0,1\}$ will then correspond to assigning a majority of variables y^i to b, i.e., assigning at least $k+1$ variables y^i to b. In order to encode this transformation in the constraints of C, intuitively, we will replace each occurrence of a variable y by the conjuction $\psi_y = \bigwedge_{1 \leq i_1 < \cdots < i_{k+1} \leq 2k+1} (y^{i_1} \vee \cdots \vee y^{i_{k+1}})$, and replace each occurrence of a literal $\neg y$ by a similar conjunction. We will then multiply the resulting formula out into CNF. Note that whenever a majority of variables y^i is set to $b \in \{0,1\}$, then the formula ψ_y will also evaluate to b.

In the construction of C, we will directly encode the CNF formula that is a result of the transformation described above. For each literal $l = y \in Y$, let l^i denote y^i, and for each literal $l = \neg y$ with $y \in Y$, let l^i denote $\neg y^i$. For each literal l over the variables $X \cup Y$, we define a set $\sigma(l)$ of clauses: $\sigma(l) = (l^{i_1} \vee \cdots \vee l^{i_{k+1}}) : 1 \leq i_1 < \cdots < i_{k+1} \leq 2k+1 \}$ if l is a literal over Y, and $\sigma(l) = l$ if l is a literal over X.

Note that for each literal l, it holds that $|\sigma(l)| \leq g(k) = \binom{2k+1}{k+1}$. Next, for each clause $c_i = l^i_1 \vee l^i_2 \vee l^i_3$ of ψ, we introduce to C a set $\sigma(c_i)$ of clauses: $\sigma(c_i) = \{ d_1 \vee d_2 \vee d_3 : d_1 \in \sigma(l^i_1), d_2 \in \sigma(l^i_2), d_3 \in \sigma(l^i_3) \}$. Note that $|\sigma(c_i)| \leq g(k)^3$. Formally, we let C be the set of constraints corresponding to the set $\bigcup_{1 \leq i \leq u} \sigma(c_i)$ of clauses. Since each such clause is of length at most $3(k+1)$, representing a clause by means of a constraint can be done by specifying $\leq 2^{3(k+1)} - 1$ tuples, i.e., all tuples satisfying the clause. Therefore, the instance (Z, D, C, k) can be constructed in fpt-time. A full proof that $(\varphi, k) \in \forall^k\exists^*$-WSAT(3CNF) if and only if $(Z, D, C, k) \in$ ROBUST-CSP-SAT can be found in the technical report. □

8 Conclusion

We developed a general theoretical framework that supports the classification of parameterized problems on whether they admit an fpt-reduction to SAT or not. Our theory is based on two new hierarchies of complexity classes, the k-$*$ and $*$-k hierarchies. We illustrated the use of this theoretical toolbox by means of two case studies, in which we studied the complexity of the consistency problem for disjunctive answer set programming and a robust version of constraint satisfaction, with respect to various natural parameters. There are many more problems that occur in knowledge representation and reasoning where our theory can be used. In the technical report corresponding to this paper, we use our theory to analyze various additional problems, including the problem of minimizing DNF formulas and the problem of minimizing implicant cores. Additionally, we illustrate the robustness of

our theory by showing a number of complete problems for the newly introduced classes from various domains, as well as providing alternative characterizations of the complexity classes based on first-order model checking and alternating Turing machines. There are many more problems that can be analyzed within our framework.

We focused our attention on the range between the first and the second level of the PH, since many natural problems lie there (Schaefer and Umans, 2002). In general, any fpt-reduction from a problem whose complexity is higher in the PH to a lower level in the PH would be interesting. With this more general aim in mind, it would be helpful to have tools to gather evidence that an fpt-reduction across some complexity border in the PH is not possible. We hope that this paper provides a starting point for further developments.

On OBDDs for CNFs of Bounded Treewidth

Abstract

In this paper we show that a CNF cannot be compiled into an Ordered Binary Decision Diagram (OBDD) of fixed-parameter size parameterized by the primal graph treewidth of the CNF. Thus we provide a parameterized separation between OBDDs and Sentential Decision Diagrams for which such fixed-parameter compilation is possible. We also show that the best existing parameterized upper bound for OBDDs in fact holds for incidence graph treewidth parameterization.

Introduction

Knowledge compilation is a rewriting approach to propositional knowledge representation. The 'knowledge base' is initially represented as a CNF or even as a Boolean circuit. For these representations many important types of queries are NP-hard to answer. Therefore, the initial representation is compiled into another one for which the minimal requirement is that the clausal entailment query (can the given partial assignment be extended to a complete satisfying assignment?) can be answered in a polynomial time (Darwiche and Marquis 2002). Such transformation can result in exponential blow up of the representation size. A possible way to circumvent this issue is to identify a structural parameter of the input CNF such that the resulting transformation is exponential in this parameter and polynomial in the number of variables. A notable result in this direction is an $O(2^k n)$ upper bound on the size of Decomposable Negation Normal Form (DNNF) (Darwiche 2001), where n is the number of variables of the given CNF and k is the treewidth of its primal graph. Quite recently, the same upper bound has been shown to hold for Sentential Decision Diagrams (SDD) (Darwiche 2011), a subclass of DNNF that can be seen as a generalization of the famous Ordered Binary Decision Diagrams (OBDD) and shares with the OBDD the key nice features (e.g. poly-time equivalence testing). It is known that a CNF of treewidth k can be compiled into an OBDD of size $O(n^k)$ (Ferrara, Pan, and Vardi 2005). A natural question is whether OBDD, similarly to SDD, admits a 'fixed-parameter' upper bound of form $f(k)n^c$ for some constant c.

In this paper we provide a negative answer to this question. In particular, we demonstrate an infinite class of CNFs of the primal graph treewidth at most k for which the OBDD size is at least $f(k)n^{k/4}$ where f is a function exponentially small in k. In other words, we show that the OBDD size of these CNFs is $\Omega(n^{k/4})$ for every fixed k. This result provides a separation from SDD and essentially matches the upper bound of (Ferrara, Pan, and Vardi 2005). In fact, this result shows impossibility of not only a fixed-parameter upper bound, but also of a sublinear dependence on k in the base of the exponent or even of an exponent k/C for some large constant C.

Our second result is 'strengthening' of the upper bound $O(n^k)$ of (Ferrara, Pan, and Vardi 2005) by showing that it holds if k is the treewidth of the *incidence* graph of the given CNF thus extending the upper bound to the case of sparse CNFs with large clauses.

In order to obtain the lower bound, we introduce a notion of *matching width* of a graph and prove that if a CNF F of the considered class has matching width r of the primal graph then for any ordering of the variables of F there is a prefix S such that the number of distinct functions that can be obtained from F by assigning the variables of S is at least 2^r. This will immediately imply that any OBDD realizing F will have at least 2^r nodes. Finally we will prove that the matching width of the considered CNFs is $\Omega(logn * k)$. Substituting this lower bound instead r will get the desired lower bound for the OBDD size.

Similarly to the case of primal graph, the upper bound is obtained by showing that if *pathwidth* of the incidence graph of the given CNF is at most p then this CNF can be compiled into an OBDD of size $O(2^p n)$. Then the $O(n^k)$ upper bound is obtained using a well known relation $p = O(k * logn)$ between the treewidth and the pathwidth of the given graph. The approach to obtain the $O(2^p n)$ bound is similar to (Ferrara, Pan, and Vardi 2005): variables are ordered 'along' the path decomposition and it is observed that the for each prefix the number of functions caused by assigning the 'previous' variables is $O(2^p)$. The technical difference is that in our case the bags of the path decomposition include clauses and this circumstance must be taken into account.

The proposed results contribute to a large body of existing results concerning the space complexity of OBDDs. To begin with, there are many results concerning the complexity of OBDDs for *particular* classes of Boolean functions, see e.g. the book (Wegener 2000) and the survey (Wegener

Copyright © 2014, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

2004). The space complexity of OBDD remains polynomial if parameterized by the treewidth of a *circuit* representing the given function (Jha and Suciu 2012), however the dependence on the treewidth becomes double exponential. A fixed-parameter upper bound can be achieved if tree of OBDDs is used instead of a single OBDD (McMillan 1994; Subbarayan, Bordeaux, and Hamadi 2007). In the complexity theory the OBDD is classified as the *oblivious read-once branching program*, see the book (Jukna 2012) for the results concerning the complexity of branching programs on particular classes of formulas

The proposed lower bound also contributes to the understanding of relationship between OBDD and SDD. Other results in this direction are (Xue, Choi, and Darwiche 2012) showing an exponential separation between SDD and OBDD based on the same order of variables (the order of variables for SDD is defined as the order of visiting the corresponding nodes of the underlying *vtree* by a left-right tree traversal algorithm) and (Choi and Darwiche 2013) empirically showing that conceptually similar heuristics produce SDDs orders of magnitude smaller than OBDDs.

The rest of the paper is structured as follows. The next section introduces the necessary background. The section after that proves the lower bound, the proofs of auxiliary statements are provided in the two following sections. Then follows the section presenting the upper bound for the parameterization by the treewidth of the incidence graph. The last section outlines relevant directions of further research.

Preliminaries

The structure of this section is the following. First, we introduce notational conventions. Then we define the OBDD and specify the approach we use to prove the lower bound. Next, we introduce terminology related to CNFs. Finally, we define the notion of treewidth.

In this paper by a *set of literals* we mean one that does not contain an occurrence of a variable and its negation. For a set S of literals we denote by $Var(S)$ the set of variables whose literals occur in S. If F is a Boolean function or its representation by a CNF or OBDD, we denote by $Var(F)$ the set of variables of F. A truth assignment to $Var(F)$ on which F is true is called a *satisfying assignment* of F. A set S of literals represents the truth assignment to $Var(S)$ where variables occurring positively in S (i.e. whose literals in S are positive) are assigned with $true$ and the variables occurring negatively are assigned with $false$. We denote by F_S a function whose set of satisfying assignments consists of S' such that $S \cup S'$ is a satisfying assignment of F. We call F_S a *subfunction* of F. In other words, a Boolean function F' is a subfunction of a Boolean function F is F' can be obtained from F by giving a truth assignment to a subset of variables of F.

An OBDD Z representing a Boolean function F is a directed acyclic graph (DAG) with one root and two leaves labelled by $true$ and $false$. The internal nodes are labelled with variables of F. There is a fixed permutation SV of $Var(F)$ (that is, elements of $Var(F)$ are linearly ordered according to SV) so that the vertices along any path from the root to a leaf are labelled with variables according to this order. Each internal vertex is associated with 2 leaving edges labelled with $true$ and $false$. Each path P from the root of Z is called a *computational path* and is associated with truth assignment to the variables labelling all the vertices but the last one. In particular, each variable is assigned with the value labelling the edge of the path that leaves the corresponding vertex. We denote by $A(P)$ the assignment associated with the computational path P. The set of all $A(P)$ where P is a computational path ending at the $true$ leaf is precisely the set of satisfying assignments of F.

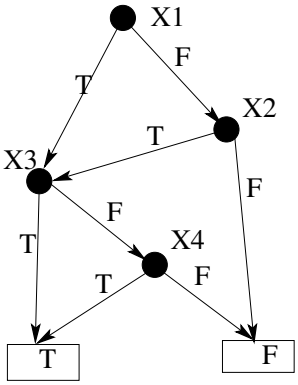

Figure 1: An OBDD for $(x_1 \vee x_2) \wedge (x_3 \vee x_4)$ under permutation (x_1, x_2, x_3, x_4)

Figure 1 shows an OBDD for the function $(x_1 \vee x_2) \wedge (x_3 \vee x_4)$ under the permutation (x_1, x_2, x_3, x_4). Consider the path $P = (x_1, x_2, x_3)$. Then $A(P) = \{\neg x_1, x_2\}$.

In order to obtain the lower bound on the OBDD size we use a standard approach of counting subfunctions. See (Wegener 2000) for examples of application of this approach. This approach is based on the following statement.

Proposition 1 *Let F be a Boolean function on a set V of variables and let SV be a permutation of V. Partition SV into a prefix SV_1 and a suffix SV_2 and suppose that the number of distinct subfunctions of F obtained by giving truth assignments to all the variables of SV_1 is at least x. Then an* OBDD *of F with the underlying order SV contains at least x nodes.*

The standard way to utilize Proposition 1 is to show that for *any* permutation SV of V there is a partition of SV into a prefix SV_1 and a suffix SV_2 such that the instantiation of variables of SV_1 results in at least x different subfunctions. Then Proposition 1 immediately implies that x is a lower bound on the size of OBDD for *any* underlying order.

Given a CNF F, its *primal graph* has the set of vertices corresponding to the variables of F. Two vertices are adjacent if and only if there is a clause of F where the corresponding variables both occur. In the *incidence graph* of F the vertices are partitioned into those corresponding to the variables of F and those corresponding to its clauses. A variable vertex is adjacent to a clause vertex if and only if the corresponding variable occurs in the corresponding clause.

Given a graph G, its *tree decomposition* is a pair $(T, \mathbf{B})$ where T is a tree and $\mathbf{B}$ is a set of bags $B(t)$ corresponding

to the vertices t of T. Each $B(t)$ is a subset of $V(G)$ and the bags obey the rules of *union* (that is, $\bigcup_{t \in V(T)} B(t) = V(G)$), *containment* (that is, for each $\{u, v\} \in E(G)$ there is $t \in V(t)$ such that $\{u, v\} \subseteq B(t)$), and *connectedness* (that is for each $u \in V(G)$, the set of all t such that $u \in B(t)$ induces a subtree of T). The *width* of $(T, \mathbf{B})$ is the size of the largest bag minus one. The treewidth of G is the smallest width of a tree decomposition of G. If T is a path then we use the respective notions of *path decomposition* and *pathwidth*.

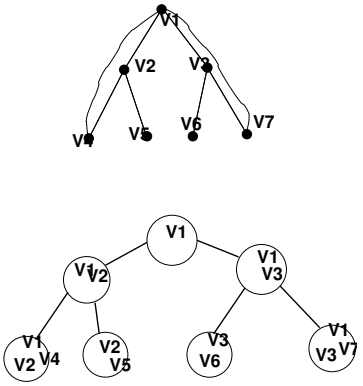

Figure 2: A graph and its tree decomposition

Figure 2 shows a graph and its tree decomposition. The width of this tree decomposition is 2 since the size of the largest bag is 3.

The lower bound

In this section, given two integers r and k we define a class of CNFs, roughly speaking, based on complete binary trees of height r where each node is associated with a clique of size k. Then we prove that the treewidth of the primal graphs of CNFs of this class is linearly bounded by k. Further on, we state the main technical theorem (proven in the next section) that claims that the smallest OBDD size for CNFs of this class exponentially depends on rk. Finally, we re-interpret this lower bound in terms of the number of variables and the treewidth to get the lower bound announced in the Introduction.

Let G be a graph. A *graph based* CNF denoted by $CNF(G)$ is defined as follows. The set of variables consists of variables X_u for each $u \in V(G)$ and variables $X_{u,v} = X_{v,u}$ for each $\{u, v\} \in E(G)$. The set of clauses consists of clauses $C_{u,v} = C_{v,u} = (X_u \vee X_{u,v} \vee X_v)$ for each $\{u, v\} \in E(G)$. In other words, the variables of $CNF(G)$ correspond to the vertices and edges of G. The clauses correspond to the edges of G.

Denote by T_r a complete binary tree of height r. Let $CT_{r,k}$ be the graph obtained from T_r by associating each vertex with a clique of size k and, for each edge $\{u, v\}$ of G, making all the vertices of the cliques associated with u and v mutually adjacent. Denote $CNF(CT_{r,k})$ by $F_{r,k}$.

Figure 3 shows T_2 and $CT_{2,3}$. To avoid shading the picture of $CT_{2,3}$ with many edges, the cliques corresponding to

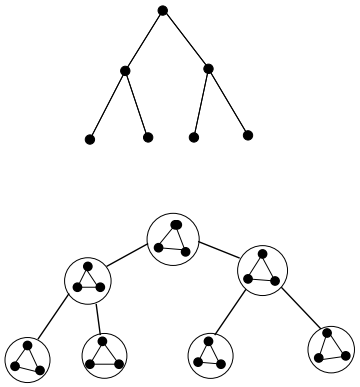

Figure 3: T_2 and $CT_{2,3}$

the vertices of T_2 are marked by circles and the bold edges between the circles mean that that there are edges between all pairs of vertices of the corresponding cliques.

Lemma 1 *The treewidth of the primal graph of $F_{r,k}$ is at least $k - 1$ at most $2k - 1$. In fact, for $r \geq 1$, this treewidth is exactly $2k - 1$.*

Proof. The primal graph of $F_{r,k}$ can be obtained from $CT_{r,k}$ by adding one vertex v_e for each edge e of $CT_{r,k}$ and making this vertex adjacent to the ends of e.

The lower bound follows from existence of a clique of size k in $CT_{r,k}$. Indeed, in any tree decomposition of $CT_{r,k}$, there is a bag containing all the vertices of such a clique (Bodlaender and Möhring 1993). Consequently, the width of any tree decomposition is at least $k - 1$. In fact if $r \geq 1$ then $CT_{r,k}$ has a clique of size $2k$ created by cliques of two adjacent nodes. Hence, due to the same argumentation, the treewidth of $CT_{r,k}$ is at least $2k - 1$ for $r \geq 1$.

For the upper bound, consider the following tree decomposition $(T, \mathbf{B})$ of $CT_{r,k}$. T is just T_r. We look upon T_r as a rooted tree, the centre of T_r being the root. The bag $B(u)$ of each node u contains the clique of $CT_{r,k}$ corresponding to u. In addition, if u is not the root vertex then $B(u)$ also contains the clique corresponding to the parent of u. Observe that $(T, \mathbf{B})$ satisfies the connectivity property. Indeed, each vertex appears in the bag corresponding to its 'own' clique and the cliques of its children. Clearly, the set of nodes corresponding to the bags induce a connected subgraph. The rest of the tree decomposition properties can be verified straightforwardly. We conclude that $(T, \mathbf{B})$ is indeed a tree decomposition of $CT_{r,k}$.

In order to 'upgrade' $(T, \mathbf{B})$, add $\binom{k}{2}$ new adjacent vertices to each vertex of T. These vertices will correspond to the edges of cliques associated with the respective nodes of T_r. In addition, add k^2 new adjacent vertices to each non-root vertex of T. These vertices will correspond to the edges between the clique associated with the corresponding node of T_r and the clique of its parent. The bag of each new vertex will contain v_e, corresponding to the edge e associated with this bag, plus the ends of e. A direct inspection shows that this is indeed a tree decomposition of the primal graph of $F_{r,k}$ and that the size of each bag is at most $2k$.

Notice that for $r \geq 1$ the lower and upper bounds coincide, thus allowing to state the treewidth precisely. ■

The following is the main technical result whose proof is given in the next section.

Theorem 1 *The size of* OBDD *computing $F_{r,k}$ is at least $2^{rk/2}$.*

Let us reformulate the statement of Theorem 1 in terms of the number of variables of $F_{r,k}$ and the treewidth of its primal graph, having in mind the bounds on the treewidth as in Lemma 1.

First of all, taking into account that $k \geq p/2$, where p is the treewidth of the primal graph of $F_{r,k}$, the lower bound can be seen as $2^{rp/4}$. Next, let m be the number of variables of $F_{r,k}$. Then, it is not hard to observe that $2^r \geq \frac{m}{2^{\binom{k}{2}}} \geq \frac{m}{2^{\binom{(p+1)}{2}}}$. Replacing 2^r this way in $2^{rp/4}$, we obtain $(\frac{m}{2^{\binom{(p+1)}{2}}})^{p/4} = \binom{2(p+1)}{2}^{-p/4} * m^{p/4}$ as a lower bound on the OBDD size for $F_{r,k}$. Clearly, if we consider p as a constant, this lower bound can be seen as $\Omega(m^{p/4})$.

Now we are ready to state the main result.

Corollary 1 *There is a function f such that for each $p \geq 1$ there is an infinite sequence of* CNFs *$F_1, F_2 \ldots$, of treewidth at most p of their primal graphs such that for each F_i the size of* OBDD *computing it is at least $f(p) * m^{p/4}$ where m is the number of variables of F_i. Put it differently, for each fixed p, there is a class of* CNFs *of treewidth at most p of the primal graph for which the* OBDD *size is $\Omega(m^{p/4})$.*

Proof. For an odd p, consider the CNFs $F_{r,(p+1)/2}$ for all $r \geq 1$ and for an even p, consider the CNFs $F_{r,p/2}$ for all $r \geq 1$. Observe that for an even p the primal graph treewidth of $F_{r,p}$ is $p-1$ and that the above argumentation still applies. Indeed, since $k = p/2$, it is legitimate to represent the lower bound as $2^{rp/4}$. Further on, in the inequality that follows, the occurrence of $p+1$ in the denominator (as an upper bound of the actual treewidth) even strengthens this inequality. ■

Proof of Theorem 1

The plan of the proof is the following. We introduce the notion of matching width of a graph. Then we provide two statements regarding this notion. The first statement (Lemma 2) claims a linear in rk lower bound for the matching width of graphs $CT_{r,k}$ underlying the considered class $F_{r,k}$ (the proof of the lemma is provided in the next section). The second statement (Lemma 3) claims that if a graph G has a matching width t then any permutation of the variables of $CNF(G)$ can be partitioned into a suffix and a prefix so that there are at least 2^t subfunctions of $CNF(G)$ resulting from instantiation of variables of the prefix. The proof of Lemma 3 constitutes the essential part of this section. Finally, we provide a proof of Theorem 1. In this proof we notice that according to the approach outlined in the Preliminaries section, Lemma 3 together with Proposition 1 implies that the size of an OBDD of $CNF(G)$ is at least 2^t. Taking $CT_{r,k}$ as G and substituting the lower bound claimed by Lemma 2, we obtain the desired lower bound for $F_{r,k} = CNF(CT_{r,k})$.

The *matching width* is defined as follows. Let SV be a *permutation* of the set $V = V(G)$ of vertices of a graph G. Let S_1 be a *prefix* of SV (i.e. all vertices of $SV \setminus S_1$ are ordered after S_1). Let us call the matching width of S_1, the largest *matching* (that is, a set of edges not having common ends) consisting of the edges between S_1 and $V \setminus S_1$ (we take the liberty to use sequences as sets, the correct use will be always clear from the context). Further on, the matching width of SV is the largest matching width of a prefix of SV. Finally the matching width of G, denoted by $mw(G)$, is the smallest matching width of a permutation of $V(G)$.

Example 1 *Consider a path of 10 vertices $v_1, \ldots, v_{10}$ so that v_i is adjacent to v_{i+1} for $1 \leq i < 10$. The matching width of permutation $(v_1, \ldots, v_{10})$ is 1 since between any suffix and prefix there is only one edge. However, the matching width of the permutation $(v_1, v_3, v_5, v_7, v_9, v_2, v_4, v_6, v_8, v_{10})$ is 5 as witnessed by the partition $\{v_1, v_3, v_5, v_7, v_9\}$ and $\{v_2, v_4, v_6, v_8, v_{10}\}$. Since the matching width of a graph is determined by the permutation having the smallest matching width, and, since the graph has edges, there cannot be a permutation of matching width 0, we conclude that the matching width of this graph is 1.*

Lemma 2 *For any r, the matching width of $CT_{r,k}$ is at least $rk/2$.*

The proof of Lemma 2 is provided is the next section.

Remark. The above definition of matching width is a special case of a more general notion of *maximum matching width* as defined in (Vatshelle 2012). In particular our notion of matching width can be seen as a variant of maximum matching width of (Vatshelle 2012) where the tree T involved in the definition is a caterpillar.

We are now showing that for CNFs of form $CNF(G)$, a large matching width of G is sufficient for establishing a strong lower bound.

Lemma 3 *Let G be a graph having matching width t. Denote $CNF(G)$ by F. Then any permutation SF of $Var(F)$ has a prefix SF_1 such that there are at least 2^t different functions of form F_{S_1} such that S_1 is a truth assignment to the variables of SF_1.*

Proof. Let us partition $Var(F)$ into sets VV of variables corresponding to the vertices of G and EV of variables corresponding to the edges of G. Let SV be the permutation of VV ordered in the way as they are ordered in SF. Let SV_1 be a prefix of SV *witnessing* the matching width t of SV. (Recall that the matching width of SV is at least the matching width of G.) The word 'witnessing' in this context means that there is a matching $M = \{\{u_1, v_1\}, \ldots, \{u_t, v_t\}\}$ between SV_1 and $V(G) \setminus SV_1$. Let SF_1 be the prefix of SF ending with the last element of SV_1. Thus the variables $X_{u_1}, \ldots X_{u_t}$ corresponding to $u_1, \ldots, u_t$ belong to SF_1 while the variables $X_{v_1}, \ldots, X_{v_t}$ corresponding to $v_1, \ldots, v_t$ do not. We denote the set of clauses $(X_{u_i} \vee X_{u_i,v_i} \vee X_{v_i})$ by TCL.

In the rest of the proof we essentially show that 2^t different assignments to variables $X_{u_1}, \ldots X_{u_t}$ produce 2^t different subfunctions of F thus confirming the lemma. Roughly speaking, this is done by showing that by a careful fixing the assignments to *the rest* of the variables of SF_1 we can achieve the effect that an assignment to X_{u_i} does not 'influence' an assignment to X_{v_j} for $i \neq j$. As a result no two assignments to $X_{u_1}, \ldots, X_{u_t}$ can have the same effect on $X_{v_1}, \ldots, X_{v_t}$ and this guarantees that desired large set of subfunctions.

We start from defining a set of 2^t assignments for which we then claim that any two assignments induce two distinct subfunctions of F. In particular, let $\mathbf{S}$ be the set of all assignments to the variables of SF_1 that assign the variables X_{u_i,v_i} (of course, those of them that belong to SF_1) with $false$ and the rest of variables except $X_{u_1}, \ldots, X_{u_t}$ with $true$. It is easy to see by construction that $\mathbf{S}$ is in a natural one-to-one correspondence with the set of possible assignments to $X_{u_1}, \ldots, X_{u_t}$. In particular, each $S \in \mathbf{S}$ corresponds to the assignment A to $X_{u_1}, \ldots, X_{u_t}$ contained in it. Indeed, the assignments of the rest of the variables are fixed in $\mathbf{S}$ by construction. It follows that the size of $\mathbf{S}$ is 2^t.

We are going to show that for any distinct $S_1, S_2 \in \mathbf{S}$, $F_{S_1} \neq F_{S_2}$, confirming the lemma. Due to the correspondence established above, we can specify u_i such that S_1 and S_2 assign X_{u_i} with distinct values. Assume w.l.o.g. that X_{u_i} is assigned with $true$ by S_1 and with $false$ by S_2. Observe that F does not have a satisfying assignment including S_2 and assigning both X_{u_i,v_i} and X_{v_i} with $false$. Indeed, as a result, the clause $(X_{u_i} \vee X_{u_i,v_i} \vee X_{v_i})$ is falsified. We are going to show that both X_{u_i,v_i} and X_{v_i} can be assigned with $false$ in a satisfying assignment of F including S_1. Indeed, assign all the variables of $Var(F) \setminus (Var(S_1) \cup \{X_{u_i,v_i}, X_{v_i}\})$ with $true$ and see that the resulting assignment together with S_1 satisfies all the clauses of F. Indeed, if a clause $(X_u \vee X_{u,v} \vee X_v)$ does not belong to TCL then $X_{u,v}$ is assigned with $true$ (by construction, the only 'edge' variables assigned by $false$ are X_{u_i,v_i}, that is those that occur in the clauses of TCL) . Furthermore, for any clause $(X_{u_j} \vee X_{u_j,v_j} \vee X_{v_j})$ of TCL such that $i \neq j$, X_{v_j} is assigned with $true$. Finally X_{u_i} is assigned with $true$ by S_1. It follows that indeed all the clauses of F are satisfied.

Assume that $X_{u_i,v_i} \notin Var(S_1)$. Then, by the reasoning as above, F_{S_1} has a satisfying assignment including $\{\neg X_{u_i,v_i}, \neg X_{v_i}\}$ while F_{S_2} does not implying that $F_{S_1} \neq F_{S_2}$. Otherwise, if $X_{u_i,v_i} \in Var(S_1)$, it is assigned with $false$ in both S_1 and S_2, by construction. It follows that F_{S_1} has a satisfying assignment including $\neg X_{v_i}$ while F_{S_2} does not. It follows again that $F_{S_1} \neq F_{S_2}$. ■

Remark. Notice the role of variables $X_{u,v}$ in the proof of Lemma 3. They allow the values of X_{u_i} to *not influence* the values of X_{v_j} for $i \neq j$ and thus keep the number of different subfunctions up to the desired bound. Due to the same reason, it is important that the edges $\{u_1, v_1\}, \ldots, \{u_r, v_r\}$ constitute a *matching*, i.e. have disjoint ends.

Proof of Theorem 1 Lemma 3 combined with Proposition 1 says that if G has matching width at least t then for any permutation of $Var(CNF(G))$ the corresponding OBDD has at least 2^t nodes. In other words, 2^t is a lower bound on the OBDD size for $CNF(G)$. Taking $G = CT_{r,k}$ and hence $CNF(G) = F_{r,k}$ and substituting $rk/2$ for t according to Lemma 2, we obtain a lower bound of $2^{rk/2}$ on the OBDD size of $F_{r,k}$, as required. ■

Proof of Lemma 2

This section is organized as follows. First, we introduce the notion of *induced permutation*. Then we provide proof of Lemma 2 for $k = 1$. After that, we outline how to upgrade this special case to a complete proof. Finally, we provide the complete proof. Note that the proof of the special case and the following outline are *technically* redundant. However, the reader may find them useful as they provide a *sketch* reflecting the proof idea.

The notion of *induced permutation* is defined as follows. Let P_1 be a permutation of elements of a set S_1 and let $S_2 \subseteq S_1$. Then P_1 induces a permutation P_2 of S_2 where the elements of S_2 are ordered exactly as they are ordered in P_1. For example, let $S_1 = \{1, \ldots, 10\}$ and let S_2 be the subset of even numbers of S_1. Let $P_1 = (1, 8, 2, 9, 5, 6, 7, 3, 4, 10)$. Then $P_2 = (8, 2, 6, 4, 10)$.

Proof of the special case of Lemma 2 for $k = 1$ We are going to prove that for an odd r, the matching width of T_r is at least $(r + 1)/2$. For an even r we can simply take a subgraph of T_r isomorphic to T_{r-1} (it is not hard to see that the matching width of a graph is not less than the matching width of its subgraph).

The proof goes by induction on r. For $r = 1$, this is clear, so consider the case $r > 1$. Imagine T_r rooted in the natural way, the root being its centre. Then T_r has 4 grandchildren, the subtree rooted by each of them being T_{r-2}. Denote these grandchildren by $T^1, \ldots, T^4$. Let PV be any permutation of the vertices of T_r. This permutation induces respective permutations $PV_1, \ldots, PV_4$ of vertices of $T^1, \ldots, T^4$ being ordered exactly as in PV. By the induction assumption, we know that each of $PV_1, \ldots, PV_4$ can be partitioned into a prefix and a suffix so that the edges between the prefix and the suffix induce graph having matching of size at least $(r-1)/2$. Each of these prefixes naturally corresponds to the prefix of PV ending with the same vertex. Since $PV_1, \ldots, PV_4$ are pairwise disjoint, this correspondence supplies 4 *distinct* prefixes $P_1^*, \ldots, PV_4^*$ of PV. Moreover, for each PV_i^* we know that the graph G_i^* induced by the edges between the vertices of PV_i^* and the rest of the vertices has a matching of size $(r-1)/2$ consisting *only* of the edges of T^i. In order to 'upgrade' this matching by 1 and hence to reach the required size of $(r + 1)/2$, all we need to show is that in an least one G_i^* there is an edge both ends are not vertices of T^i and hence this edge can be safely added to the matching.

At this point we make a notational assumption that does not lead to loss of generality and is convenient for the further exposition. By construction, $PV_1^*, \ldots, PV_4^*$ are linearly ordered by containment and we assume w.l.o.g. that the ordering is by the increasing order of the subscript, that is $PV_1^* \subset PV_2^* \subset PV_3^* \subset PV_4^*$. We claim that the upgrade to the matching as specified above is possible for PV_2^*.

Indeed, observe that $T_r \setminus T^2$ is a connected graph. Thus

all we need to show is that at least one vertex of $T_r \setminus T^2$ gets into PV_2^* and at least one vertex of $T_r \setminus T^2$ gets outside PV_2^*, that is in $V(T_r) \setminus PV_2^*$.

For the former, recall that $PV_1^* \subset PV_2^*$ and that by construction, PV_1^* contains $(r-1)/2$ vertices of T^1 being a subgraph of $T_r \setminus T^2$. Thus we conclude that PV_2^* contains vertices of $T_r \setminus T^2$ For the latter, observe that since $PV_2^* \subset PV_3^*, V(T_r) \setminus PV_3^* \subset V(T_r) \setminus PV_2^*$. Furthermore, by construction, $V(T_r) \setminus PV_3^*$ contains $(r-1)/2$ vertices of T^3 being a subgraph of $T_r \setminus T^2$. Thus we conclude that $V(T_r) \setminus PV_2^*$ contains vertices of $T_r \setminus T^2$ as well, thus finishing the proof. ■

A proof for the general case of Lemma 2 proceeds by induction on r similarly to the special case above. Of course we need to keep in mind that instead of nodes of T_r we have cliques of size k. The consequence of this substitution is that at the inductive step of moving from T_{r-2} to T_r we can increase the matching width by k rather than by 1 as above. The auxiliary Lemma 4 allows us to demonstrate the possibility of this upgrade essentially in the same way as we did for $k = 1$: we just show that the considered prefix and suffix of the given permutation both contain at least k vertices outside the grandchild serving the part of the matching guaranteed by the induction assumption.

Lemma 4 *Let T be a tree with at least 2 nodes and let k be a positive integer. Let CT be a graph obtained from T by associating with each vertex of T a clique of an arbitrary size $k' \geq k$ and making the vertices of cliques associated with adjacent vertices of T mutually adjacent. Let W, B standing for 'white' and 'black' be a partition of $V(CT)$ such that $|W| \geq k$ and $|B| \geq k$. Then CT has a matching of size k formed by edges with one white and one black end.*

Proof. The proof is by induction on the number of nodes of T. It is clearly true when there are 2 nodes. Assume that the tree has $n > 2$ nodes and let u be a leaf of T and v be its only neighbour.

Let $k' \geq k$ be the size of the clique VU associated with u in CT. Assume w.l.o.g. that $|W \cap VU| \leq |B \cap VU|$. Denote $|W \cap VU|$ by k_1. Clearly, the k_1 vertices of $W \cap VU$ can be matched with the vertices of $B \cap VU$. If $k_1 \geq k$, we are done. Next, if $|B \setminus VU| \geq k - k_1$, then the lemma follows by induction assumption applied on $T \setminus u$.

Consider the remaining possibility where $|B \setminus VU| = k - k_1 - t$ for some $t > 0$. Observe that $t \leq k' - 2k_1$. Indeed, the total number of vertices of B is $k' - k_1 + k - k_1 - t$ so, $t > k' - 2k_1$ will imply $|B| < k$, a contradiction.

Let VV be the clique associated with the neighbour v of u. It follows from our assumption that $|W \cap VV| \geq k_1 + t$ because at most $k - k_1 - t$ vertices of VV can be black. Match k_1 vertices of $W \cap VU$ with vertices of $B \cap VU$ (this is possible due to our assumption that $|W \cap VU| \leq |B \cap VU|$). Match t unmatched vertices of $B \cap VU$ (there are $k' - 2k_1$ unmatched vertices of $B \cap VU$ and we have just shown that $t \leq k' - 2k_1$) with t vertices of $W \cap VV$. We are in the situation where in $G \setminus u$ there are at least $k - k_1 - t$ vertices of W, at least $k - k_1 - t$ vertices of B and the size of each associated clique is clearly at least $k - k_1 - t$. Hence, the lemma follows by the induction assumption. ■

Proof of Lemma 2. We prove that for an odd r, the matching width of $CT_{r,k}$ is at least $(r+1)k/2$. For an even r, it will be enough to consider a subgraph of $CT_{r,k}$ being isomorphic to $CT_{r-1,k}$. The proof is by induction on r. Assume first that $r = 1$. Then the lemma holds according to Lemma 4.

For $r > 1$, let us view T_r as a rooted tree with its centre rt being the root. Let $T^1, \ldots, T^4$ be the 4 subtrees of T_r rooted by the 'grandchildren' of rt. Let $K_1, \ldots, K_4$ be the subgraphs of $CT_{r,k}$ 'corresponding' to $T^1, \ldots, T^4$. That is, each K_i is a subgraph of $CT_{r,k}$ induced by (the vertices of) cliques associated with the vertices of T^i. It is not hard to see that each T^i is isomorphic to T_{r-2} and each K_i is isomorphic to $CT_{r-2,k}$ and that $K_1, \ldots, K_4$ are pairwise disjoint.

Let PV be an arbitrary permutation of $V(CT_{r,k})$. Let $PV_1, \ldots, PV_4$ be the respective permutations of $V(K_1), \ldots, V(K_4)$ induced by PV. By the induction assumption for each PV_i there is a prefix PV_i' such that the edges of K_i with one end in PV_i' and the other end in $PV_i \setminus PV_i'$ induce a graph having matching of size at least $(r-1)k/2$. Let $u_1, \ldots, u_4$ be the last vertices of $PV_1', \ldots PV_4'$, respectively. Assume w.l.o.g. that these vertices occur in PV in exactly this order. Let PV' be the prefix of PV with final vertex u_2. We are going to show that the subgraph of $CT_{r,k}$ induced by the edges between PV' and $PV \setminus PV'$ has matching of size at least $(r+1)k/2$. In fact, as specified above, we already have matching of size $(r-1)k/2$ if we confine ourself to the edges between $PV' \cap PV_2$ and $(PV \setminus PV') \cap PV_2$. Thus, it only remains to show the existence of matching of size k in the subgraph of $CT_{r,k}$ induced by the edges between $PV_1^* = PV' \setminus PV_2$ and $PV_2^* = (PV \setminus PV') \setminus PV_2$. Observe that PV_1^*, PV_2^* is a partition of vertices of $CT_{r,k} \setminus K_2$. Therefore, it is sufficient to show that $|PV_1^*| \geq k$ and $|PV_2^*| \geq k$ and then the existence of the desired matching of size k will follow from Lemma 4.

Due to our assumption that u_1 precedes u_2 in PV, it follows that PV_1' is contained in PV'. Moreover, since K_1 and K_2 are disjoint, PV_1' is disjoint with PV_2 and hence $PV_1' \subseteq PV_1^*$. Recall that by the induction assumption, the vertices of PV_1' serve as ends of a matching of size $(r-1)k/2$ with no two vertices sharing the same edge of the matching. That is $|PV_1'| \geq (r-1)k/2$. Since $r > 1$ by assumption, we conclude that $|PV_1'| \geq k$ and hence $|PV_1^*| \geq k$.

The proof that $|PV_2^*| \geq k$ is symmetrical. By our assumption, u_2 precedes u_3 is PV and hence $PV_3 \setminus PV_3'$ is contained in $PV \setminus PV'$ and due to the disjointness of K_2 and K_3, $PV_3 \setminus PV_3'$ is in fact contained in PV_2^*. That $|PV_3 \setminus PV_3'| \geq k$ is derived analogously to the proof that $|PV_1'| \geq k$. ■

OBDDs parameterized by the treewidth of the incidence graph

Recall that the incidence graph of the given CNF F has the set of vertices corresponding to its variables and clauses and a variable vertex is adjacent to a clause vertex if and only

if the corresponding variable occurs in the corresponding clause. The upper bound of (Ferrara, Pan, and Vardi 2005) does not straightforwardly apply to the case of incidence graphs because there are classes of CNFs having constant treewidth of the incidence graph and unbounded treewidth of the primal graph. Indeed, consider, for example a CNF with one large clause. Nevertheless, we show in this section that the $O(n^k)$ upper bound on the size of OBDD holds if k is the treewidth of the incidence graph of the considered CNF.

As in (Ferrara, Pan, and Vardi 2005), we show that if p is the pathwidth of the *incidence graph* G of the given CNF F then the function of F can be realized by an OBDD of size $O(2^p n)$ implying (through the $k = O(p * logn)$) the $O(n^k)$ upper bound where k is the treewidth of G. The resulting OBDD is seen as a DAG whose nodes are partitioned into layers, each layer consisting of nodes labelled by the same variable. The main technical lemma shows that under the right permutation of variables the nodes of each layer correspond to $O(2^p)$ subfunctions of F. Consequently, $O(2^p)$ nodes per layer are sufficient, which in turn, immediately implies the desired upper bound.

Let us start from fixing the notation. Let F be a CNF and G be its incidence graph, whose nodes are $X_1, \ldots, X_n$ (corresponding to the variables of F) and $C_1, \ldots, C_m$ (corresponding to the clauses of F) and X_i and adjacent to C_j if and only if X_i occurs in C_j (for the sake of brevity, we identify the vertices of G with the corresponding variables and clauses). Let $(P, \mathbf{B})$ be a path decomposition of G. Fix an end vertex of P and enumerate the vertices of P along the path starting from this fixed vertex. Let $v_1, \ldots, v_r$ be the enumeration. For each X_i, let $f(X_i)$ be the smallest j such that $X_i \in B(v_j)$. We call a linear ordering SV of $X_1, \ldots, X_n$ such $X_i < X_j$ whenever $f(X_i) < f(X_j)$ an ordering *respecting* f.

Now we are ready to prove the main technical lemma.

Lemma 5 *Let SV be an ordering respecting f. Let SV_1 be a prefix of SV. Then the number of distinct F_S such that S is an assignment to SV_1 is at most $1 + 2 * 2^p$ where p is the width of $(P, \mathbf{B})$.*

Proof. Let X be the last variable of SV_1. Denote $f(X)$ by q. We assume w.l.o.g. that all the clauses of F are pairwise distinct and hence identify a CNF with its set of clauses. Partition F into three sets of clauses: FP, consisting of those that appear in some $B(v_j)$ for $j < q$ and do not appear in $B(v_q)$; FC, consisting of those that appear in $B(V_q)$ and FF consisting of those that appear in $B(v_j)$ for some $j > q$ and do not appear in $B(V_q)$. Observe that this is indeed a partition of clauses. Indeed, otherwise $FP \cap FF \neq \emptyset$ as all other possibilities contradict the definition of the sets FP, FC, FF. Then due to the connectedness property of $(P, \mathbf{B})$, either $FP \cap B(v_q) \neq \emptyset$ or $FF \cap B(v_q) \neq \emptyset$. However, both these possibilities contradict the definition of FP and FF. We conclude that FP, FC, FF indeed partition the clauses of F.

Denote by $\mathbf{FS}$ the set of all functions F_S such that S is an assignment to SV_1. Denote by $\mathbf{FPS}$, $\mathbf{FCS}$, $\mathbf{FFS}$ the analogous sets regarding FP, FC, and FF, respectively.

Let us compute the sizes of the latter 3 sets. Let C be a clause of FP. By definition $Var(C)$ is a subset of variables appearing in the bags $B(v_j)$ for $j < q$. By definition, these variables are ordered *before* X. It follows that $Var(C) \subset Var(SV_1)$ and hence any assignment to SV_1 either satisfies or falsifies C. Consequently FP_S is either $true$ or $false$.

It is not hard to see that FC_S is obtained from FC by removal of all the clauses that are satisfied by S and removal of the occurrences of $Var(S)$ from the rest of the clauses. It follows that if FC_{S_1} and FC_{S_2} have the same set of satisfied clauses then $FC_{S_1} = FC_{S_2}$ in other words, FC_S is completely determined by a set of satisfied clauses. Hence $|\mathbf{FCS}|$ is bounded above by the number of subsets of clauses of FCS, i.e. it is at most 2^{t_1} where t_1 is the number of clauses of FCS.

Finally let $SV^* = SV_1 \cap Var(FF)$. It is not hard to see that for an assignment S to SV_1, FF_S is completely determined by the subset of S assigning the variables of SV^*. Therefore, the number of distinct functions FF_S is at most as the number of distinct assignments to SV^*, which is 2^{t_2} where $t_2 = |SV^*|$.

Let S be an assignment on SV_1. It is not hard to see that $F_S = FP_S \wedge FC_S \wedge FF_S$. If $FP_S = false$ then $F_S = false$. Otherwise, $FP_S = true$ and hence $F_S = FC_S \wedge FF_S$. In other words, F_S is either false or there are $F_1 \in \mathbf{FCS}$ and $F_2 \in \mathbf{FFS}$ such that $F_S = F_1 \wedge F_2$. That is $|\mathbf{FS}| \leq 1 + 2^{t_1 + t_2}$.

We claim that $t_1 + t_2 \leq p+1$ implying the lemma. Indeed, the clauses of FC all belong to $B(v_q)$ by definition. Observe that $SV^* \subseteq B(v_q)$ as well. Indeed, let $Y \in SV^*$. Since Y is either X or ordered before X, there must be $j_1 \leq q$ such that $Y \in B(v_{j_1})$. On the other hand, by definition of FF, there must be $j_2 > q$ such that $Y \in B(v_{j_2})$. By the connectedness property $Y \in B(v_q)$. Since FC and SV^* are clearly disjoint being a set of 'clause vertices' and a set of 'variable vertices', the size of their union is the sum of their sizes and the size of their union cannot be larger that $|B(v_q)| \leq p + 1$, as required. ■

The upper bound can now be formally stated.

Theorem 2 *Let F be a CNF with n variables and the pathwidth p of its incidence graph. Then F can be compiled into an OBDD of size $O(2^p n)$.*

Proof. In fact we prove that the $O(2^p n)$ upper bound holds even for *uniform* OBDDs where each path from the root to a leaf includes *all* the variables. Notice that the uniformity is not required by the definition of the OBDD, only the order of variables along a computational path is essential. For instance, the OBDD shown in Figure 1 is not uniform.

Let SV be an ordering respecting f as above. Let Z be a smallest possible uniform OBDD of F with SV being the underlying ordering. It is well known that the subgraph of Z induced by any internal node u and all the vertices reachable from u (the labels on vertices and edges are retained) is an OBDD whose function is $F_{A(P)}$ where P is an arbitrary path from the root to u. Moreover, the minimality of Z implies that all the nodes marked with the same variable represent distinct functions. Indeed, if there are 2 nodes representing the same function then one of them can be removed, with the in-edges of the removed node becoming the in-edges of an-

other node associated with the same function and with possible removal of some nodes that become not reachable from the root. This produces another uniform OBDD implementing the same function and having a smaller size in contradiction to the minimality of Z.

By construction the function of a node labeled with a variable x of F is a subfunction of F obtained by an assignment to the variables preceding x in SV. According to Lemma 5 the number of such subfunctions is $O(2^p)$. Since distinct nodes labeled by x are associated with distinct subfunctions, there are $O(2^p)$ nodes labeled by x. Multiplying this by the number n of variables of F, we obtain the desired $O(2^p n)$ bound on the number of nodes of Z. ■

Corollary 2 *A* CNF *with n variables and having treewidth k can be compiled into an* OBDD *of size $O(n^k)$.*

We close this section with discussion of yet another parameter of CNFs, introduced in (Huang and Darwiche 2004), whose fixed value guarantees a linear size OBDD. In (Huang and Darwiche 2004) this parameter has not been given a name so, let us name it *combined width*. Let SV be a linear ordering on variables of the given CNF F. For each variable x in this ordering we define the *cutwidth* of x (w.r.t. to SV) as the number of clauses with one variable ordered before x and one variable ordered after x in SV. Further on, we define the *pathwidth* of x (w.r.t. to SV) as the number of variables ordered before x that occur in clauses having at least one occurrence of a variable ordered after x. The combined width of x is the minimum of the cutwidth and the pathwdith of x. The combined width of SV is the maximum over all the combined widths of the variables. Finally, the combined width of F is the minimum of combined widths of all possible orders of the variables of F. It is shown in (Huang and Darwiche 2004) that a CNF of combined width w can be complied into an OBDD of size $O(2^w n)$.

The combined width of F is a mixture of two parameters of the primary graph of F: the cutwidth (maximum cutwidth of a variable in the given permutation taken minimum over all permutations) and the pathwidth. Moreover, the combined width is not just their minimum but can in fact be much smaller than both cutwidth and pathwidth. Consider for example a CNF $F = F_1 \wedge F_2$ where F_1 and F_2 are CNFs defined as follows. $F_1 = (x \vee x_1) \wedge \ldots \wedge (x \vee x_m)$ and $F_2 = (y_1, \ldots, y_m)$ We assume that the variables of F_1 are disjoint with the variables of F_2 and that m can be arbitrarily large. The primary graph of F_1 has a large cutwidth. Indeed, for any ordering of variables of F_1 there is a subset V' of $\{x_1, \ldots, x_m\}$ of size at least $m/2$ that are either all smaller than x or all larger than x. Specify a variable $y \in V'$ that is a 'median' of V' according to the considered order. Then the cutwidth of this variable will be about $m/4$. Furthermore, the pathwidth of the primary graph of F_2 is large because this graph is just one big clique. On the other hand, the combined width of F_1 and F_2 is small. Indeed, order the variables as follows: $x, x_1, \ldots, x_m, y_1, \ldots, y_m$. Then the pathwidth index of the first $m + 1$ variables is 1 and hence the combined width will be at most 1 as well. Further, the cutwidth of the last m variable is 1 and hence the combined width of these variables is 1 as well. Thus the combined width of this order is 1 and hence the combined width of $F_1 \wedge F_2$ is at most 1 which is clearly much smaller than the minimum of the pathwdith and the cutwidth of F (determined by the respective connected components of the primary graph of F). We leave the relationship between the incidence graph treewidth and the combined width as an open question.

Discussion

In this paper we have demonstrated an infinite class of CNFs of primal graph treewidth at most k their primal graphs for which the sizes of respective OBDDs are at least $f(k)n^{k/4}$ for some function f. This result rules out the possibility of compiling a CNF into an OBDD of fixed-parameter size parameterized by the primal graph treewidth of the CNF. Our second result shows that a CNF of incidence graph treewidth at most k can be compiled into an OBDD of size at most $O(n^k)$.

Two open questions naturally arise from these results. For the first question recall that the Free Binary Decision Diagram FBDD (a.k.a. read-once branching program) is a generalization of OBDD that allows querying variables in different orders along different computational paths. Does the above lower bound hold for FBDDs realizing CNFs of bounded treewidth? The second question is: what is the space complexity of SDD parameterized by the *incidence graph treewidth* of the input CNF?

Analyzing the Computational Complexity of Abstract Dialectical Frameworks via Approximation Fixpoint Theory

Vienna University of Technology, Austria

Abstract

Abstract dialectical frameworks (ADFs) have recently been proposed as a versatile generalization of Dung's abstract argumentation frameworks (AFs). In this paper, we present a comprehensive analysis of the computational complexity of ADFs. Our results show that while ADFs are one level up in the polynomial hierarchy compared to AFs, there is a useful subclass of ADFs which is as complex as AFs while arguably offering more modeling capacities. As a technical vehicle, we employ the approximation fixpoint theory of Denecker, Marek and Truszczyński, thus showing that it is also a useful tool for complexity analysis of operator-based semantics.

Introduction

Formal models of argumentation are increasingly being recognized as viable tools in knowledge representation and reasoning (Bench-Capon and Dunne 2007). A particularly popular formalism are Dung's abstract argumentation frameworks (AFs) (1995). AFs treat arguments as abstract entities and natively represent only attacks between them using a binary relation. Typically, abstract argumentation frameworks are used as a target language for translations from more concrete languages. For example, the Carneades formalism for structured argumentation (Gordon, Prakken, and Walton 2007) has been translated to AFs (Van Gijzel and Prakken 2011); Caminada and Amgoud (2007) and Wyner et al. (2013) translate rule-based defeasible theories into AFs. Despite their popularity, abstract argumentation frameworks have limitations. Most significantly, their limited modeling capacities are a notable obstacle for applications: arguments can only attack one another. Furthermore, Caminada and Amgoud (2007) observed how AFs that arise as translations of defeasible theories sometimes lead to unintuitive conclusions.

To address the limitations of abstract argumentation frameworks, researchers have proposed quite a number of generalizations of AFs (Brewka, Polberg, and Woltran 2013). Among the most general of those are Brewka and Woltran's *abstract dialectical frameworks (ADFs)* (2010). ADFs are even more abstract than AFs: while in AFs arguments are abstract and the relation between arguments is fixed to attack, in ADFs also the relations are abstract (and called *links*). The relationship between different arguments (called *statements* in ADFs) is specified by *acceptance conditions*. These are Boolean functions indicating the conditions under which a statement s can be accepted when given the acceptance status of all statements with a direct link to s (its *parents*). ADFs have been successfully employed to address the shortcomings of AFs: Brewka and Gordon (2010) translated Carneades to ADFs and for the first time allowed cyclic dependencies amongst arguments; for rule-based defeasible theories we (Strass 2013b) showed how to deal with the problems observed by Caminada and Amgoud (2007).

There is a great number of semantics for AFs already, and many of them have been generalized to ADFs. Thus it might not be clear to potential ADF users which semantics are adequate for a particular application domain. In this regard, knowing the computational complexity of semantics can be a valuable guide. However, existing complexity results for ADFs are scattered over different papers, miss several semantics and some of them present upper bounds only. In this paper, we provide a comprehensive complexity analysis for ADFs. In line with the literature, we represent acceptance conditions by propositional formulas as they provide a compact and elegant way to represent Boolean functions.

Technically, we base our complexity analysis on the approximation fixpoint theory (AFT) by Denecker, Marek and Truszczyński (2000; 2003; 2004). This powerful framework provides an algebraic account of how monotone and non-monotone two-valued operators can be approximated by monotone three- or four-valued operators. (As an example of an operator to be approximated, think of the two-valued van Emden-Kowalski consequence operator from logic programming.) AFT embodies the intuitions of decades of KR research; we believe that this is very valuable also for relatively recent languages (such as ADFs), because we get the enormously influential formalizations of intuitions of Reiter and others for free. (As a liberal variation on Newton, we could say that approximation fixpoint theory allows us to take the elevator up to the shoulders of giants instead of walking up the stairs.) In fact, approximation fixpoint theory can be and partially has already been used to define some of the semantics of ADFs (Brewka et al. 2013; Strass 2013a). There, we generalized various AF and logic programming semantics to ADFs using AFT, which has provided us with two families of semantics, that we call – for rea-

sons that will become clear later – *approximate* and *ultimate*, respectively. Intuitively speaking, both families approximate the original two-valued model semantics of ADFs, where the ultimate family is more *precise* in a formally defined sense. The present paper employs approximating operators for complexity analysis and thus shows that AFT is also well-suited for studying the computational complexity of formalisms.

Along with providing a comparison of the approximate and ultimate families of semantics, our main results can be summarized as follows. We show that: (1) the computational complexity of ADF decision problems is one level up in the polynomial hierarchy from their AF counterparts (Dunne and Wooldridge 2009); (2) the ultimate semantics are as complex as the approximate semantics, with the notable exception of two-valued stable models; (3) there is a certain subclass of ADFs, called *bipolar* ADFs (BADFs), which is of the same complexity as AFs. Intuitively, in bipolar ADFs all links between statements are supporting or attacking. To formalize these notions, Brewka and Woltran (2010) gave a precise semantical definition of support and attack. In our work, we assume that the link types are specified by the user along with the ADF. We consider this a harmless assumption since the existing applications of ADFs produce bipolar ADFs where the link types are known (Brewka and Gordon 2010; Strass 2013b). This attractiveness of bipolar ADFs from a KR point of view is the most significant result of the paper: it shows that BADFs offer – in addition to AF-like and more general notions of attack – also syntactical notions of support *without any increase in computational cost*.

Previously, Brewka, Dunne and Woltran (2011) translated BADFs into AFs for two-valued semantics and suggested indirectly that the complexities align. Here we go a direct route, which has more practical relevance since it immediately affects algorithm design. Our work was also inspired by the complexity analysis of assumption-based argumentation by Dimopoulos, Nebel and Toni (2002) – they derived generic results in a way similar to ours.

The paper proceeds as follows. We first provide the background on approximation fixpoint theory, abstract dialectical frameworks and the necessary elements of complexity theory. In the section afterwards, we define the relevant decision problems, survey existing complexity results, use examples to illustrate how operators revise ADF interpretations and show generic upper complexity bounds. In the main section on complexity results for general ADFs, we back up the upper bounds with matching lower bounds; the section afterwards does the same for bipolar ADFs. We end with a brief discussion of related and future work. An earlier version of this paper with more details and all proofs is available as a technical report (Strass and Wallner 2013).

Background

A *complete lattice* is a partially ordered set $(A, \sqsubseteq)$ where every subset of A has a least upper and a greatest lower bound. In particular, a complete lattice has a least and a greatest element. An operator $O : A \to A$ is *monotone* if for all $x \sqsubseteq y$ we find $O(x) \sqsubseteq O(y)$. An $x \in A$ is a *fixpoint* of O if $O(x) = x$; an $x \in A$ is a *prefixpoint* of O if $O(x) \sqsubseteq x$ and a *postfixpoint* of O if $x \sqsubseteq O(x)$. Due to a fundamental result by Tarski and Knaster, for any monotone operator O on a complete lattice, the set of its fixpoints forms a complete lattice itself (Davey and Priestley 2002, Theorem 2.35). In particular, its least fixpoint $lfp(O)$ exists.

In this paper, we will be concerned with more general algebraic structures: complete partially ordered sets (CPOs). A CPO is a partially ordered set with a least element where each directed subset has a least upper bound. A set is directed iff it is nonempty and each pair of elements has an upper bound in the set. Clearly every complete lattice is a complete partially ordered set, but not necessarily vice versa. Fortunately, complete partially ordered sets still guarantee the existence of (least) fixpoints for monotone operators.

Theorem 1 ((Davey and Priestley 2002, Theorem 8.22))**.** *In a complete partially ordered set $(A, \sqsubseteq)$, any $\sqsubseteq$-monotone operator $O : A \to A$ has a least fixpoint.*

Approximation Fixpoint Theory

Denecker, Marek and Truszczyński (2000) introduce the important concept of an approximation of an operator. In the study of semantics of knowledge representation formalisms, elements of lattices represent objects of interest. Operators on lattices transform such objects into others according to the contents of some knowledge base. Consequently, fixpoints of such operators are then objects that are fully updated – informally, the knowledge base can neither increase nor decrease the amount of information in a fixpoint.

To study fixpoints of operators O, DMT study their *approximation operators* $\mathcal{O}$. When O operates on a set A, its approximation $\mathcal{O}$ operates on pairs $(x, y) \in A \times A$. Such a pair (x, y) can be seen as representing a *set* of lattice elements by providing a lower bound x and an upper bound y. Consequently, (x, y) approximates all $z \in A$ such that $x \sqsubseteq z \sqsubseteq y$. We will restrict our attention to *consistent* pairs – those where $x \sqsubseteq y$, that is, the set of approximated elements is nonempty; we denote the set of all consistent pairs over A by A^c. A pair (x, y) with $x = y$ is called *exact* – it "approximates" a single element of the original lattice.

It is natural to order approximating pairs according to their information content. Formally, for $x_1, x_2, y_1, y_2 \in A$ define the *information ordering* $(x_1, y_1) \leq_i (x_2, y_2)$ iff $x_1 \sqsubseteq x_2$ and $y_2 \sqsubseteq y_1$. This ordering and the restriction to consistent pairs leads to a complete partially ordered set $(A^c, \leq_i)$, the *consistent CPO*. For example, the *trivial pair* $(\bot, \top)$ consisting of $\sqsubseteq$-least $\bot$ and $\sqsubseteq$-greatest lattice element $\top$ approximates all lattice elements and thus contains no information – it is the least element of the CPO $(A^c, \leq_i)$; exact pairs (x, x) are the maximal elements of $(A^c, \leq_i)$.

To define an approximation operator $\mathcal{O} : A^c \to A^c$, one essentially has to define two functions: a function $\mathcal{O}' : A^c \to A$ that yields a revised *lower* bound (first component) for a given pair; and a function $\mathcal{O}'' : A^c \to A$ that yields a revised *upper* bound (second component) for a given pair. Accordingly, the overall approximation is then given by $\mathcal{O}(x, y) = (\mathcal{O}'(x, y), \mathcal{O}''(x, y))$ for $(x, y) \in A^c$. The operator $\mathcal{O} : A^c \to A^c$ is *approximating* iff it is $\leq_i$-monotone and it satisfies $\mathcal{O}'(x, x) = \mathcal{O}''(x, x)$ for all $x \in A$, that is, $\mathcal{O}$ assigns exact pairs to exact pairs. Such an $\mathcal{O}$ then *ap-*

Kripke-Kleene semantics	$lfp(\mathcal{O})$	grounded pair
admissible/reliable pair (x, y)	$(x, y) \leq_i \mathcal{O}(x, y)$	admissible pair
three-valued supported model (x, y)	$(x, y) = \mathcal{O}(x, y)$	complete pair
M-supported model (x, y)	$(x, y) \leq_i \mathcal{O}(x, y)$ and (x, y) is $\leq_i$-maximal	preferred pair
two-valued supported model (x, x)	$(x, x) = \mathcal{O}(x, x)$	model
two-valued stable model (x, x)	$x = lfp(\mathcal{O}'(\cdot, x))$	stable model

Table 1: Operator-based semantical notions (and their argumentation names on the right) for a complete lattice $(A, \sqsubseteq)$ and an approximating operator $\mathcal{O} : A^c \to A^c$ on the consistent CPO. While an approximating operator always possesses three-valued (post-)fixpoints, two-valued fixpoints need not exist. Clearly, any two-valued stable model is a two-valued supported model is a preferred pair is a complete pair is an admissible pair; furthermore the grounded semantics is a complete pair.

proximates an operator $O : A \to A$ on the original lattice iff $\mathcal{O}'(x, x) = O(x)$ for all $x \in A$.

The main contribution of Denecker, Marek and Truszczyński (2000) was the association of the *stable operator* to an approximating operator. Their original definition was four-valued; in this paper we are only interested in two-valued stable models and simplified the definitions. For an approximating operator $\mathcal{O}$ on a consistent CPO, a (two-valued) pair $(x, x) \in A^c$ is a (two-valued) *stable model of* $\mathcal{O}$ iff x is the least fixpoint of the operator $\mathcal{O}'(\cdot, x)$ defined by $w \mapsto \mathcal{O}'(w, x)$ for $w \sqsubseteq x$. This general, lattice-theoretic approach yields a uniform treatment of the standard semantics of the major nonmonotonic knowledge representation formalisms – logic programming, default logic and autoepistemic logic (Denecker, Marek, and Truszczyński 2003).

In subsequent work, Denecker, Marek and Truszczyński (2004) presented a general, abstract way to define the most precise – called the *ultimate* – approximation of a given operator O. Most precise here refers to a generalisation of $\leq_i$ to operators, where for $\mathcal{O}_1, \mathcal{O}_2$, they define $\mathcal{O}_1 \leq_i \mathcal{O}_2$ iff for all $(x, y) \in A^c$ it holds that $\mathcal{O}_1(x, y) \leq_i \mathcal{O}_2(x, y)$. Denecker, Marek and Truszczyński (2004) show that the most precise approximation of O is $\mathcal{U}_O : A^c \to A^c$ that maps (x, y) to

$$\left(\bigsqcap \{O(z) \mid x \sqsubseteq z \sqsubseteq y\}, \bigsqcup \{O(z) \mid x \sqsubseteq z \sqsubseteq y\}\right)$$

where $\sqcap$ denotes the greatest lower bound and $\sqcup$ the least upper bound in the complete lattice $(A, \sqsubseteq)$.

In recent work, we defined new operator-based semantics inspired by semantics from logic programming and abstract argumentation (Strass 2013a).[1] An overview is in Table 1.

Abstract Dialectical Frameworks

An abstract dialectical framework (ADF) is a directed graph whose nodes represent statements or positions which can be accepted or not. The links represent dependencies: the status of a node s only depends on the status of its parents (denoted $par(s)$), that is, the nodes with a direct link to s. In addition, each node s has an associated acceptance condition C_s specifying the exact conditions under which s is accepted. C_s is a function assigning to each subset of $par(s)$ one of the truth values $\mathbf{t}$, $\mathbf{f}$. Intuitively, if for some $R \subseteq par(s)$ we have $C_s(R) = \mathbf{t}$, then s will be accepted provided the nodes in R are accepted and those in $par(s) \setminus R$ are not accepted.

Definition 1. An *abstract dialectical framework* is a tuple $\Xi = (S, L, C)$ where

- S is a set of statements (positions, nodes),
- $L \subseteq S \times S$ is a set of links,
- $C = \{C_s\}_{s \in S}$ is a collection of total functions $C_s : 2^{par(s)} \to \{\mathbf{t}, \mathbf{f}\}$, one for each statement s. The function C_s is called *acceptance condition of* s.

It is often convenient to represent acceptance conditions by propositional formulas. In particular, we will do so for the complexity results of this paper. There, each C_s is represented by a propositional formula φ_s over $par(s)$. Then, clearly, $C_s(R \cap par(s)) = \mathbf{t}$ iff $R \models \varphi_s$. Furthermore, throughout the paper we will denote ADFs by Ξ and tacitly assume that $\Xi = (S, L, C)$ unless stated otherwise.

Brewka and Woltran (2010) introduced a useful subclass of ADFs called *bipolar*: Intuitively, in bipolar ADFs (BADFs) each link is supporting or attacking (or both). Formally, a link $(r, s) \in L$ is *supporting in* Ξ iff for all $R \subseteq par(s)$, we have that $C_s(R) = \mathbf{t}$ implies $C_s(R \cup \{r\}) = \mathbf{t}$; symmetrically, a link $(r, s) \in L$ is *attacking in* Ξ iff for all $R \subseteq par(s)$, we have that $C_s(R \cup \{r\}) = \mathbf{t}$ implies $C_s(R) = \mathbf{t}$. An ADF $\Xi = (S, L, C)$ is *bipolar* iff all links in L are supporting or attacking or both; we use L^+ to denote all supporting and L^- to denote all attacking links of L in Ξ. For an $s \in S$ we define $att_\Xi(s) = \{x \mid (x, s) \in L^-\}$ and $supp_\Xi(s) = \{x \mid (x, s) \in L^+\}$.

The semantics of ADFs can be defined using approximating operators. For two-valued semantics of ADFs we are interested in sets of statements, that is, we work in the complete lattice $(A, \sqsubseteq) = (2^S, \subseteq)$. To approximate elements of this lattice, we use consistent pairs of sets of statements and the associated consistent CPO $(A^c, \leq_i)$ – the *consistent CPO over S-subset pairs*. Such a pair $(X, Y) \in A^c$ can be regarded as a three-valued interpretation where all elements in X are true, those in $Y \setminus X$ are unknown and those in $S \setminus Y$ are false. (This allows us to use "pair" and "interpretation" synonymously from now on.) The following definition specifies how to revise a given three-valued interpretation.

Definition 2 ((Strass 2013a, Definition 3.1))**.** Let Ξ be an

[1] To be precise, we used a slightly different technical setting there. The results can however be transferred to the present setting (Denecker, Marek, and Truszczyński 2004, Theorem 4.2).

ADF. Define an operator $\mathcal{G}_\Xi : 2^S \times 2^S \to 2^S \times 2^S$ by

$$\mathcal{G}_\Xi(X,Y) = (\mathcal{G}'_\Xi(X,Y), \mathcal{G}'_\Xi(Y,X))$$
$$\mathcal{G}'_\Xi(X,Y) = \{s \in S \mid B \subseteq par(s), C_s(B) = \mathbf{t}, B \subseteq X, (par(s) \setminus B) \cap Y = \emptyset\}$$

Intuitively, statement s is included in the revised lower bound iff the input pair provides sufficient reason to do so, given acceptance condition C_s. Although the operator is defined for all pairs (including inconsistent ones), its restriction to consistent pairs is well-defined since it maps consistent pairs to consistent pairs. This operator defines the *approximate* family of ADF semantics according to Table 1. Based on the three-valued operator $\mathcal{G}_\Xi$, a two-valued one-step consequence operator for ADFs can be defined by $G_\Xi(X) = \mathcal{G}'_\Xi(X,X)$. The general result of Denecker, Marek and Truszczyński (2004) (Theorem 5.6) then immediately defines the ultimate approximation of G_Ξ as the operator $\mathcal{U}_\Xi$ given by $\mathcal{U}_\Xi(X,Y) = (\mathcal{U}'_\Xi(X,Y), \mathcal{U}''_\Xi(X,Y))$ with

- $\mathcal{U}'_\Xi(X,Y) = \{s \in S \mid \text{ for all } X \subseteq Z \subseteq Y, Z \models \varphi_s\}$ and
- $\mathcal{U}''_\Xi(X,Y) = \{s \in S \mid \text{ for some } X \subseteq Z \subseteq Y, Z \models \varphi_s\}$.

Incidentally, Brewka and Woltran (2010) already defined this operator, which was later used to define the *ultimate* family of ADF semantics according to Table 1 (Brewka et al. 2013).[2] In this paper, we will refer to the two families of three-valued semantics as "approximate σ" and "ultimate σ" for σ among admissible, grounded, complete, preferred and stable. For two-valued supported models (or simply models), approximate and ultimate semantics coincide.

Finally, for a propositional formula φ over vocabulary P and $X \subseteq Y \subseteq P$ we define the *partial valuation of φ by* (X,Y) as $\varphi^{(X,Y)} = \varphi[p/\mathbf{t} : p \in X][p/\mathbf{f} : p \in P \setminus Y]$. This partial evaluation takes the two-valued part of (X,Y) and replaces the evaluated variables by their truth values. Naturally, $\varphi^{(X,Y)}$ is a formula over the vocabulary $Y \setminus X$.

Complexity theory

We assume familiarity with the complexity classes P, NP and coNP, as well as with polynomial reductions and hardness and completeness for these classes. We also make use of the polynomial hierarchy, that can be defined (using oracle Turing machines) as follows: $\Sigma_0^P = \Pi_0^P = \Delta_0^P = \mathsf{P}$, $\Sigma_{i+1}^P = \mathsf{NP}^{\Sigma_i^P}$, $\Pi_{i+1}^P = \mathsf{coNP}^{\Sigma_i^P}$, $\Delta_{i+1}^P = \mathsf{P}^{\Sigma_i^P}$ for $i \geq 0$.

As a somewhat non-standard polynomial hierarchy complexity class, we use D_i^P, a generalisation of the complexity class DP to the polynomial hierarchy. A language is in DP iff it is the intersection of a language in NP and a language in coNP. Generally, a language is in D_i^P iff it is the intersection of a language in Σ_i^P and a language in Π_i^P. The canonical problem of $\mathsf{DP} = \mathrm{D}_1^P$ is SAT-UNSAT, the problem to decide for a given pair (ψ_1, ψ_2) of propositional formulas whether ψ_1 is satisfiable and ψ_2 is unsatisfiable. Obviously, by definition $\Sigma_i^P, \Pi_i^P \subseteq \mathrm{D}_i^P \subseteq \Delta_{i+1}^P$ for all $i \geq 0$.

[2] Technically, Brewka et al. (2013) represented interpretations not by pairs $(X,Y) \in A^c$ but by mappings $v : S \to \{\mathbf{t}, \mathbf{f}, \mathbf{u}\}$ into the set of truth values $\mathbf{t}$ (true), $\mathbf{f}$ (false) and $\mathbf{u}$ (unknown or undecided). Clearly the two representations are interchangeable.

Preparatory Considerations

We first introduce some notation to make precise what decision problems we will analyze. For a set S, let

- $(A^c, \leq_i)$ be the consistent CPO of S-subset pairs,
- $\mathcal{O}$ an approximating operator on $(A^c, \leq_i)$,
- $\sigma \in \{adm, com, grd, pre, 2su, 2st\}$ a semantics among admissible, complete, grounded, preferred, two-valued supported and two-valued stable semantics, respectively.

In the *verification* problem we decide whether $(X,Y) \in A^c$ is a σ-model/pair of $\mathcal{O}$, denoted by $\mathsf{Ver}_\sigma^\mathcal{O}(X,Y)$. In the *existence* problem we ask whether there exists a σ-model/pair of $\mathcal{O}$ which is non-trivial, that is, different from $(\emptyset, S)$, denoted by $\mathsf{Exists}_\sigma^\mathcal{O}$. For query reasoning and $s \in S$ we consider the problem of deciding whether there exists a σ-model/pair (X,Y) of $\mathcal{O}$ such that $s \in X$, denoted by $\mathsf{Cred}_\sigma^\mathcal{O}(s)$ (*credulous* reasoning) and the problem of deciding whether in all σ-models/pairs (X,Y) of $\mathcal{O}$ we have $s \in X$, denoted by $\mathsf{Skept}_\sigma^\mathcal{O}(s)$ (*skeptical* reasoning). Note that it is no restriction to check only for truth of a statement $s \in S$, since checking for falsity can be modeled by introducing a new statement s' that behaves like the logical negation of s, by setting its acceptance condition to $\varphi_{s'} = \neg s$.

Existing results

We briefly survey – to the best of our knowledge – all existing complexity results for abstract dialectical frameworks. For general ADFs Ξ and the ultimate family of semantics, Brewka et al. (2013) have shown the following:

- $\mathsf{Ver}_{\mathsf{2su}}^{\mathcal{U}_\Xi}$ is in P, $\mathsf{Exists}_{\mathsf{2su}}^{\mathcal{U}_\Xi}$ is NP-complete (Proposition 5)
- $\mathsf{Ver}_{\mathsf{adm}}^{\mathcal{U}_\Xi}$ is coNP-complete (Proposition 10)
- $\mathsf{Ver}_{\mathsf{grd}}^{\mathcal{U}_\Xi}$ and $\mathsf{Ver}_{\mathsf{com}}^{\mathcal{U}_\Xi}$ are DP-complete (Theorem 6, Cor. 7)
- $\mathsf{Ver}_{\mathsf{2st}}^{\mathcal{U}_\Xi}$ is in DP (Proposition 8)
- $\mathsf{Exists}_{\mathsf{2st}}^{\mathcal{U}_\Xi}$ is Σ_2^P-complete (Theorem 9)

For bipolar ADFs, Brewka and Woltran (2010) showed that $\mathsf{Ver}_{\mathsf{grd}}^{\mathcal{U}_\Xi}$ is in P (Proposition 15). So particularly for BADFs, this paper will greatly illuminate the complexity landscape.

Relationship between the operators

Since $\mathcal{U}_\Xi$ is the ultimate approximation of G_Ξ it is clear that for any $X \subseteq Y \subseteq S$ we have $\mathcal{G}_\Xi(X,Y) \leq_i \mathcal{U}_\Xi(X,Y)$. In other words, the ultimate revision operator produces new bounds that are at least as tight as those of the approximate operator. More explicitly, the ultimate new lower bound always contains the approximate new lower bound: $\mathcal{G}'_\Xi(X,Y) \subseteq \mathcal{U}'_\Xi(X,Y)$; conversely, the ultimate new upper bound is contained in the approximate new upper bound: $\mathcal{U}''_\Xi(X,Y) \subseteq \mathcal{G}''_\Xi(X,Y)$. Somewhat surprisingly, it turns out that the revision operators for the upper bound coincide.

Lemma 2. *Let $\Xi = (S, L, C)$ be an ADF and $X \subseteq Y \subseteq S$.*

$$\mathcal{G}''_\Xi(X,Y) = \mathcal{U}''_\Xi(X,Y)$$

The operators for computing a new lower bound are demonstrably different, since we can find Ξ and (X,Y) with $\mathcal{U}'_\Xi(X,Y) \not\subseteq \mathcal{G}'_\Xi(X,Y)$, as the following ADF shows.

Example 1. Consider the ADF $D = (\{a\}, \{(a, a)\}, \{\varphi_a\})$ with one self-dependent statement a that has acceptance formula $\varphi_a = a \vee \neg a$. In Figure 1, we show the relevant CPO and the behavior of approximate and ultimate operators: we see that $\mathcal{G}_D(\emptyset, \{a\}) <_i \mathcal{U}_D(\emptyset, \{a\})$, which shows that in some cases the ultimate operator is strictly more precise.

So in a sense the approximate operator cannot see beyond the case distinction $a \vee \neg a$. As we will see shortly, this difference really amounts to the capability of tautology checking.

Example 2. ADF $E = (\{a, b\}, \{(b, a), (b, b)\}, \{\varphi_a, \varphi_b\})$ has acceptance formulas $\varphi_a = b \vee \neg b$ and $\varphi_b = \neg b$. So b is self-attacking and the link from b to a is redundant. In Figure 1 on the next page, we show the relevant CPO and the behavior of the operators $\mathcal{U}_E$ and $\mathcal{G}_E$ on this CPO.

The examples show that the approximate and ultimate families of semantics really are different, save for one straightforward inclusion relation in case of admissible.

Corollary 3. *For any ADF Ξ, we have the following:*

1. *An approximate admissible pair is an ultimate admissible pair, but not vice versa.*
2. *With respect to their sets of pairs, the approximate and ultimate versions of preferred/complete/grounded semantics are $\subseteq$-incomparable.*

Operator complexities

We next analyze the computational complexity of deciding whether a single statement is contained in the lower or upper bound of the revision of a given pair. This then leads to the complexity of checking whether current lower/upper bounds are pre- or postfixpoints of the revision operators for computing new lower/upper bounds, that is, whether the revisions represent improvements in terms of the information ordering. Intuitively, these results describe how hard it is to "use" the operators and lay the foundation for the rest of the complexity results.

Proposition 4. *Let Ξ be an ADF, $s \in S$ and $X \subseteq Y \subseteq S$.*

1. *Deciding $s \in \mathcal{G}'_\Xi(X, Y)$ is in* P.
2. *Deciding $\mathcal{G}'_\Xi(X, Y) \subseteq X$ is in* P.
3. *Deciding $X \subseteq \mathcal{G}'_\Xi(X, Y)$ is in* P.

Now let $\mathcal{O} \in \{\mathcal{G}_\Xi, \mathcal{U}_\Xi\}$.

4. *Deciding $s \in \mathcal{O}''(X, Y)$ is* NP*-complete.*
5. *Deciding $\mathcal{O}''(X, Y) \subseteq Y$ is* coNP*-complete.*
6. *Deciding $Y \subseteq \mathcal{O}''(X, Y)$ is* NP*-complete.*

Proof. We only show 1 and 4 as the rest follows suit.

1. Since $X \subseteq Y$, we have that whenever there exists a $B \subseteq X \cap par(s)$ with $C_s(B) = \mathbf{t}$ and $(par(s) \setminus B) \cap Y = \emptyset$, we know that $B = X \cap par(s)$. Thus $s \in \mathcal{G}'_\Xi(X, Y)$ iff $C_s(X \cap par(s)) = \mathbf{t}$ and $(par(s) \setminus X) \cap Y = \emptyset$. For acceptance functions represented by propositional formulas, both conditions can be checked in polynomial time.
4. Deciding $s \in \mathcal{G}''_\Xi(X, Y)$ is NP-complete:
   in NP: By definition, $\mathcal{G}''_\Xi(X, Y) = \mathcal{G}'_\Xi(Y, X)$. To verify $s \in \mathcal{G}'_\Xi(Y, X)$, we can guess a set $M \subseteq S$ and verify that $M \subseteq Y$, $par(s) \setminus M \subseteq S \setminus X$ and $M \models \varphi_s$.
   NP-hard: For hardness, we provide a reduction from SAT. Let ψ be a propositional formula over vocabulary P. Define an ADF $\Xi = (S, L, C)$ with $S = P \cup \{z\}$ where $z \notin P$, $\varphi_z = \psi$ and $\varphi_p = p$ for all $p \in P$. Observe that $par(z) = P$, and set $X = \emptyset$ and $Y = P$. Now $z \in \mathcal{G}''_\Xi(X, Y)$ iff $z \in \mathcal{G}'_\Xi(Y, X)$ iff $z \in \mathcal{G}'_\Xi(P, \emptyset)$ iff there is an $M \subseteq P$ with $P \setminus M \cap \emptyset = \emptyset$ and $M \models \varphi_z$ iff there is an $M \subseteq P$ with $M \models \psi$ iff ψ is satisfiable. □

These results can also be formulated in terms of partial evaluations of acceptance formulas: We have $s \in \mathcal{G}'_\Xi(X, Y)$ iff the partial evaluation $\varphi_s^{(X,Y)}$ is a formula without variables that has truth value $\mathbf{t}$. Similarly, we have $s \in \mathcal{G}''_\Xi(X, Y)$ iff the partial evaluation $\varphi_s^{(X,Y)}$ is satisfiable. Under standard complexity assumptions, computing a new lower bound with the ultimate operator is harder than with the approximate operator. This is because, intuitively, $s \in \mathcal{U}'_\Xi(X, Y)$ iff the partial evaluation $\varphi_s^{(X,Y)}$ is a tautology.

Proposition 5. *Let Ξ be an ADF, $s \in S$ and $X \subseteq Y \subseteq S$.*

1. *Deciding $s \in \mathcal{U}'_\Xi(X, Y)$ is* coNP*-complete.*
2. *Deciding $\mathcal{U}'_\Xi(X, Y) \subseteq X$ is* NP*-complete.*
3. *Deciding $X \subseteq \mathcal{U}'_\Xi(X, Y)$ is* coNP*-complete.*

Proof. We only show the first item since the remaining proofs work along the same lines. The hardness proof uses the ADF from Proposition 4.

in coNP: To decide that $s \notin \mathcal{U}'_\Xi(X, Y)$, we guess a Z with $X \subseteq Z \subseteq Y$ and verify that $Z \not\models \varphi_s$.

coNP-hard: Set $X = \emptyset$ and $Y = P$. Now $z \in \mathcal{U}'_\Xi(X, Y)$ iff $z \in \mathcal{U}'_\Xi(\emptyset, P)$ iff for all $Z \subseteq P$, we have $Z \models \varphi_z$ iff for all $Z \subseteq P$, we have $Z \models \psi$ iff ψ is a tautology. □

The next result considerably simplifies the complexity analysis of deciding the existence of non-trivial pairs.

Lemma 6. *Let $(A, \sqsubseteq)$ be a complete lattice and $\mathcal{O}$ an approximating operator on A^c. The following are equivalent:*

1. *$\mathcal{O}$ has a non-trivial admissible pair.*
2. *$\mathcal{O}$ has a non-trivial preferred pair.*
3. *$\mathcal{O}$ has a non-trivial complete pair.*

Proof. "(1) ⇒ (2)": Let $(\bot, \top) <_i (x, y) \leq_i \mathcal{O}(x, y)$. We show that there is a preferred pair $(p, q) \geq_i (x, y)$. Define $D = \{(a, b) \mid (x, y) \leq_i (a, b)\}$, then the pair $(D, \leq_i)$ is a CPO on which $\mathcal{O}$ is an approximating operator. (Obviously $(a, b) \in D$ implies $(x, y) \leq_i (a, b)$ whence by presumption and $\leq_i$-monotonicity of $\mathcal{O}$ we get $(x, y) \leq_i \mathcal{O}(x, y) \leq_i \mathcal{O}(a, b)$ and $\mathcal{O}(a, b) \in D$.) Now any sequence $(a, b) \leq_i \mathcal{O}(a, b) \leq_i \mathcal{O}(\mathcal{O}(a, b)) \leq_i \ldots$ is a non-empty chain in D and therefore has an upper bound in D. By Zorn's lemma, the set of all $\mathcal{O}$-admissible pairs in A has a maximal element $(p, q) \geq_i (x, y) >_i (\bot, \top)$.

"(2) ⇒ (3)": By (Strass 2013a, Theorem 3.10), every preferred pair is complete.

"(3) ⇒ (1)": Any complete pair is admissible (Table 1). □

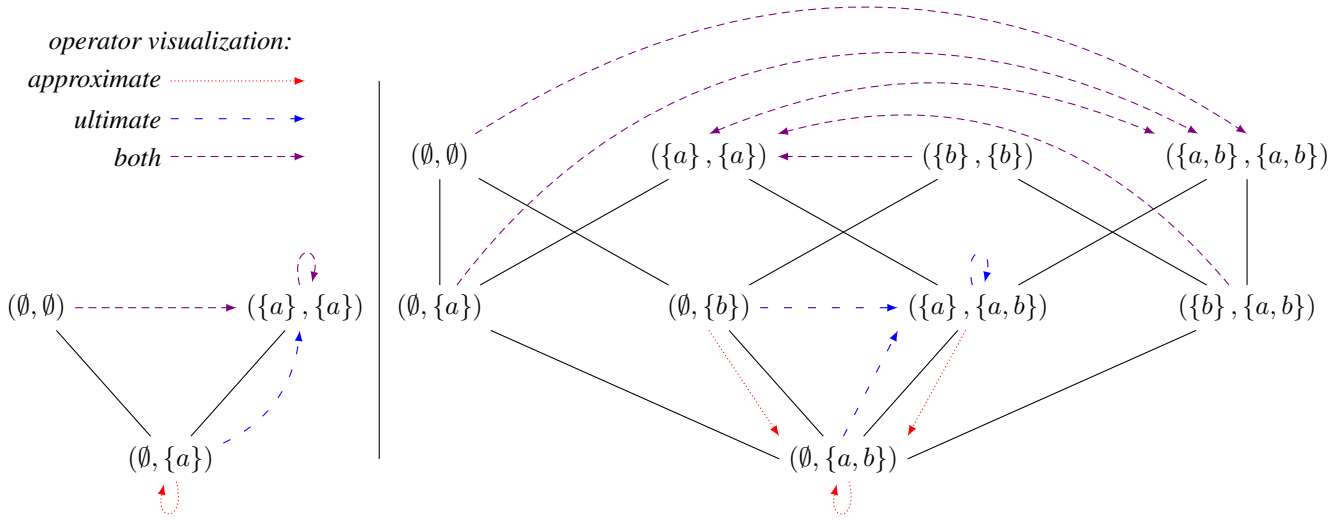

Figure 1: Hasse diagrams of consistent CPOs for the ADFs from Example 1 (left) and Example 2 (right). Solid lines represent the information ordering $\leq_i$. Directed arrows express how revision operators map pairs to other pairs. For pairs where the revisions coincide, the arrows are densely dashed and violet. When the operators revise a pair differently, we use a dotted red arrow for the ultimate and a loosely dashed blue arrow for the approximate operator. Exact (two-valued) pairs are the $\leq_i$-maximal elements. For those pairs, (and any ADF Ξ) it is clear that the operators $\mathcal{U}_\Xi$ and $\mathcal{G}_\Xi$ coincide since they approximate the same two-valued operator G_Ξ. In Example 1 on the left, we can see that the ultimate operator maps all pairs to its only fixpoint $(\{a\},\{a\})$ where a is true. The approximate operator has an additional fixpoint, $(\emptyset,\{a\})$, where a is unknown. In Example 2 on the right, the major difference between the operators is whether statement a can be derived given that b has truth value unknown. This is the case for the ultimate, but not for the approximate operator. Since there is no fixpoint in the upper row (showing the two-valued operator G_E), the ADF E does not have a two-valued model. Each of the revision operators has however exactly one three-valued fixpoint, which thus constitutes the respective grounded, preferred and complete semantics.

This directly shows the equivalence of the respective decision problems, that is, $\mathsf{Exists}^{\mathcal{O}}_{\mathsf{adm}} = \mathsf{Exists}^{\mathcal{O}}_{\mathsf{pre}} = \mathsf{Exists}^{\mathcal{O}}_{\mathsf{com}}$.

Regarding decision problems for querying, skeptical reasoning w.r.t. admissibility is trivial, i.e. $(\emptyset, S)$ is always an admissible pair in any ADF. Further credulous reasoning w.r.t. admissibility, complete and preferred semantics coincides.

Lemma 7. *Let Ξ be an ADF, $\mathcal{O} \in \{\mathcal{G}_\Xi, \mathcal{U}_\Xi\}$ and $s \in S$. Then $\mathsf{Cred}^{\mathcal{O}}_{\mathsf{adm}}(s)$ iff $\mathsf{Cred}^{\mathcal{O}}_{\mathsf{com}}(s)$ iff $\mathsf{Cred}^{\mathcal{O}}_{\mathsf{pre}}(s)$.*

Proof. Assume (X, Y) with $s \in X$ is admissible w.r.t. $\mathcal{O}$, then there exists a (X', Y') with $(X, Y) \leq_i (X', Y')$ which is preferred with respect to $\mathcal{O}$ and where $s \in X'$, see proof of Lemma 6. Since any preferred pair is also complete and any complete pair is also admissible the claim follows. □

Generic upper bounds

We now show generic upper bounds for the computational complexity of the considered problems. This kind of analysis is in the spirit of the results of Dimopoulos, Nebel and Toni (2002) (Section 4). The first item is furthermore a straightforward generalization of Theorem 6.13 in (Denecker, Marek, and Truszczyński 2004).

Theorem 8. *Let S be a finite set, define $A = 2^S$ and let $\mathcal{O}$ be an approximating operator on $(A^c, \leq_i)$, the consistent CPO of S-subset pairs. For a pair $(X, Y) \in A^c$ and an $s \in S$, let the problem of deciding whether $s \in \mathcal{O}'(X, Y)$ be in Π^P_i; let the problem of deciding $s \in \mathcal{O}''(X, Y)$ be in Σ^P_i. For $(X, Y) \in A^c$ and a statement $s \in S$, we have:*

1. *The least fixpoint of $\mathcal{O}$ can be computed in polynomial time with a polynomial number of calls to a Σ^P_i-oracle.*
2. *$\mathsf{Ver}^{\mathcal{O}}_{\mathsf{adm}}(X, Y)$ is in Π^P_i; $\mathsf{Cred}^{\mathcal{O}}_{\mathsf{adm}}(s)$ is in Σ^P_{i+1};*
3. *$\mathsf{Ver}^{\mathcal{O}}_{\mathsf{com}}(X, Y)$ is in D^P_i; $\mathsf{Cred}^{\mathcal{O}}_{\mathsf{com}}(s)$ is in Σ^P_{i+1};*
4. *$\mathsf{Ver}^{\mathcal{O}}_{\mathsf{pre}}(X, Y)$ is in Π^P_{i+1}; $\mathsf{Cred}^{\mathcal{O}}_{\mathsf{pre}}(s)$ is in Σ^P_{i+1}; $\mathsf{Skept}^{\mathcal{O}}_{\mathsf{pre}}(s)$ is in Π^P_{i+2}.*

Proof. 1. For any $(V, W) \in A^c$ we can use the oracle to compute an application of $\mathcal{O}'$ by simply asking whether $z \in \mathcal{O}'(V, W)$ for each $z \in S$. This means we can compute with a linear number of oracle calls the sets $\mathcal{O}'(V, W)$ and $\mathcal{O}''(V, W)$, thus the pair $\mathcal{O}(V, W)$. Hence we can compute the sequence $(\emptyset, S) \leq_i \mathcal{O}(\emptyset, S) \leq_i \mathcal{O}(\mathcal{O}(\emptyset, S)) \leq_i \ldots$ which converges to the least fixpoint of $\mathcal{O}$ after a linear number of operator applications.

2. We can decide $\mathcal{O}'(X, Y) \subseteq X$ and $Y \subseteq \mathcal{O}''(X, Y)$ in Σ^P_i, $X \subseteq \mathcal{O}'(X, Y)$ and $\mathcal{O}''(X, Y) \subseteq Y$ in Π^P_i; all by combining independent guesses. Then $\mathsf{Ver}^{\mathcal{O}}_{\mathsf{adm}}(X, Y)$ is in Π^P_i. For $\mathsf{Cred}^{\mathcal{O}}_{\mathsf{adm}}(s)$, we guess a pair (X_1, Y_1) with $s \in X_1$ and check if it is admissible.

3. $\mathsf{Ver}^{\mathcal{O}}_{\mathsf{com}}(X, Y)$ is in D^P_i by the same method as for admissibility. $\mathsf{Cred}^{\mathcal{O}}_{\mathsf{com}}(s) = \mathsf{Cred}^{\mathcal{O}}_{\mathsf{adm}}(s)$ by Lemma 7.

4. For $\mathsf{Ver}^{\mathcal{O}}_{\mathsf{pre}}(X,Y)$, consider the co-problem, i.e. deciding whether (X,Y) is not a preferred pair. We first check if (X,Y) is a complete pair, which is in D^P_i. If this holds, we guess an (X_1,Y_1) with $(X,Y) <_i (X_1,Y_1)$ and check if it is complete. $\mathsf{Cred}^{\mathcal{O}}_{\mathsf{pre}}(X,Y)$: coincides with credulous reasoning w.r.t. admissibility, see Lemma 7. $\mathsf{Skept}^{\mathcal{O}}_{\mathsf{pre}}(s)$: Consider the co-problem, i.e. deciding whether there exists a preferred pair (X_1,Y_1) with $X_1 \cap \{a\} = \emptyset$. We guess such a pair (X_1,Y_1) and check if it is preferred. □

Naturally, the capability of solving the functional problem of *computing* the grounded semantics allows us to solve the associated decision problems.

Corollary 9. *Under the assumptions of Theorem 8, the problems* $\mathsf{Ver}^{\mathcal{O}}_{\mathsf{grd}}$ *and* $\mathsf{Exists}^{\mathcal{O}}_{\mathsf{grd}}$ *are in* Δ^P_{i+1}.

Complexity of General ADFs

Due to the coincidence of $\mathcal{G}''_\Xi$ and $\mathcal{U}''_\Xi$, the computational complexities of decision problems that concern only the upper bound operator also coincide. This will save both work and space in the subsequent developments. Additionally, for all containment results (except for the grounded semantics), we can use Theorem 8 and need only show hardness.

Proposition 10. *Let* Ξ *be an ADF,* $X, Y \subseteq S$ *and consider any* $\mathcal{O} \in \{\mathcal{G}_\Xi, \mathcal{U}_\Xi\}$. $\mathsf{Ver}^{\mathcal{O}}_{\mathsf{adm}}(X,Y)$ *is* coNP*-complete.*

Proof. Hardness follows from Proposition 4, item 5. □

Recall that a pair (X,Y) is an approximate/ultimate complete pair iff it is a fixpoint of the corresponding (approximate/ultimate) operator. Given the complexities of operator computation, it is straightforward to show the following.

Proposition 11. *Let* Ξ *be an ADF,* $X \subseteq Y \subseteq S$ *and consider any* $\mathcal{O} \in \{\mathcal{G}_\Xi, \mathcal{U}_\Xi\}$. $\mathsf{Ver}^{\mathcal{O}}_{\mathsf{com}}(X,Y)$ *is* DP*-complete.*

Next, we analyze the complexity of verifying that a given pair is the approximate (ultimate) Kripke-Kleene semantics of an ADF Ξ, that is, the least fixpoint of $\mathcal{G}_\Xi$ ($\mathcal{U}_\Xi$). Although interesting, the proof is lengthy and technical, so we unfortunately have to omit it due to space constraints. Interestingly, the membership part is the tricky one, where we encode the steps of the operator computation into propositional logic.

Theorem 12. *Let* Ξ *be an ADF,* $X \subseteq Y \subseteq S$ *and consider any operator* $\mathcal{O} \in \{\mathcal{G}_\Xi, \mathcal{U}_\Xi\}$. $\mathsf{Ver}^{\mathcal{O}}_{\mathsf{grd}}(X,Y)$ *is* DP*-complete.*

We next ask whether there exists a *non-trivial* admissible pair, that is, if at least one statement has a truth value other than unknown. Clearly, we can guess a pair and perform the coNP-check to show that it is admissible. The next result shows that this is also the best we can do. Again, the proof is lengthy and technical and we could not include it here.

Theorem 13. *Let* Ξ *be an ADF and consider any operator* $\mathcal{O} \in \{\mathcal{G}_\Xi, \mathcal{U}_\Xi\}$. $\mathsf{Exists}^{\mathcal{O}}_{\mathsf{adm}}$ *is* Σ^P_2*-complete.*

Lemma 6 implies the same complexity for the existence of non-trivial complete and preferred pairs.

Corollary 14. *Let* Ξ *be an ADF,* $\sigma \in \{com, pre\}$ *and consider any operator* $\mathcal{O} \in \{\mathcal{G}_\Xi, \mathcal{U}_\Xi\}$. $\mathsf{Exists}^{\mathcal{O}}_{\sigma}$ *is* Σ^P_2*-complete.*

By corollary to Theorem 12, the existence of a non-trivial grounded pair can be decided in DP by testing whether the trivial pair $(\emptyset, S)$ is (not) a fixpoint of the relevant operator. The following result shows that this bound can be improved. We cannot present the proof here but can say that intuitively, half of the usual subset checks can be left out due to using the trivial pair.

Proposition 15. *Let* Ξ *be an ADF and consider any operator* $\mathcal{O} \in \{\mathcal{G}_\Xi, \mathcal{U}_\Xi\}$. $\mathsf{Exists}^{\mathcal{O}}_{\mathsf{grd}}$ *is* coNP*-complete.*

Using the result for existence of non-trivial admissible pairs, the verification complexity for the preferred semantics is straightforward to obtain, similarly as in the case of AFs (Dimopoulos and Torres 1996).

Proposition 16. *Let* Ξ *be an ADF,* $X \subseteq Y \subseteq S$ *and consider any* $\mathcal{O} \in \{\mathcal{G}_\Xi, \mathcal{U}_\Xi\}$. $\mathsf{Ver}^{\mathcal{O}}_{\mathsf{pre}}(X,Y)$ *is* Π^P_2*-complete.*

Considering query reasoning we now show that on general ADFs credulous reasoning with respect to admissibility is harder than on AFs. By Lemma 7, the same lower bound holds for complete and preferred semantics.

Proposition 17. *Let* Ξ *be an ADF,* $\mathcal{O} \in \{\mathcal{G}_\Xi, \mathcal{U}_\Xi\}$ *be an operator and* $s \in S$. $\mathsf{Cred}^{\mathcal{O}}_{\mathsf{adm}}(s)$ *is* Σ^P_2*-complete.*

For credulous and skeptical reasoning with respect to the grounded semantics, we first observe that the two coincide since there is always a unique grounded pair. Furthermore, a statement s is true in the approximate grounded pair iff s is true in the least fixpoint (of $\mathcal{G}_\Xi$) iff s is true in all fixpoints iff there is no fixpoint where s is unknown or false. This condition can be encoded in propositional logic and leads to the next result. For the ultimate operator we can use results for the verification problem (Brewka et al. 2013, Theorem 6). Briefly put, the problem is in coNP since the NP-hardness comes from verifying that certain arguments are undefined in the ultimate grounded pair, which is not needed for credulous reasoning. For coNP-hardness the proof of (Brewka and Woltran 2010, Proposition 13) can be easily adapted.

Proposition 18. *Let* Ξ *be an ADF,* $\mathcal{O} \in \{\mathcal{G}_\Xi, \mathcal{U}_\Xi\}$, $s \in S$. *Both* $\mathsf{Cred}^{\mathcal{O}}_{\mathsf{grd}}(s)$ *and* $\mathsf{Skept}^{\mathcal{O}}_{\mathsf{grd}}(s)$ *are* coNP*-complete.*

Regarding skeptical reasoning for the remaining semantics we need only show the results for complete and preferred semantics, in all other cases the complexity coincides with credulous reasoning or is trivial. For complete semantics it is easy to see that skeptical reasoning coincides with skeptical reasoning under grounded semantics, since the grounded pair is the $\leq_i$-least complete pair.

Corollary 19. *Let* Ξ *be an ADF,* $\mathcal{O} \in \{\mathcal{G}_\Xi, \mathcal{U}_\Xi\}$ *and* $s \in S$. $\mathsf{Skept}^{\mathcal{O}}_{\mathsf{com}}(s)$ *is* coNP*-complete.*

Similar to reasoning on AFs, we step up one level of the polynomial hierarchy by changing from credulous to skeptical reasoning with respect to preferred semantics, which makes skeptical reasoning under preferred semantics particularly hard. We apply proof ideas by (Dunne and Bench-Capon 2002) to prove Π^P_3-hardness.

Theorem 20. *Let* Ξ *be an ADF,* $\mathcal{O} \in \{\mathcal{G}_\Xi, \mathcal{U}_\Xi\}$ *and* $s \in S$. $\mathsf{Skept}^{\mathcal{O}}_{\mathsf{pre}}(s)$ *is* Π^P_3*-complete.*

Two-valued semantics

The complexity results we have obtained so far might lead the reader to ask why we bother with the approximate operator $\mathcal{G}_\Xi$ at all: the ultimate operator $\mathcal{U}_\Xi$ is at least as precise and for all the semantics considered up to now, it has the same computational costs. We now show that for the verification of two-valued stable models, the operator for the upper bound plays no role and therefore the complexity difference between the lower bound operators for approximate (in P) and ultimate (coNP-hard) semantics comes to bear.

For the ultimate two-valued stable semantics, Brewka et al. (2013) already have some complexity results: model verification is in DP (Proposition 8), and model existence is Σ_2^P-complete (Theorem 9). We will show next that we can do better for the approximate version.

Proposition 21. *Let Ξ be an ADF and $X \subseteq Y \subseteq S$. Verifying that X is the least fixpoint of $\mathcal{G}'_\Xi(\cdot, Y)$ is in* P.

Proof sketch. Roughly, we construct the sequence defined by $X_0 = \emptyset$ and $X_{i+1} = \mathcal{G}'_\Xi(X_i, Y)$ for $i \geq 0$, as long as $X_i \subseteq Y$. By $\leq_i$-monotonicity of $\mathcal{G}_\Xi$, this sequence is monotonically $\subseteq$-increasing and so the procedure terminates after a linear number of steps. We then check if $X_{i+1} = X_i = X$, that is, the right fixpoint was reached. □

In particular, the procedure can decide whether Y is the least fixpoint of $\mathcal{G}'_\Xi(\cdot, Y)$, that is, whether (Y, Y) is a two-valued stable model of $\mathcal{G}_\Xi$. This yields the next result.

Theorem 22. *Let Ξ be an ADF and $X \subseteq S$. 1.* $\mathsf{Ver}^{\mathcal{G}_\Xi}_{\mathsf{2st}}(X, X)$ *is in* P. *2.* $\mathsf{Exists}^{\mathcal{G}_\Xi}_{\mathsf{2st}}$ *is* NP*-complete.*

The hardness direction of the second part is clear since the respective result from stable semantics of abstract argumentation frameworks carries over.

Brewka et al. (2013) showed that $\mathsf{Ver}^{\mathcal{U}_\Xi}_{\mathsf{2st}}$ is in DP (Proposition 8). As one of the most surprising results of this paper, we can improve that upper bound to coNP. The proof is not at all trivial, but basically the operator for the upper bound (contributing the NP part) is not really needed. Using the complexity of the lower revision operator $\mathcal{U}'_\Xi$, we can even show completeness for coNP.

Proposition 23. *Let Ξ be an ADF and $X \subseteq S$.* $\mathsf{Ver}^{\mathcal{U}_\Xi}_{\mathsf{2st}}(X, X)$ *is* coNP*-complete.*

We now turn to the credulous and skeptical reasoning problems for the two-valued semantics. We first recall that a two-valued pair (X, X) is a supported model (or model for short) of an ADF Ξ iff $\mathcal{G}_\Xi(X, X) = (X, X)$. Thus it could equally well be characterized by the two-valued operator by saying that X is a model iff $G_\Xi(X) = X$. Now since $\mathcal{U}_\Xi$ is the ultimate approximation of G_Ξ, also $\mathcal{U}_\Xi(X, X) = (X, X)$ in this case. Rounding up, this recalls that approximate and ultimate two-valued supported models coincide. Hence we get the following results for reasoning with this semantics.

Corollary 24. *Let Ξ be an ADF, $\mathcal{O} \in \{\mathcal{G}_\Xi, \mathcal{U}_\Xi\}$ be an operator and $s \in S$. The problem* $\mathsf{Cred}^{\mathcal{O}}_{\mathsf{2su}}(s)$ *is* NP*-complete;* $\mathsf{Skept}^{\mathcal{O}}_{\mathsf{2su}}(s)$ *is* coNP*-complete.*

For the approximate two-valued stable semantics, the fact that model verification can be decided in polynomial time leads to the next result.

$\mathcal{O}$	$\mathcal{G}_\Xi, \mathcal{U}_\Xi$				$\mathcal{G}_\Xi, \mathcal{U}_\Xi$	$\mathcal{G}_\Xi$	$\mathcal{U}_\Xi$
σ	adm	com	pre	grd	2su	2st	2st
$\mathsf{Ver}^{\mathcal{O}}_\sigma$	coNP-c	DP-c	Π_2^P-c	DP-c	in P		coNP-c
$\mathsf{Exists}^{\mathcal{O}}_\sigma$	Σ_2^P-c	Σ_2^P-c	Σ_2^P-c	coNP-c	NP-c		Σ_2^P-c
$\mathsf{Cred}^{\mathcal{O}}_\sigma$	Σ_2^P-c	Σ_2^P-c	Σ_2^P-c	coNP-c	NP-c		Σ_2^P-c
$\mathsf{Skept}^{\mathcal{O}}_\sigma$	trivial	coNP-c	Π_3^P-c	coNP-c	coNP-c		Π_2^P-c

Table 2: Complexity results for semantics of ADFs.

Corollary 25. *Let Ξ be an ADF and $s \in S$.* $\mathsf{Cred}^{\mathcal{G}_\Xi}_{\mathsf{2st}}(s)$ *is* NP*-complete;* $\mathsf{Skept}^{\mathcal{G}_\Xi}_{\mathsf{2st}}(s)$ *is* coNP*-complete.*

For the ultimate two-valued stable semantics, things are bit more complex. The hardness reduction in the proof of Theorem 9 in (Brewka et al. 2013) makes use of a statement z that is false in any ultimate two-valued stable model. This can be used to show the same hardness for the credulous reasoning problem for this semantics: we introduce a new statement x that behaves just like $\neg z$, then x is true in some model if and only if there exists a model.

Proposition 26. *Let Ξ be an ADF and $s \in S$. The problem* $\mathsf{Cred}^{\mathcal{U}_\Xi}_{\mathsf{2st}}(s)$ *is Σ_2^P-complete.*

A similar argument works for the skeptical reasoning problem: Given a QBF $\forall P \exists Q \psi$, we construct its negation $\exists P \forall Q \neg \psi$, whose associated ADF D has an ultimate two-valued stable model (where z is false) iff $\exists P \forall Q \neg \psi$ is true iff the original QBF $\forall P \exists Q \psi$ is false. Hence $\forall P \exists Q \psi$ is true iff z is true in all ultimate two-valued stable models of D.

Proposition 27. *Let Ξ be an ADF and $s \in S$. The problem* $\mathsf{Skept}^{\mathcal{U}_\Xi}_{\mathsf{2st}}(s)$ *is Π_2^P-complete.*

Complexity of Bipolar ADFs

We first note that since BADFs are a subclass of ADFs, all membership results from the previous section immediately carry over. However, we can show that many problems will in fact become easier. Intuitively, computing the revision operators is now P-easy because the associated satisfiability/tautology problems only have to treat restricted acceptance formulas. In bipolar ADFs, by definition, if in some three-valued pair (X, Y) a statement s is accepted by a revision operator ($s \in \mathcal{O}'(X, Y)$), it will stay so if we set its undecided supporters to true and its undecided attackers to false. Symmetrically, if a statement is rejected by an operator ($s \notin \mathcal{O}''(X, Y)$), it will stay so if we set its undecided supporters to false and its undecided attackers to true. This is the key idea underlying the next result.

Proposition 28. *Let Ξ be a BADF with $L = L^+ \cup L^-$, $\mathcal{O} \in \{\mathcal{G}_\Xi, \mathcal{U}_\Xi\}$, $s \in S$ and $X \subseteq Y \subseteq S$.*

1. *Deciding $s \in \mathcal{O}'(X, Y)$ is in* P.
2. *Deciding $s \in \mathcal{O}''(X, Y)$ is in* P.

Using the generic upper bounds of Theorem 8, it is now straightforward to show membership results for BADFs with known link types.

Corollary 29. *Let Ξ be a BADF with $L = L^+ \cup L^-$, consider any operator $\mathcal{O} \in \{\mathcal{G}_{\Xi}, \mathcal{U}_{\Xi}\}$ and semantics $\sigma \in \{adm, com\}$. For $X \subseteq Y \subseteq S$ and $s \in S$, we find that*

- $\mathsf{Ver}^{\mathcal{O}}_{\sigma}(X, Y)$ *and* $\mathsf{Ver}^{\mathcal{O}}_{\mathsf{grd}}(X, Y)$ *are in* P*;*
- $\mathsf{Ver}^{\mathcal{O}}_{\mathsf{pre}}(X, Y)$ *is in* coNP*;*
- $\mathsf{Exists}^{\mathcal{O}}_{\sigma}$, $\mathsf{Exists}^{\mathcal{O}}_{\mathsf{pre}}$, $\mathsf{Cred}^{\mathcal{O}}_{\sigma}(s)$ *and* $\mathsf{Cred}^{\mathcal{O}}_{\mathsf{pre}}(s)$ *are in* NP*;*
- $\mathsf{Exists}^{\mathcal{O}}_{\mathsf{grd}}$, $\mathsf{Cred}^{\mathcal{O}}_{\mathsf{grd}}(s)$, $\mathsf{Skept}^{\mathcal{O}}_{\mathsf{grd}}(s)$, $\mathsf{Skept}^{\mathcal{O}}_{\mathsf{com}}(s)$ *are in* P*;*
- $\mathsf{Skept}^{\mathcal{O}}_{\mathsf{pre}}(s)$ *is in* Π^P_2*.*

Proof. Membership is due to Theorem 8 and the complexity bounds of the operators in BADFs in Proposition 28, just note that $\Sigma^P_0 = \Pi^P_0 = \mathsf{P}$. $\mathsf{Ver}^{\mathcal{O}}_{\mathsf{grd}}(X, Y)$ is in $\mathsf{P}^{\mathsf{P}} = \mathsf{P}$ by Corollary 9. For the existence of non-trivial pairs we can simply guess and check in polynomial time for admissible pairs and thus also for complete and preferred semantics. □

Hardness results straightforwardly carry over from AFs.

Proposition 30. *Let Ξ be a BADF with $L = L^+ \cup L^-$, consider any operator $\mathcal{O} \in \{\mathcal{G}_{\Xi}, \mathcal{U}_{\Xi}\}$ and semantics $\sigma \in \{adm, com, pre\}$. For $X \subseteq Y \subseteq S$ and $s \in S$:*

- $\mathsf{Ver}^{\mathcal{O}}_{\mathsf{pre}}(X, Y)$ *is* coNP*-hard;*
- $\mathsf{Exists}^{\mathcal{O}}_{\sigma}$ *and* $\mathsf{Cred}^{\mathcal{O}}_{\sigma}(s)$ *are* NP*-hard;*
- $\mathsf{Skept}^{\mathcal{O}}_{\mathsf{pre}}(s)$ *is* Π^P_2*-hard.*

Proof. Hardness results from AFs for these problems carry over to BADFs as for all semantics AFs are a special case of BADFs (Brewka et al. 2013; Strass 2013a). The complexities of the problems on AFs for admissible and preferred semantics are shown by (Dimopoulos and Torres 1996), except for the Π^P_2-completeness result of skeptical preferred semantics, which is shown by (Dunne and Bench-Capon 2002). The complete semantics is studied by (Coste-Marquis, Devred, and Marquis 2005). □

We next show that there is no hope that the existence problems for approximate and ultimate two-valued stable models coincide as there are cases when the semantics differ.

Example 3. Consider the BADF $F = (S, L, C)$ with statements $S = \{a, b, c\}$ and acceptance formulas $\varphi_a = \mathbf{t}$, $\varphi_b = a \vee c$ and $\varphi_c = a \vee b$. The only two-valued supported model is (S, S) where all statements are true. This pair is also an ultimate two-valued stable model, since $\mathcal{U}'_F(\emptyset, S) = \{a\}$, and both $\varphi_b^{(\{a\},S)} = \mathbf{t} \vee c$ and $\varphi_c^{(\{a\},S)} = \mathbf{t} \vee b$ are tautologies, whence $\mathcal{U}'_F(\{a\}, S) = S$. However, (S, S) is not an approximate two-valued stable model: although $\mathcal{G}'_F(\emptyset, S) = \{a\}$, then $\mathcal{G}'_F(\{a\}, S) = \{a\}$ and we thus cannot reconstruct the upper bound S. Thus F has no approximate two-valued stable models.

So approximate and ultimate two-valued stable model semantics are indeed different. However, we can show that the respective existence problems have the same complexity.

Proposition 31. *Let Ξ be a BADF with $L = L^+ \cup L^-$, $\mathcal{O} \in \{\mathcal{G}_{\Xi}, \mathcal{U}_{\Xi}\}$ an operator and semantics $\sigma \in \{2su, 2st\}$. For $X \subseteq S$, $\mathsf{Ver}^{\mathcal{O}}_{\sigma}(X, X)$ is in P; $\mathsf{Exists}^{\mathcal{O}}_{\sigma}$ is NP-complete.*

σ	adm	com	pre	grd	2su	2st
$\mathsf{Ver}^{\mathcal{O}}_{\sigma}$	in P	in P	coNP-c	in P	in P	in P
$\mathsf{Exists}^{\mathcal{O}}_{\sigma}$	NP-c	NP-c	NP-c	in P	NP-c	NP-c
$\mathsf{Cred}^{\mathcal{O}}_{\sigma}$	NP-c	NP-c	NP-c	in P	NP-c	NP-c
$\mathsf{Skept}^{\mathcal{O}}_{\sigma}$	trivial	in P	Π^P_2-c	in P	coNP-c	coNP-c

Table 3: Complexity results for semantics of bipolar Abstract Dialectical Frameworks for $\mathcal{O} \in \{\mathcal{G}_{\Xi}, \mathcal{U}_{\Xi}\}$.

Proof. Membership carries over – for supported models from (Brewka et al. 2013, Proposition 5), for approximate stable models from Theorem 22. For membership for ultimate stable models, we can use Proposition 28 to adapt the decision procedure of Proposition 21. In any case, hardness carries over from AFs (Dimopoulos and Torres 1996). □

For credulous and skeptical reasoning over the two-valued semantics, membership is straightforward and hardness again carries over from argumentation frameworks.

Corollary 32. *Let Ξ be a BADF with $L = L^+ \cup L^-$; consider any operator $\mathcal{O} \in \{\mathcal{G}_{\Xi}, \mathcal{U}_{\Xi}\}$ and semantics $\sigma \in \{2su, 2st\}$. For $s \in S$, $\mathsf{Cred}^{\mathcal{O}}_{\sigma}(s)$ is NP-complete; $\mathsf{Skept}^{\mathcal{O}}_{\sigma}(s)$ is coNP-complete.*

Discussion

In this paper we studied the computational complexity of abstract dialectical frameworks using approximation fixpoint theory. We showed numerous novel results for two families of ADF semantics, the approximate and ultimate semantics, which are themselves inspired by argumentation and AFT. We showed that in most cases the complexity increases by one level of the polynomial hierarchy compared to the corresponding reasoning tasks on AFs. A notable difference between the two families of semantics lies in the stable semantics, where the approximate version is easier than its ultimate counterpart. For the restricted, yet powerful class of bipolar ADFs we proved that for the corresponding reasoning tasks AFs and BADFs have the same complexity, which suggests that many types of relations between arguments can be introduced without increasing the worst-time complexity. On the other hand, our results again emphasize that arbitrary (non-bipolar) ADFs cannot be compiled into equivalent Dung AFs in deterministic polynomial time, unless the polynomial hierarchy collapses to the first level. Under the same assumption, ADFs cannot be implemented directly with methods that are typically applied to AFs, for example answer-set programming (Egly, Gaggl, and Woltran 2010).

Our results lay the foundation for future algorithms and their implementation, for example augmenting the ADF system DIAMOND (Ellmauthaler and Strass 2013) to support also the approximate semantics family, as well as devising efficient methods for the interesting class of BADFs.

For further future work several promising directions are possible. Studying easier fragments of ADFs as well as parameterized complexity analysis can lead to efficient decision

procedures, as is witnessed for AFs (Dvořák et al. 2014; Dvořák, Ordyniak, and Szeider 2012). We also deem it auspicious to use alternative representations of acceptance conditions, for instance by employing techniques from knowledge compilation (Darwiche and Marquis 2002).

A detailed complexity analysis of other useful AF semantics would also reveal further insights, e.g. semi-stable semantics (Caminada, Carnielli, and Dunne 2012), naive-based semantics, such as cf2 (Baroni, Giacomin, and Guida 2005), or a recently proposed extension-based semantics for ADFs (Polberg, Wallner, and Woltran 2013). For semantical analysis, it would be useful to consider principle-based evaluations for ADFs (Baroni and Giacomin 2007). Furthermore it appears natural to compare (ultimate) ADF semantics and ultimate logic programming semantics (Denecker, Marek, and Truszczyński 2004) in approximation fixpoint theory, in particular with respect to computational complexity.

Abstract

First-order model counting emerged recently as a novel reasoning task, at the core of efficient algorithms for probabilistic logics. We present a Skolemization algorithm for model counting problems that eliminates existential quantifiers from a first-order logic theory without changing its weighted model count. For certain subsets of first-order logic, lifted model counters were shown to run in time polynomial in the number of objects in the domain of discourse, where propositional model counters require exponential time. However, these guarantees apply only to Skolem normal form theories (i.e., no existential quantifiers) as the presence of existential quantifiers reduces lifted model counters to propositional ones. Since textbook Skolemization is not sound for model counting, these restrictions precluded efficient model counting for directed models, such as probabilistic logic programs, which rely on existential quantification. Our Skolemization procedure extends the applicability of first-order model counters to these representations. Moreover, it simplifies the design of lifted model counting algorithms.

1 Introduction

Weighted model counting (WMC) is a generalization of model counting (Gomes, Sabharwal, and Selman 2009). In model counting, also known as #SAT, one counts the number of satisfying assignments of a propositional sentence. In WMC, each assignment has an associated weight and the task is to compute the *sum of the weights* of all satisfying assignments. One application of WMC is to probabilistic graphical models. For example, exact inference algorithms for Bayesian networks encode probabilistic inference as a WMC task, which can then be solved by knowledge compilation (Darwiche 2002) or exhaustive DPLL search (Sang, Beame, and Kautz 2005).

WMC also plays an important role in *first-order probabilistic* representations. These became popular in recent years, in statistical relational learning (Getoor and Taskar 2007) and probabilistic logic learning (De Raedt et al. 2008), which are concerned with modeling and learning complex logical and probabilistic interactions between large numbers of objects. Efficient algorithms again reduce exact probabilistic inference to a WMC problem on a propositional knowledge base (Chavira, Darwiche, and Jaeger 2006; Fierens et al. 2011; 2013). Encoding first-order probabilistic models into propositional logic retains a key advantage of the Bayesian network algorithms: WMC naturally exploits determinism and local structure in the probabilistic model (Boutilier et al. 1996; Chavira and Darwiche 2005). A disadvantage is that the high-level first-order structure is lost. Poole (2003) observed that knowing the *symmetries* that are abundant in first-order structure can speed up probabilistic inference. Lifted inference algorithms reason about groups of objects as a whole, similar to the high-level reasoning of first-order resolution. This has lead Van den Broeck et al. (2011) and Gogate and Domingos (2011) to propose *weighted first-order model counting* (WFOMC) as the core reasoning task underlying lifted inference algorithms. WFOMC assigns a weight to interpretations in finite-domain, function-free first-order logic, and computes the sum of the weights of all models.

Counting models at the first-order level has computational advantages. For certain classes of theories, knowing the first-order structure gives exponential speedups (Van den Broeck 2011). For example, counting the models of a first-order universally quantified CNF with up to two logical variables per clause can always be done in time polynomial in the size of the domain of discourse. In contrast, a propositionalization of these CNFs will often have a treewidth polynomial in the domains size, and propositional model counting runs in exponential time.

One major limitation of first-order model counters, however, is that they require input in *Skolem normal form* (i.e., without existential quantifiers). This is a common requirement for first-order automated reasoning algorithms, such as theorem provers. It is usually dealt with by Skolemization, which introduces Skolem constants and functions. However, the introduction of functions is problematic for first-order model counters as they expect a function-free input.

The main contribution of this paper is a *Skolemization procedure* that is specific for weighted first-order model counting. The procedure maps a logical input theory to an output theory that is devoid of existential quantifiers and functions, yet has an identical weighted first-order model count. The procedure is modular, in that it remains sound when extending the input and output theories with a new

sentence. Furthermore, it is purely first-order as it is independent of the domain of discourse.

The proposed Skolemization algorithm has a range of implications. First, it opens up new possibilities for lifted inference algorithms. For example, on Markov Logic Networks with quantifiers (Richardson and Domingos 2006), and various forms of *Probabilistic Logic Programs* (e.g., De Raedt, Kimmig, and Toivonen (2007)), lifted algorithms currently provide little or no benefit over propositional ones. The main reason is that the WFOMC form of these representations generally contain existential quantifiers. The proposed Skolemization algorithm allows us, for the first time, to perform lifted inference on these representations. Second, there are *liftability theorems* that define classes of theories for which WFOMC is domain-lifted, meaning that it runs in time polynomial in the domain size (Jaeger and Van den Broeck 2012). These theorems had to assume Skolem normal form for the mentioned reason, but now apply more generally. Finally, the Skolemization algorithm averts the need for special inference rules that deal with existential quantifiers, *simplifying the design* of future WFOMC algorithms.

2 Weighted First-Order Model Counting

We start by formally defining the weighted first-order model counting task. We also compare it to propositional weighted model counting and discuss existing algorithms.

Background

Throughout this paper, we will work with the *function-free finite-domain* fragment of first-order logic (FOL), which we now briefly review. An *atom* $\mathtt{P}(t_1, \ldots, t_n)$ consists of predicate $\mathtt{P}/n$ of arity n followed by n arguments, which are either *constants* from a finite domain $\mathbf{D} = \{\mathsf{A}, \mathsf{B}, \ldots\}$ or *logical variables* $\{x, y, \ldots\}$. We use $\mathbf{y}$ to denote a sequence of logical variables. A *literal* is an atom or its negation. A *formula* combines atoms with logical connectives and quantifiers $\exists$ and $\forall$. A logical variable x is *quantified* if it is enclosed by a $\forall x$ or $\exists x$. A *free variable* is one that is not quantified. A *sentence* is a formula without free variables. A formula is *ground* if it contains no logical variables. A *clause* is a disjunction of literals and a *CNF* is a conjunction of clauses. The *groundings* of a quantifier-free formula is the set of formulas obtained by instantiating the free variables with any possible combination of constants from $\mathbf{D}$. The grounding of $\forall x, \phi$ and $\exists x, \phi$ is the conjunction resp. disjunction of all groundings of ϕ.

We will make use of *Herbrand semantics* (Hinrichs and Genesereth 2006), as is customary in statistical relational learning and probabilistic logic learning. The *Herbrand base* of sentence Δ for domain $\mathbf{D}$ is the set of all ground atoms that can be constructed from predicates and constants in $\mathbf{D}$. A *Herbrand interpretation* is a truth-value assignment to all atoms in the Herbrand base. We will find it convenient to represent interpretations as sets of literals. A Herbrand model of Δ is a Herbrand interpretation ω that satisfies Δ, denoted by $\omega \models_{\mathbf{D}} \Delta$.

Definitions

We first review propositional weighted model counting.

Definition 1 (WMC). Given
- a *sentence* Δ in propositional logic over literals $\mathcal{L}$, and
- a *weight function* $\mathrm{w} : \mathcal{L} \to \mathbb{R}^{\geq 0}$,

the *weighted model count* (WMC) is

$$\mathrm{WMC}(\Delta, \mathrm{w}) = \sum_{\omega \models \Delta} \prod_{l \in \omega} \mathrm{w}(l).$$

WFOMC lifts WMC to the first-order level as follows.

Definition 2 (WFOMC[1]). Given
- a *sentence* Δ in FOL containing predicates $\mathcal{P}$,
- a set of constants $\mathbf{D}$, including the constants in Δ, and
- a pair of *weight functions* $\mathrm{w}, \bar{\mathrm{w}} : \mathcal{P} \to \mathbb{R}$,

the *weighted first-order model count* (WFOMC) is

$$\mathrm{WFOMC}(\Delta, \mathbf{D}, \mathrm{w}, \bar{\mathrm{w}}) = \sum_{\omega \models_{\mathbf{D}} \Delta} \prod_{l \in \omega_0} \bar{\mathrm{w}}(\mathrm{pred}(l)) \prod_{l \in \omega_1} \mathrm{w}(\mathrm{pred}(l)),$$

where ω_0 and ω_1 consists of the true, respectively false, literals in ω, and pred maps literals to their predicate.

The weight functions assign a weight to each predicate. The weight of a positive (negative) literal is the weight of its predicate in w ($\bar{\mathrm{w}}$). The weight of a model is the product of its literal weights. Finally, the total count is the sum of the weights of all the Herbrand models of Δ.

Our WFOMC definition deviates from WMC in two ways. First, WMC directly assigns weights to *literals*. WFOMC instead assigns weights to *predicates*, and defines literal weights in terms of predicate weights. This distinguishes WFOMC from probabilistic databases (see Section 6). If for modeling reasons, certain literals need to be assigned unique weights, this can always be achieved by introducing new predicates.

Second, our definition permits predicate weights to be *negative* numbers. Negative weights will turn out to be crucial for our Skolemization algorithm. Historically, the WMC weight function has mostly been used to represent probabilities. This led to the (sometimes implicit) assumption that weights are between zero and one, or at least non-negative. Nevertheless, all exact weighted model counters we are aware of can handle negative weights.[2] It appears that the positive weight assumption is more intrinsic to approximate weighted model counters (Wei and Selman 2005; Gogate and Dechter 2011). Section 6 discusses negative weights in more detail.

Motivation

A WFOMC problem can always be propositionalized into a WMC problem. We can ground Δ for $\mathbf{D}$, turn every atom

[1] This definition is based on Van den Broeck et al. (2011). WFOMC is called *Lifted WMC* in Gogate and Domingos (2011).

[2] In fact, the only underlying requirement of exact model counting approaches is that literal weights are elements from a *commutative semiring* (Kimmig, Van den Broeck, and De Raedt 2012).

in the Herbrand base into a propositional atom, and associate with every propositional literal the weight of its original predicate. One may wonder why we define this task at the first-order level.

Our motivation is computational. Similar to how a single step of first-order resolution can perform a large number of propositional resolution steps, a WFOMC solver can often provide exponential speedups over WMC solvers. First-order quantifiers make statements about groups of symmetric objects, which we can reason about jointly.

Without going into algorithmic details, we will now illustrate this principle on concrete examples. For the sake of simplicity, the examples are non-weighted model counting problems, corresponding to WFOMC problems where $\mathrm{w}(\mathtt{P}) = \bar{\mathrm{w}}(\mathtt{P}) = 1$ for all predicates $\mathtt{P}$. Consider Δ to be

$$\mathtt{Stress}(\mathsf{A}) \Rightarrow \mathtt{Smokes}(\mathsf{A}). \tag{1}$$

Assuming that $\mathbf{D} = \{\mathsf{A}\}$, every interpretation of $\mathtt{Stress}(\mathsf{A})$ and $\mathtt{Smokes}(\mathsf{A})$ satisfies Δ, except when $\mathtt{Stress}(\mathsf{A})$ is true and $\mathtt{Smokes}(\mathsf{A})$ is false. Therefore, the model count is 3. Now let Δ be

$$\forall x,\ \mathtt{Stress}(x) \Rightarrow \mathtt{Smokes}(x). \tag{2}$$

Without changing $\mathbf{D}$, the model count is still 3. When we expand $\mathbf{D}$ to contain n constants, we get n independent copies of Formula 1. For each person x, atoms $\mathtt{Stress}(x)$ and $\mathtt{Smokes}(x)$ can jointly take 3 values, and the total model count becomes 3^n.

This example already demonstrates the benefits of first-order counting. A *propositional* model counter on the groundings of Formula 2 would detect that all n clauses are independent, recompute for every clause that it has 3 models, and multiply these counts n times. Propositional model counters have no elementary operation for exponentiation. A *first-order* model counter reads from the first-order structure that it suffices to compute the model count of a single ground clause, and then knows to exponentiate. It never actually grounds the formula, and given the size of $\mathbf{D}$, it runs in logarithmic time. This gives an exponential speedup over propositional counting, which runs in linear time.

These first-order counting techniques can interplay with propositional ones. Take for example Δ to be

$$\forall y,\ \mathtt{ParentOf}(y) \wedge \mathtt{Female} \Rightarrow \mathtt{MotherOf}(y). \tag{3}$$

This sentence is about a specific individual who may be a female, depending on whether the proposition $\mathtt{Female}$ is true. We can separately count the models in which $\mathtt{Female}$ is true, and those in which it is false (i.e., a Shannon decomposition). When $\mathtt{Female}$ is false, Δ is satisfied, and the $\mathtt{ParentOf}$ and $\mathtt{MotherOf}$ atoms can take on any value. This gives 4^n models. When $\mathtt{Female}$ is true, Δ is structurally identical to Formula 2, and has 3^n models. The total model count is then $3^n + 4^n$.

These concepts can be applied recursively to count more complicated formulas. Take for example

$$\forall x, \forall y,\ \mathtt{ParentOf}(x, y) \wedge \mathtt{Female}(x) \Rightarrow \mathtt{MotherOf}(x, y).$$

There is now a partition of the ground clauses into n independent sets of n clauses. The sets correspond to values of x, and the individual clauses to values of y. The formula for each specific x, that is, each set of clauses, is structurally identical to Formula 3 and has count of $3^n + 4^n$. The total model count is then $(3^n + 4^n)^n$.

The most impressive improvements are attained when propositional model counters run in time *exponential* in n, yet first-order model counters run in *polynomial* time. To consider an example where this comes up, let Δ be

$$\forall x, \forall y,\ \mathtt{Smokes}(x) \wedge \mathtt{Friends}(x, y) \Rightarrow \mathtt{Smokes}(y). \tag{4}$$

This time, the clauses in the grounding of Δ are no longer independent, and it would be wrong to simply exponentiate their counts. Let us first assume that we know a partial interpretation of the $\mathtt{Smokes}$ atoms with k positive literals (i.e., k people smoke). The question is now: how many models extend this partial interpretation? Formula 4 encodes that a smoker cannot be friends with a non smoker. Hence, out of n^2 $\mathtt{Friends}$ atoms, $k(n-k)$ have to be false, and the others can take either truth value. Thus, the number of models is $2^{n^2-k(n-k)}$. Second, we know that there are $\binom{n}{k}$ partial interpretations with k smokers, and k can range from 0 to n. This results in the total model count of

$$\sum_{k=0}^{n} \binom{n}{k} 2^{n^2-k(n-k)}.$$

In fact, the systems discussed in the next section can automatically construct this formula and compute the model count of Formula 4 in time polynomial in n. On the other hand, existing propositional WMC algorithms require time that is exponential in n on this problem. We note here that the *treewidth* of the grounding of Δ is linear in n.

There are space considerations that motivate first-order model counting as well. When converting a WFOMC problem to WMC, the grounding of Δ has size polynomial in the size of $\mathbf{D}$, but the degree of this polynomial can be high. When the grounding does not fit into memory, even approximate WMC becomes a problem.

Algorithms

Several algorithms exist for solving propositional WMC. Exact solvers are based on either exhaustive DPLL search (Sang, Beame, and Kautz 2005), or knowledge compilation to a circuit language that supports efficient model counting, such as `d-DNNF` (Darwiche 2002; Chavira and Darwiche 2008) or `SDD` (Choi, Kisa, and Darwiche 2013). Approximate WMC algorithms use local search (Wei and Selman 2005) or sampling (Gogate and Dechter 2011).

More recently, algorithms were introduced that directly solve the WFOMC task. They take a WFOMC problem and automatically generate and evaluate the types of expressions shown in the previous section. Their elementary operations include exponentiation, summation and binomial coefficients. They are called *lifted inference* algorithms. In particular, two lifted algorithms were proposed for *exact* WFOMC, one based on first-order knowledge compilation (Van den Broeck et al. 2011; Van den Broeck 2011; Van den Broeck 2013), and the other based on first-order DPLL search (Gogate and Domingos 2011). Approximate

algorithms were also proposed, including lifted importance sampling (Gogate and Domingos 2011; Gogate, Jha, and Venugopal 2012). More generally, there is a large literature on exact and approximate *lifted probabilistic inference* in statistical relational models, which can be adapted to solve certain WFOMC tasks. See Kersting (2012) for an overview.

Normal Forms

It is common for logical reasoning algorithms to operate on *normal form* representations instead of arbitrary sentences. For example, propositional SAT solvers and weighted model counters often expect CNF inputs. We distinguish the following first-order normal forms.

- A theory in *prenex normal form* consists of formulas $Q_1 x_1, \ldots, Q_n x_n,\ \phi$, where each Q_i is either a universal or existential quantifier, and ϕ is quantifier-free.
- A theory in *prenex clausal form* is a theory in prenex normal form where ϕ is a clause.
- A theory in *Skolem normal form* is a theory in prenex normal form where all Q_i are universal quantifiers.
- A *first-order CNF* is a theory in Skolem and prenex clausal form. Thus, all sentences take the form $\forall x_1, \ldots, \forall x_n,\ l_1 \vee \cdots \vee l_m$.

Existing WFOMC algorithms require a theory to be in *first-order CNF*. The same requirement is often posed by automated theorem provers, such as first-order resolution.

3 Skolemization for WFOMC

It is well known that one can take any arbitrary formula and convert it to prenex clausal form. This involves pushing negations inside, pushing quantifiers to the front, and distributing disjunctions over conjunctions. The situation for Skolem normal form is different.

Motivation

Not every formula can be transformed into an equivalent Skolem normal form. This problem is typically dealt with by *Skolemization*, which eliminates existential quantifiers from a prenex normal form. This is done by replacing existentially quantified variables by Skolem constants and functions. The result is not logically equivalent to the original formula, but only *equisatisfiable* (i.e., satisfiable precisely when the original formula is satisfiable).

The standard Skolemization algorithm is specific to the satisfiability task and may be unsuitable for other tasks. It is particularly unsuitable for WFOMC as it may produce a result with functions, which are not permitted in the WFOMC task. For example, standard Skolemization would transform the formula

$$\forall x, \exists y,\ \texttt{WorksFor}(x, y) \vee \texttt{Boss}(x) \tag{5}$$

into the following formula with the Skolem function $\mathsf{Sk}()$.

$$\forall x,\ \texttt{WorksFor}(x, \mathsf{Sk}(x)) \vee \texttt{Boss}(x).$$

As soon as we allow functions, the Herbrand base becomes infinite, which makes the model counting task ill-defined, therefore, ruling out standard Skolemization for WFOMC.[3]

Algorithm

This section introduces a Skolemization technique for WFOMC. It takes as input a triple $(\Delta, \mathrm{w}, \bar{\mathrm{w}})$ whose Δ is an arbitrary sentence and returns a triple $(\Delta', \mathrm{w}', \bar{\mathrm{w}}')$ whose Δ' is in Skolem normal form (i.e., no existential quantifiers). Such a Δ' can then be turned into first-order CNF using standard transformations. The proposed technique does not introduce functions. It satisfies two properties, one is essential and the other expands the applications of the technique.

The essential property is soundness.

Property 1 (Soundness). *Skolemization of* $(\Delta, \mathrm{w}, \bar{\mathrm{w}})$ *to* $(\Delta', \mathrm{w}', \bar{\mathrm{w}}')$ *is sound iff for any* $\mathbf{D}$*, we have that*

$$\mathrm{WFOMC}(\Delta, \mathbf{D}, \mathrm{w}, \bar{\mathrm{w}}) = \mathrm{WFOMC}(\Delta', \mathbf{D}, \mathrm{w}', \bar{\mathrm{w}}').$$

To motivate the second property, we note that one may be interested in queries of the form $\mathrm{WFOMC}(\Delta \wedge \phi, \mathbf{D}, \mathrm{w}, \bar{\mathrm{w}})$, where Δ, w and $\bar{\mathrm{w}}$ are fixed, but where ϕ is changing. For example, we will see in Section 4 that probabilistic inference can be reduced to these types of queries. Therefore, we want to achieve a stronger form of soundness.

Property 2 (Modularity). *Skolemization of* $(\Delta, \mathrm{w}, \bar{\mathrm{w}})$ *to* $(\Delta', \mathrm{w}', \bar{\mathrm{w}}')$ *is modular iff for any* $\mathbf{D}$ *and any sentence* ϕ*,*

$$\mathrm{WFOMC}(\Delta \wedge \phi, \mathbf{D}, \mathrm{w}, \bar{\mathrm{w}}) = \mathrm{WFOMC}(\Delta' \wedge \phi, \mathbf{D}, \mathrm{w}', \bar{\mathrm{w}}').$$

That is, by replacing ϕ, one does not invalidate the Skolemization obtained under a different ϕ.

The proposed Skolemization algorithm eliminates existential quantifiers one by one. Its basic building block is the following transformation.

Definition 3. Suppose that Δ contains a subexpression of the form $\exists x, \phi(x, \mathbf{y})$, where $\phi(x, \mathbf{y})$ is an arbitrary sentence containing the free logical variables x and $\mathbf{y}$. Let n be the number of variables in $\mathbf{y}$. First, we introduce two new predicates: the *Tseitin predicate* $\mathtt{Z}/n$ and the *Skolem predicate* $\mathtt{S}/n$. Second, we replace the expression $\exists x, \phi(x, \mathbf{y})$ in Δ by the atom $\mathtt{Z}(\mathbf{y})$, and append the formulas

$$\begin{aligned} \forall \mathbf{y}, \forall x,\ \mathtt{Z}(\mathbf{y}) \vee \neg\phi(x, \mathbf{y}) \\ \forall \mathbf{y},\ \mathtt{S}(\mathbf{y}) \vee \ \ \mathtt{Z}(\mathbf{y}) \\ \forall \mathbf{y}, \forall x,\ \mathtt{S}(\mathbf{y}) \vee \neg\phi(x, \mathbf{y}). \end{aligned}$$

The functions w' and $\bar{\mathrm{w}}'$ are equal to w and $\bar{\mathrm{w}}$, except that $\mathrm{w}'(\mathtt{Z}) = \bar{\mathrm{w}}'(\mathtt{Z}) = \mathrm{w}'(\mathtt{S}) = 1$ and $\bar{\mathrm{w}}'(\mathtt{S}) = -1$.

In the resulting theory Δ', a single existential quantifier is now eliminated. This building block can eliminate single universal quantifiers as well. When Δ contains a subexpression $\forall x, \phi(x, \mathbf{y})$, we replace it by $\neg\exists x, \neg\phi(x, \mathbf{y})$, whose existential quantifier can be eliminated with Definition 3.

We can now show the following.

[3] One could obtain a Skolem normal form by grounding existential quantifiers, replacing them by large, but finite disjunctions. While this may still permit limited runtime improvements on vacuous formulas, it is for all practical purposes equivalent to reducing the WFOMC problem to a WMC problem. Moreover, that transformation is dependent on the domain and leads to large formulas whose conversion to CNF blows up (e.g., when grounding $\exists x \forall y$).

Theorem 3 (Modularity). *Repeated application of Definition 3 comprises a modular Skolemization algorithm.*

The detailed proof can be found in the appendix.

Intuition

Our Skolemization algorithm implicitly tries to enforce an equivalence between the eliminated subexpression and the Tseitin predicate[4], which is explicitly written as

$$\forall \mathbf{y},\ \mathtt{Z}(\mathbf{y}) \Leftrightarrow [\exists x, \phi(x, \mathbf{y})]\,.$$

This equivalence contains an existential quantifier so it cannot be represented explicitly. Instead, the algorithms enforces a relaxed equivalence, represented by the three formulas in Definition 3. The intuition is that by relaxing the equivalence we introduce additional models to the theory, but for every additional model with weight W, there is exactly one additional model with weight $-W$.[5] The WFOMC therefore stays the same.

The interaction between the three relaxed formulas, the intended equivalence, and the model weights becomes more apparent after a case analysis on $\mathtt{Z}(\mathbf{y})$:

1. When $\mathtt{Z}(\mathbf{y})$ is false, it implies that $\exists x, \phi(x, \mathbf{y})$ is false, which is intended. It also implies that $\mathtt{S}(\mathbf{y})$ is true, which does not change the model count, since we multiply by 1.
2. When $\mathtt{Z}(\mathbf{y})$ is true, it implies that only three states of $\mathtt{S}(\mathbf{y})$ and $\exists x, \phi(x, \mathbf{y})$ are allowed:
   (a) $\exists x, \phi(x, \mathbf{y})$ is true and $\mathtt{S}(\mathbf{y})$ is true. This is again intended, because $\mathtt{Z}(\mathbf{y})$ and $\exists x, \phi(x, \mathbf{y})$ are equivalent.
   (b) $\exists x, \phi(x, \mathbf{y})$ is false and $\mathtt{S}(\mathbf{y})$ is true. This is an unintended state with a positive weight W.
   (c) $\exists x, \phi(x, \mathbf{y})$ is true and $\mathtt{S}(\mathbf{y})$ is false. This is an unintended state with a weight $-W$. The negative weight comes from the fact that $\bar{\mathrm{w}}(\mathtt{S}) = -1$.

The weights of the unintended models cancel each other out.

Examples

We will now illustrate our Skolemization algorithm on concrete examples. Suppose that Δ is Formula 5, that is,

$$\forall x, \exists y,\ \mathtt{WorksFor}(x, y) \vee \mathtt{Boss}(x).$$

We can apply Definition 3 to the subexpression $\exists y,\ \mathtt{WorksFor}(x, y) \vee \mathtt{Boss}(x)$, resulting in a Δ' equal to

$$\begin{aligned}
&\forall x,\ \mathtt{Z}(x)\\
\forall x, \forall y,\ &\mathtt{Z}(x) \vee \neg\left[\mathtt{WorksFor}(x, y) \vee \mathtt{Boss}(x)\right]\\
&\forall x,\ \mathtt{Z}(x) \vee \mathtt{S}(x)\\
\forall x, \forall y,\ &\mathtt{S}(x) \vee \neg\left[\mathtt{WorksFor}(x, y) \vee \mathtt{Boss}(x)\right].
\end{aligned}$$

The first formulas is the original formula with the subexpression substituted by $\mathtt{Z}(x)$.

To get a better insight into the result, we will simplify it using first-order unit propagation (Van den Broeck et al. 2011) while noting that the first formula is a unit clause. The simplified theory is

$$\begin{aligned}
\forall x, \forall y,\ &\mathtt{S}(x) \vee \neg\mathtt{WorksFor}(x, y)\\
\forall x,\ &\mathtt{S}(x) \vee \neg\mathtt{Boss}(x).
\end{aligned}$$

We verify the correctness of this Skolemization as follows.

- When $\mathtt{Boss}(x)$ is true, the formula is satisfied for x, and the models of Δ' are intended, that is, they correspond to models of Δ. Indeed, $\mathtt{S}(x)$ is entailed to be true and the model weights are multiplied by one.
- When $\mathtt{Boss}(x)$ is false and $\mathtt{WorksFor}(x, y)$ is true for at least one y, then $\mathtt{S}(x)$ is entailed to be true. Again these models are intended, because $\exists y,\ \mathtt{WorksFor}(x, y) \vee \mathtt{Boss}(x)$ is now satisfied for x. The model weights are multiplied by one.
- When $\mathtt{Boss}(x)$ is false and $\mathtt{WorksFor}(x, y)$ is false for all y then $\mathtt{S}(x)$ can be either true or false. This is where unintended models appear, once with $\mathtt{S}(x)$ true and once with $\mathtt{S}(x)$ false. Because they have opposing weights, the contributions of these unintended models cancel out.

As a second example, consider Δ to be

$$\forall x, \exists y, \exists \mathtt{z},\ \mathtt{Parents}(x, y, \mathtt{z}) \vee \mathtt{Adam}(x).$$

Skolemization of the inner existential quantifier results in

$$\begin{aligned}
&\forall x, \exists y,\ \mathtt{Z}_1(x, y)\\
\forall x, \forall y, \forall \mathtt{z},\ &\mathtt{Z}_1(x, y) \vee \neg\left[\mathtt{Parents}(x, y, \mathtt{z}) \vee \mathtt{Adam}(x)\right]\\
&\forall x, \forall y,\ \mathtt{Z}_1(x, y) \vee \mathtt{S}_1(x, y)\\
\forall x, \forall y, \forall \mathtt{z},\ &\mathtt{S}_1(x, y) \vee \neg\left[\mathtt{Parents}(x, y, \mathtt{z}) \vee \mathtt{Adam}(x)\right]
\end{aligned}$$

This example shows the need for a Tseitin predicate $\mathtt{Z}_1$. The first sentence still contains an existential quantifier. One more elimination and unit propagation step replaces that sentence by $\forall y, \forall x,\ \mathtt{S}_2(\mathbf{y}) \vee \neg\mathtt{Z}_1(x, y)$ and the result is in Skolem normal form.

Properties

Theorem 3 suggests the repeated application of Definition 3, as long as the sentence contains an existential quantifier, or a universal quantifier not in prenex form. This approach has one caveat: eliminating $\exists x, \phi(x, \mathbf{y})$ adds the expression $\neg\phi(x, \mathbf{y})$ to Δ'. When we eliminate quantifiers from left to right, $\phi(x, \mathbf{y})$ itself can contain quantifiers. This operation will introduce new quantifiers in $\neg\phi(x, \mathbf{y})$ and cause a blow up due to the duplication in the newly added formulas. This can be avoided by eliminating from right to left, that is, from innermost to outermost. We can show the following theorem, whose proof is in the appendix.

Theorem 4 (Termination and Complexity). *Repeated application of Definition 3 will terminate with a sentence in Skolem normal form. Moreover, this can be achieved in time polynomial in the size of* Δ.

The resulting Skolem normal form sentence can subsequently be transformed into first-order CNF. When using Tseitin's transformation (Tseitin 1983), this can even be done in polynomial time.

[4]This equivalence represents a set of propositional Tseitin encodings, in which each $\mathtt{Z}$ atom is a Tseitin variable (Tseitin 1983).

[5]This is not dissimilar to the inclusion-exclusion principle.

In our first example, the Tseitin predicate $\mathtt{Z}$ could be removed from Δ' by unit propagation. The following proposition generalizes that observation.

Proposition 5. *Suppose that we are eliminating a subexpression $\exists x, \phi(x, \mathbf{y})$ from a sentence $\forall \mathbf{y}, \exists \mathbf{x}, \phi(x, \mathbf{y})$ using the procedure of Definition 3. That is, the existential quantifier in this subexpression is only preceded by universal quantifiers. Then, we can avoid adding Tseitin predicate $\mathtt{Z}$ and instead define Δ' to be*

$$\forall \mathbf{y}, \forall x,\ \mathtt{S}(\mathbf{y}) \vee \neg\phi(x, \mathbf{y}).$$

This simplifies the transformation when applicable, in particular when Δ is already in prenex normal form.

4 WFOMC Encodings

We will show in this section how the proposed Skolemization technique can extend the scope of first-order model counters to new situations. We will consider in particular one undirected first-order probabilistic language (Markov Logic) and one directed language (Probabilistic Logic Programs). First-order model counters currently apply to a subset of the first representation, and not to the second representation. With Skolemization, these model counters can now be applied to both. Our treatment is based on providing WFOMC encodings of these representations, to which our Skolemization technique is then applied.[6]

Consider a first-order probabilistic model that induces the distribution $\Pr_{\mathbf{D}}(.)$ for domain $\mathbf{D}$. A *WFOMC encoding* of this model is a triple $(\Delta, \mathrm{w}, \bar{\mathrm{w}})$ which guarantees that for any sentence ϕ (usually a conjunction of literals) and domain $\mathbf{D}$, we have that

$$\Pr_{\mathbf{D}}(\phi) = \frac{\mathrm{WFOMC}(\Delta \wedge \phi, \mathbf{D}, \mathrm{w}, \bar{\mathrm{w}})}{\mathrm{WFOMC}(\Delta, \mathbf{D}, \mathrm{w}, \bar{\mathrm{w}})}.$$

Markov Logic Networks

We will now introduce a WFOMC encoding for *Markov logic networks* (MLN) (Richardson and Domingos 2006).

Representation An MLN is a set of tuples (w, ψ), where w is a real number representing a weight and ψ is a formula in first-order logic. When w is infinite, ψ represents a first-order logic constraint, also called a *hard formula*.

Building further on the example given before, consider the following MLN

$$1.3 \quad \exists y,\ \mathtt{WorksFor}(x, y) \vee \mathtt{Boss}(x). \tag{6}$$

This statement softens the logical sentence we saw earlier. Instead of saying that every person either has a boss, or is a boss, it states that worlds with many employed people are more likely. That is, it is now possible to have a world with unemployed people, but the more unemployed people there are, the lower the probability of that world.

The semantics of a first-order MLN Φ is defined in terms of its *grounding* for a given domain of constants $\mathbf{D}$. The grounding of Φ is the MLN obtained by first grounding all its quantifiers and then replacing each formula in Φ with all its groundings (using the same weight). With the domain $\mathbf{D} = \{\mathsf{A}, \mathsf{B}\}$ (e.g., two people, Alice and Bob), the above first-order MLN represents the following grounding.

$$1.3 \quad \mathtt{WorksFor}(\mathsf{A}, \mathsf{A}) \vee \mathtt{WorksFor}(\mathsf{A}, \mathsf{B}) \vee \mathtt{Boss}(\mathsf{A})$$
$$1.3 \quad \mathtt{WorksFor}(\mathsf{B}, \mathsf{A}) \vee \mathtt{WorksFor}(\mathsf{B}, \mathsf{B}) \vee \mathtt{Boss}(\mathsf{B})$$

This ground MLN contains six different random variables, which correspond to all groundings of atoms $\mathtt{WorksFor}(x, y)$ and $\mathtt{Boss}(x)$. This leads to a distribution over 2^6 possible worlds (i.e., interpretation). The weight of each world is simply the product of all weights e^w, where (w, γ) is a ground MLN formula and γ is satisfied by the world. The weights of worlds that do not satisfy a hard formula are set to zero. The probabilities of worlds are obtained by normalizing their weights.

Encoding a Markov Logic Network

Definition 4. The WFOMC encoding $(\Delta, \mathrm{w}, \bar{\mathrm{w}})$ of an MLN is constructed as follows. For each MLN formula $(w_i, \phi_i(\mathbf{x}_i))$, where $\mathbf{x}_i$ denotes the free logical variables in ϕ_i, we introduce a parameter predicate $\mathtt{P_i}/|\mathbf{x}_i|$. For each MLN formula, Δ contains the sentence $\forall \mathbf{x}_i,\ \mathtt{P_i}(\mathbf{x}_i) \Leftrightarrow \phi_i(\mathbf{x}_i)$. The weight function sets $\mathrm{w}(\mathtt{P_i}) = e^{w_i}$, $\bar{\mathrm{w}}(\mathtt{P_i}) = 1$, and $\mathrm{w}(\mathtt{Q}) = \bar{\mathrm{w}}(\mathtt{Q}) = 1$ for all other predicates $\mathtt{Q}$.

Each $\mathtt{P_i}$ captures the truth value of ϕ_i and carries its weight. Hard formulas can directly be encoded as constraints.

The encoding of Formula 6 has Δ equal to

$$\forall x,\ \mathtt{P}(x) \Leftrightarrow \exists y,\ \mathtt{WorksFor}(x, y) \vee \mathtt{Boss}(x).$$

Its w maps $\mathtt{P}$ to $e^{1.3}$ and all other predicates to 1. Its $\bar{\mathrm{w}}$ maps all predicates to 1.

As discussed in Section 2, WFOMC algorithms require first-order CNF input. Definition 4 will only yield a Δ in Skolem normal form (and thus rewritable into CNF) if the MLN formulas are quantifier-free. Then, the only quantifiers in Δ are the universal ones introduced by the encoding itself. Therefore, Van den Broeck et al. (2011) and Gogate and Domingos (2011) resort to *grounding all quantifiers* in the MLN formulas so as to obtain a CNF. This makes the WFOMC encoding specific to the domain $\mathbf{D}$, and partly removes first-order structure from the problem.

Our discussion is based on Van den Broeck et al. (2011). It is similar to the encoding of Gogate and Domingos (2011), whose parameter predicates have more arguments. While these encodings are specific to MLNs, it is straightforward to generalize them to other undirected languages, such as *parfactor graphs* (Poole 2003).

Applying Skolemization We can now perform WFOMC inference in MLNs with quantifiers. Skolemization and CNF

[6] These encodings are implemented in the WFOMC system: http://dtai.cs.kuleuven.be/wfomc

conversion for the example above results in a Δ' equal to

$$\begin{aligned}
&\forall x,\ \mathtt{P}(x) \vee \neg \mathtt{Z}(x)\\
&\forall x,\ \neg \mathtt{P}(x) \vee \mathtt{Z}(x)\\
\forall x, \forall y,\ &\mathtt{S}(x) \vee \neg \mathtt{WorksFor}(y, x)\\
&\forall x,\ \mathtt{S}(x) \vee \neg \mathtt{Boss}(x)\\
&\forall x,\ \mathtt{S}(x) \vee \mathtt{Z}(x)\\
\forall x, \forall y,\ &\mathtt{Z}(x) \vee \neg \mathtt{WorksFor}(x, y)\\
\forall x, \forall y,\ &\mathtt{Z}(x) \vee \neg \mathtt{Boss}(x)
\end{aligned}$$

This theory can be used for WFOMC inference.

Probabilistic Logic Programs

We now show a WFOMC encoding for a directed first-order probabilistic language. The encoding is explained for the *ProbLog* language (De Raedt, Kimmig, and Toivonen 2007; Fierens et al. 2013).

ProbLog Representation ProbLog extends logic programs with facts that are annotated with probabilities. A ProbLog program Φ is a set of probabilistic facts F and a regular logic program L. A probabilistic fact $p :: a$ consists of a probability p and an atom a. A logic program is a set of rules, with the form `Head :- Body`, where the head is an atom and the body is a conjunction of literals. For example,

$$\begin{aligned}
&0.1 :: \mathtt{Attends}(x).\\
&0.3 :: \mathtt{ToSeries}(x).\\
&\mathtt{Series} \text{ :- } \mathtt{Attends}(x), \mathtt{ToSeries}(x).
\end{aligned}$$

This program expresses that if more people attend a workshop, it more likely turns into a series of workshops.

The semantics of a ProbLog program Φ are defined by a distribution over the *groundings* of the probabilistic facts for a given domain of constants $\mathbf{D}$ (Sato 1995).[7] The probabilistic facts $p_i :: a_i$ induce a set of possible worlds, one for each possible partition of a_i in positive and negative literals. The set of true a_i literals with the logic program L define a well-founded model (Van Gelder, Ross, and Schlipf 1991). The probability of such a model is the product of p_i for all true a_i literals and $1 - p_i$ for all false a_i literals.

For the domain $\mathbf{D} = \{A, B\}$ (two people), the above first-order ProbLog program represents the following grounding:

$$\begin{aligned}
&0.1 :: \mathtt{Attends}(A).\\
&0.1 :: \mathtt{Attends}(B).\\
&0.3 :: \mathtt{ToSeries}(A).\\
&0.3 :: \mathtt{ToSeries}(B).\\
&\mathtt{Series} \text{ :- } \mathtt{Attends}(A), \mathtt{ToSeries}(A).\\
&\mathtt{Series} \text{ :- } \mathtt{Attends}(B), \mathtt{ToSeries}(B).
\end{aligned}$$

This ground ProbLog program contains 4 probabilistic facts which corresponds to 2^4 possible worlds. The weight of, for example, the world in which $\mathtt{Attends}(A)$ and $\mathtt{ToSeries}(A)$ are true would be $0.1 \cdot (1 - 0.1) \cdot 0.3 \cdot (1 - 0.3) = 0.0189$ and the model would be $\{\mathtt{Attends}(A), \mathtt{ToSeries}(A), \mathtt{Series}\}$.

Encoding a ProbLog Program The transformation from a ProbLog program to a first-order logic theory is based on Clark's completion (Clark 1978). This is a transformation from logic programs to first-order logic. For certain classes of programs, called *tight* logic programs (Fages 1994), it is correct, in the sense that every model of the logic program is a model of the completion, and vice versa. Intuitively, for each predicate `P`, the completion contains a single sentence encoding all its rules. These rules have the form $\mathtt{P}(\mathbf{x}) \text{ :- } b_i(\mathbf{x}, \mathbf{y}_i)$, where b_i is a body and $\mathbf{y}_i$ are the variables that appear in the body b_i but not in the head. The sentence encoding these rules in the completion is $\forall \mathbf{x},\ \mathtt{P}(\mathbf{x}) \Leftrightarrow \bigvee_i \exists \mathbf{y}_i,\ b_i(\mathbf{x}, \mathbf{y}_i)$. If the program contains cyclic rules, the completion is not sound, and, it is necessary to first apply a conversion to remove positive loops (Janhunen 2004).

Definition 5. The WFOMC encoding $(\Delta, \mathrm{w}, \bar{\mathrm{w}})$ of a tight ProbLog program has Δ equal to Clark's completion of L. For each probabilistic fact[8] $p :: a$ we set the weight function to $\mathrm{w}(\mathrm{pred}(a)) = p$ and $\bar{\mathrm{w}}(\mathrm{pred}(a)) = 1 - p$.

Again, a Skolem normal form is required to use WFOMC. However, we get this form only when the variables that appear in the body of a rule also appear in the head of a rule. This is not the case for most Prolog programs though. For example, if we apply Definition 5 to the example above, an existential quantifier appears in the sentence:

$$\mathtt{Series} \Leftrightarrow \exists x, \mathtt{Attends}(x) \wedge \mathtt{ToSeries}(x).$$

Furthermore, w maps `Attends` to 0.1 and `ToSeries` to 0.3, and $\bar{\mathrm{w}}$ maps `Attends` to 0.9 and `ToSeries` to 0.7. Both w and $\bar{\mathrm{w}}$ are 1 for all other predicates. This example is not in Skolem normal form and requires Skolemization before it can be processed by WFOMC algorithms.

Applying Skolemization Skolemization followed by CNF conversion gives a Δ' equal to

$$\begin{aligned}
&\mathtt{Series} \vee \neg \mathtt{Z}\\
&\neg \mathtt{Series} \vee \mathtt{Z}\\
\forall x,\ &\mathtt{Z} \vee \neg \mathtt{Attends}(x) \vee \neg \mathtt{ToSeries}(x)\\
&\mathtt{Z} \vee \mathtt{S}\\
\forall x,\ &\mathtt{S} \vee \neg \mathtt{Attends}(x) \vee \neg \mathtt{ToSeries}(x)
\end{aligned}$$

Sentence Δ' is in Skolem normal form and is now processable by WFOMC algorithms.

A simple ProbLog program as the one above is identical to a noisy-or structure (Cozman 2004), popular in Bayesian network modeling. Skolemization thus offers a fundamental method to lift first-order, directed structures, such as the noisy-or, in a generic manner (see also Section 6).

[7] Our treatment assumes a function-free and finite-domain fragment of ProbLog. Starting from classical ProbLog semantics, one can obtain the a finite function-free domain for a given query by exhaustively executing the Prolog program and keeping track of the goals that are called during resolution.

[8] If multiple probabilistic facts are defined for the same predicate, auxiliary predicates need to be introduced.

5 Liftability Implications

In our motivation for introducing first-order model counting, we touched upon the runtime and complexity improvements that can be attained by first-order counting. These complexity improvements have inspired a particular notion of lifted inference, called *domain-lifted* inference, which says that a WFOMC algorithm is lifted when it runs in time polynomial in the size of $\mathbf{D}$ (Van den Broeck 2011).

While this notion of lifted inference may not capture everyone's perception of lifting, it does provide a clear formal framework. In particular, we can now talk about classes of sentences Δ for which an algorithm is domain-lifted. We say that the algorithm is *complete* for those classes. We can also talk about classes of sentences Δ for which there exists, or cannot exist a domain-lifted algorithm. We call the former classes *liftable* (Jaeger and Van den Broeck 2012).

All existing completeness and liftability theorems require that Δ is in first-order CNF. This requirement carries over from the existing WFOMC algorithms. Given our Skolemization algorithm, we can now restate these theorems to apply more generally. For example, the positive liftability result of Van den Broeck (2011) becomes the following

Corollary 6. *Suppose that Δ is a theory of sentences with up to two logical variables, and otherwise arbitrary structure. The complexity of computing the WFOMC of Δ is polynomial in the size of $\mathbf{D}$. That is, this class is domain-liftable.*

Other notions of liftability also include queries ϕ in the complexity analysis, since they are important for lifted probabilistic inference. Based on Van den Broeck and Davis (2012), and Van den Broeck and Darwiche (2013), we can now claim the following.

Corollary 7. *Suppose that Δ is a theory of sentences with up to two logical variables, and otherwise arbitrary structure. The complexity of computing the WFOMC of $\Delta \wedge \phi$ is polynomial in the size of $\mathbf{D}$ and ϕ, provided that ϕ is a conjunction of only unary literals, and binary literals of bounded Boolean rank.*

These WFOMC liftability theorems have direct implications for all languages with a WFOMC encoding. For example, we can now say that MLNs with up to two logical variables per formula are domain-liftable, regardless of the quantifiers used. Previously, this was only true for quantifier-free MLNs. We can now also show that ProbLog programs with up to two logical variables per clause are guaranteed to be liftable. This is the first such liftability result for probabilistic logic programs.

6 Related Work

In the encodings for MLNs and probabilistic logics, the weight functions (indirectly) represent probabilities and are therefore always positive. Our Skolemization algorithm introduces negative weights. This might appear odd when interpreting the weights as negative probabilities. This issue has been discussed before. For example, Feynman (1987) writes *"Negative probabilities allow an abstract calculation which permits freedom to do mathematical calculations in any order simplifying the analysis enormously"*.

The potential of negative probabilities was already observed by Jha and Suciu (2012) for answering queries in probabilistic databases and served as inspiration for our approach. Probabilistic databases (Suciu et al. 2011) are fundamentally a type of first-order probabilistic model. It can be viewed as a special type of weighted model counting problem (Δ, w), where the weight function encodes the probability $w(t)$ with which a tuple t can be found in the database. A query on such a database is typically a union of conjunctive queries (UCQ), which corresponds to a monotone DNF sentence Δ. A noticeable difference with most WMC solvers (and WFOMC) is that the solvers for probabilistic databases expect the theory Δ to be in DNF instead of CNF. Different from WFOMC is that although the query (i.e., Δ) is first-order, the weight function is defined on the propositional level like in WMC. Weights are thus assigned to ground literals (the tuples) whereas for WFOMC weights are assigned to predicates (the tables). This allows WFOMC to exploit more types of symmetries.

Jha and Suciu (2012) propose to extend probabilistic databases with MarkoViews, a representation similar to MLNs, in which each weighted formula is again a UCQ query, that is, a monotone DNF. To compute the probability of a query, they introduce negative tuple probabilities.

The use of negative probabilities has also come up for optimizing calculations for specific structures in probabilistic graphical models like noisy-or (Díez and Galán 2003). This particular case has been translated to the first-order case by Kisynski and Poole (2011) and resulted in an approach to lift noisy-or structures. In Section 4 we showed how the application of Skolemization leads to lifting noisy-or and both methods turn out to output a similar encoding for this particular case. Therefore, the approach followed by Kisynski and Poole (2011) can be considered a special case of the Skolemization algorithm applied to a noisy-or model.

Jaeger (2012) shows a negative liftability proof that uses *relational Skolemization*. Similar to our approach, subexpressions containing an existential quantifier are transformed and relaxed to eliminate the quantifier. Relational Skolemization, however, does not guarantee a correct model count. It rather guarantees that if the weight of a model is non-zero it will also be non-zero in the Skolemized version.

7 Conclusions

In this paper, we introduced a Skolemization procedure that is sound for weighted first-order model counting. It extends the applicability of first-order model counters to encodings which require an existential quantifier such as Markov logic models with quantifiers and probabilistic logic programs. It also extends the class of first-order sentences whose models we can count efficiently.

Appendix

A Proof of Theorem 3

We will now prove the sequence of steps that leads to the removal of an existential quantifier in Δ to obtain Δ', w' and $\bar{\mathrm{w}}'$ while maintaining modularity. To replace the expression $\exists x, \phi(x, \mathbf{y})$ we perform the following steps.

Isolate the Quantifier Introduce a new *Tseitin* predicate $\mathtt{Z}/n$, whose arity n is the number of $\mathbf{y}$ variables. Set $\mathrm{w}'(\mathtt{Z}) = \bar{\mathrm{w}}'(\mathtt{Z}) = 1$ and for all other predicates $\mathtt{P}$, set $\mathrm{w}'(\mathtt{P}) = \mathrm{w}(\mathtt{P})$ and $\bar{\mathrm{w}}'(\mathtt{P}) = \bar{\mathrm{w}}(\mathtt{P})$. Construct Δ' by replacing the expression $\exists x, \phi(x, \mathbf{y})$ in Δ by the atom $\mathtt{Z}(\mathbf{y})$, and appending the equivalence .

In any grounding of Δ, this step performs a Tseitin encoding of all groundings of $\exists x, \phi(x, \mathbf{y})$. The groundings of $\mathtt{Z}(\mathbf{y})$ play the role of Tseitin variables. This step therefore satisfies Property 2.

Split the Equivalence Rewrite equivalence $\forall \mathbf{y},\ \mathtt{Z}(\mathbf{y}) \Leftrightarrow \exists x, \phi(x, \mathbf{y})$ as two implications, $\forall \mathbf{y},\ \mathtt{Z}(\mathbf{y}) \Rightarrow \exists x, \phi(x, \mathbf{y})$ and $\forall \mathbf{y},\ \mathtt{Z}(\mathbf{y}) \Leftarrow \exists x, \phi(x, \mathbf{y})$. In clausal form, these become

$$\forall \mathbf{y}, \exists x,\ \neg \mathtt{Z}(\mathbf{y}) \vee \quad \phi(x, \mathbf{y})$$
$$\forall \mathbf{y}, \forall x,\quad \mathtt{Z}(\mathbf{y}) \vee \neg \phi(x, \mathbf{y}).$$

This step satisfies Property 2 because it is a logical equivalence.

Convert to a Feature Introduce a new *Skolem predicate* predicate $\mathtt{S}/n$. Set $\mathrm{w}(\mathtt{S}) = 1$ and $\bar{\mathrm{w}}(\mathtt{S}) = 0$ and replace the sentence $\forall \mathbf{y}, \exists x,\ \neg \mathtt{Z}(\mathbf{y}) \vee \phi(x, \mathbf{y})$ by

$$\forall \mathbf{y},\ \mathtt{S}(\mathbf{y}) \Leftrightarrow \exists x, \neg \mathtt{Z}(\mathbf{y}) \vee \phi(x, \mathbf{y}).$$

In all models of the resulting theory where $\forall \mathbf{y}, \exists x,\ \neg \mathtt{Z}(\mathbf{y}) \vee \phi(x, \mathbf{y})$ is not satisfied, there will exist a $\mathbf{y}$ for which $\exists x, \neg \mathtt{Z}(\mathbf{y}) \vee \phi(x, \mathbf{y})$ is not satisfied. This will cause at least one $\mathtt{S}(\mathbf{y})$ atom to be false in those models, which means that the weight of those models is multiplied by 0. The weight of all other models remains the same. This step therefore satisfies Property 2.

Convert to an Implication Set $\bar{\mathrm{w}}(\mathtt{S}) = -1$ and turn the equivalence $\forall \mathbf{y},\ \mathtt{S}(\mathbf{y}) \Leftrightarrow \exists x, \neg \mathtt{Z}(\mathbf{y}) \vee \phi(x, \mathbf{y})$ into an implication $\forall \mathbf{y},\ \mathtt{S}(\mathbf{y}) \Leftarrow \exists x, \neg \mathtt{Z}(\mathbf{y}) \vee \phi(x, \mathbf{y})$, which in clausal form becomes

$$\forall \mathbf{y},\ \mathtt{S}(\mathbf{y}) \vee \quad \mathtt{Z}(\mathbf{y})$$
$$\forall \mathbf{y}, \forall x,\ \mathtt{S}(\mathbf{y}) \vee \neg \phi(x, \mathbf{y}).$$

Replacing the equivalence by an implication and changing $\bar{\mathrm{w}}(\mathtt{S})$ to -1 is correct for the following reason. Let $\mathtt{S}(\mathbf{y}) \Leftrightarrow \Sigma(\mathbf{y})$ be the above equivalence which is in Δ, and let Γ represent all other sentences in Δ (i.e., $\Delta \equiv (\Sigma(\mathbf{y}) \Leftrightarrow \mathtt{S}(\mathbf{y})) \wedge \Gamma$). Our goal is now to construct a triple $(\Delta', \mathrm{w}', \bar{\mathrm{w}}')$, where $\Delta' \equiv (\Sigma(\mathbf{y}) \Rightarrow \mathtt{S}(\mathbf{y})) \wedge \Gamma$, such that $\mathrm{WFOMC}(\Delta \wedge \phi, \mathbf{D}, \mathrm{w}, \bar{\mathrm{w}}) = \mathrm{WFOMC}(\Delta' \wedge \phi, \mathbf{D}, \mathrm{w}', \bar{\mathrm{w}}')$ for all domains $\mathbf{D}$ and all sentences ϕ.

Let $\Sigma(\mathtt{A})$ and $\mathtt{S}(\mathtt{A})$ be any arbitrary grounding of $\Sigma(\mathbf{y})$ and $\mathtt{S}(\mathbf{y})$. A case analysis on the values of $\Sigma(\mathtt{A})$ and $\mathtt{S}(\mathtt{A})$ shows that $\mathrm{WFOMC}(\Delta \wedge \phi, \mathbf{D}, \mathrm{w}, \bar{\mathrm{w}})$ and $\mathrm{WFOMC}(\Delta' \wedge \phi, \mathbf{D}, \mathrm{w}', \bar{\mathrm{w}}')$ consist of the following terms (for compactness we drop $\mathbf{D}$ from the notation since it doesn't change).

$\Sigma(\mathbf{A})$	$\mathtt{S}(\mathbf{A})$	$\mathrm{WFOMC}(\Delta \wedge \phi, \mathrm{w}, \bar{\mathrm{w}})$
1	1	$\mathrm{w}(\mathtt{S}) \cdot \mathrm{WFOMC}(\Gamma \wedge \Sigma(\mathbf{A}) \wedge \phi, \mathrm{w}, \bar{\mathrm{w}})$
1	0	0
0	1	0
0	0	$\bar{\mathrm{w}}(\mathtt{S}) \cdot \mathrm{WFOMC}(\Gamma \wedge \neg\Sigma(\mathbf{A}) \wedge \phi, \mathrm{w}, \bar{\mathrm{w}})$

$\Sigma(\mathbf{A})$	$\mathtt{S}(\mathbf{A})$	$\mathrm{WFOMC}(\Delta' \wedge \phi, \mathrm{w}', \bar{\mathrm{w}}')$
1	1	$\mathrm{w}'(\mathtt{S}) \cdot \mathrm{WFOMC}(\Gamma \wedge \Sigma(\mathbf{A}) \wedge \phi, \mathrm{w}', \bar{\mathrm{w}}')$
1	0	0
0	1	$\mathrm{w}'(\mathtt{S}) \cdot \mathrm{WFOMC}(\Gamma \wedge \neg\Sigma(\mathbf{A}) \wedge \phi, \mathrm{w}', \bar{\mathrm{w}}')$
0	0	$\bar{\mathrm{w}}'(\mathtt{S}) \cdot \mathrm{WFOMC}(\Gamma \wedge \neg\Sigma(\mathbf{A}) \wedge \phi, \mathrm{w}', \bar{\mathrm{w}}')$

Note that $\bar{\mathrm{w}}(\mathtt{S}) = 0$ in the encoding of Δ, and that thus

$$\begin{aligned}
&\mathrm{WFOMC}(\Delta \wedge \phi, \mathrm{w}, \bar{\mathrm{w}}) = \\
&\quad \mathrm{w}(\mathtt{S}) \cdot \mathrm{WFOMC}(\Gamma \wedge \Sigma(\mathbf{A}) \wedge \phi, \mathrm{w}, \bar{\mathrm{w}}) \\
&\quad + 0 \cdot \mathrm{WFOMC}(\Gamma \wedge \neg\Sigma(\mathbf{A}) \wedge \phi, \mathrm{w}, \bar{\mathrm{w}}) \\
&\mathrm{WFOMC}(\Delta' \wedge \phi, \mathrm{w}', \bar{\mathrm{w}}') = \\
&\quad \mathrm{w}'(\mathtt{S}) \cdot \mathrm{WFOMC}(\Gamma \wedge \Sigma(\mathbf{A}) \wedge \phi, \mathrm{w}', \bar{\mathrm{w}}') \\
&\quad + [\mathrm{w}'(\mathtt{S}) + \bar{\mathrm{w}}'(\mathtt{S})] \\
&\qquad \cdot \mathrm{WFOMC}(\Gamma \wedge \neg\Sigma(\mathbf{A}) \wedge \phi, \mathrm{w}', \bar{\mathrm{w}}')
\end{aligned}$$

Setting $\mathrm{w}'(\mathtt{P}) = \mathrm{w}(\mathtt{P})$ for all predicates $\mathtt{P}$ except for $\mathtt{S}$ ensures that $\mathrm{WFOMC}(\Gamma \wedge \Sigma(\mathbf{A}) \wedge \phi, \mathrm{w}, \bar{\mathrm{w}}) = \mathrm{WFOMC}(\Gamma \wedge \Sigma(\mathbf{A}) \wedge \phi, \mathrm{w}', \bar{\mathrm{w}}')$, that $\mathrm{WFOMC}(\Gamma \wedge \neg\Sigma(\mathbf{A}) \wedge \phi, \mathrm{w}, \bar{\mathrm{w}}) = \mathrm{WFOMC}(\Gamma \wedge \neg\Sigma(\mathbf{A}) \wedge \phi, \mathrm{w}', \bar{\mathrm{w}}')$. Furthermore, set $\mathrm{w}(\mathtt{S}) = \mathrm{w}'(\mathtt{S})$. What remains for $\mathrm{WFOMC}(\Delta \wedge \phi, \mathrm{w}, \bar{\mathrm{w}})$ to equal $\mathrm{WFOMC}(\Delta' \wedge \phi, \mathrm{w}', \bar{\mathrm{w}}')$ is that $\mathrm{w}'(\mathtt{S}) + \bar{\mathrm{w}}'(\mathtt{S}) = \mathrm{w}(\mathtt{S}) + \bar{\mathrm{w}}'(\mathtt{S}) = 0$, which is achieved by setting $\bar{\mathrm{w}}'(\mathtt{S}) = -\mathrm{w}(\mathtt{S}) = -1$.

B Proof of Theorem 4

Proof. We begin by proving termination. Let the *internal quantifier count* of a sentence be the number of quantifiers it contains, excluding the leading universal quantifiers. Suppose that a sentence has an internal quantifier count of m. We can select any subexpression that starts with a quantifier and apply Skolemization to it (potentially converting $\forall$ into $\exists$ first). This reduces the internal quantifier count of Δ to be at most $m - 1$ because at least one quantifier is removed. New sentences are added, however, containing the Tseitin and Skolem predicates, and expressions $\neg\phi(x, \mathbf{y})$. These sentences also have an internal quantifier count of at most $m-1$. Suppose that the sentences in Δ have an internal quantifier count of at most m_{max}. Applying Skolemization to one quantifier in each sentence reduces the maximal internal quantifier count to at most $m_{max} - 1$. Therefore, by repeating this procedure for a finite number of steps, we obtain a theory with an internal quantifier count of zero, which is in Skolem normal form.

Next, we prove polynomial complexity. We can remove the quantifiers in a sentence Δ one by one, starting from the innermost quantifier. The removed subexpression $\phi(x, \mathbf{y})$ does not contain any quantifiers, so the internal quantifier count of the added formulas is zero. They are in Skolem normal form. The innermost subexpression is replaced by a Tseitin predicate, reducing the internal quantifier count by

one. The number of required elimination steps before the entire sentence is in Skolem normal form is thus equal to the number of quantifiers in Δ. Moreover, the number of added formulas, and their size, is polynomial in the size of Δ. □

Abstract

Belief merging aims at defining the beliefs of a group of agents from the beliefs of each member of the group. It is related to more general notions of aggregation from economics (social choice theory). Two main subclasses of belief merging operators exist: majority operators which are related to utilitarianism, and arbitration operators which are related to egalitarianism. Though utilitarian (majority) operators have been extensively studied so far, there is much less work on egalitarian operators. In order to fill the gap, we investigate possible translations in a belief merging framework of some egalitarian properties and concepts coming from social choice theory, such as Sen-Hammond equity, Pigou-Dalton property, median, and Lorenz curves. We study how these properties interact with the standard rationality conditions considered in belief merging. Among other results, we show that the distance-based merging operators satisfying Sen-Hammond equity are mainly those for which $leximax$ is used as the aggregation function.

Introduction

The aim of belief merging is to define a coherent belief base from a set of jointly incoherent belief bases, representing the beliefs of a group of agents. The rationality properties of belief merging operators have been studied in (Revesz 1997; Lin and Mendelzon 1999; Konieczny and Pino Pérez 2002a; Konieczny, Lang, and Marquis 2004; Everaere, Konieczny, and Marquis 2010b). Especially, in (Konieczny and Pino Pérez 2002a), a number of postulates characterizing the so called IC merging operators have been identified. At the same time, many definitions of propositional belief merging operators have been pointed out. Most of these operators are distance-based ones, which means that they can be defined using a distance between interpretations and an aggregation function (Revesz 1997; Lin and Mendelzon 1999; Konieczny, Lang, and Marquis 2004; Everaere, Konieczny, and Marquis 2010a).

Two main subclasses of IC belief merging operators have been defined in (Konieczny and Pino Pérez 2002a): majority operators, which solve conflicts using majority, and arbitration operators, which try to find a consensual result. However, while many distance-based majority merging operators have been defined in the literature, very few arbitration operators have been identified so far. To be more precise, the only arbitration IC merging operators we are aware of are distance-based operators using $leximax$ as aggregation function.

As already discussed in previous merging papers, usual IC merging operators can be used to merge either beliefs or goals. This distinction between belief and goals do not seem to impact any of the usual IC postulates. It is natural to consider egalitarian merging operators when merging goals, if one tries to achieve a "fair" result. This could be important to ensure full adhesion of (autonomous) agents towards the obtained (merged) group goals. As to the belief merging issue, when the aim is to find the correct state of the world, majority methods may seem more appealing. In (Everaere, Konieczny, and Marquis 2010b) we discussed the truth-tracking problem for merging, and we made a distinction between two possible views of belief merging. The one relating to truth-tracking is called the epistemic view, and in this case it is natural to consider only majority operators (this is a consequence of Condorcet Jury Theorem (Everaere, Konieczny, and Marquis 2010b)). But there is a second possible view, called the synthesis view, where the aim is to best represent the opinion of the group (profile). This view has nothing to do with the correct state of the world, the merging process only cares about individual opinions. In this case egalitarian operators prove useful, since they provide in a sense a more robust (i.e. more consensual) view of the opinion of the group than majority operators.

Majority merging operators are closely related to the utilitarian social welfare approaches, where the aim is to determine solutions with the best aggregated utility (Harsanyi 1955; Moulin 1988; Sen 2005). On the other hand, arbitration operators are related to the egalitarian social welfare approaches, where the objective is to find solutions which are as fair as possible; this usually means that they give as much as possible to the poorest agents. To this extent, poverty measures (Rawls 1971; Gini 1921; Sen 1973; Dutta 2002) are relevant to the design of egalitarian approaches.

The aim of this paper is to introduce and study new egal-

Copyright © 2014, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

itarian merging operators, by exhibiting other fairness conditions than arbitration and by pointing out belief merging operators satisfying them. The methodology we follow to reach our goal consists in investigating equity conditions considered in social choice theory (Arrow, Sen, and Suzumura 2002) in order to determine if they can be reasonably imported in the belief merging setting. Thus, in the following, we translate to the belief merging framework two egalitarian conditions coming from social choice theory: Sen-Hammond equity, and Pigou-Dalton property. We show that the distance-based merging operators satisfying Sen-Hammond equity are mainly those for which $leximax$ is used as the aggregation function. We also introduce two new families of belief merging operators, based respectively on the median and on an aggregated sum (Lorenz curves). We identify the rationality properties satisfied by these operators and study in particular their egalitarian behaviour.

The rest of the paper is organized as follows. First we give some preliminaries on propositional belief merging, focusing on IC merging operators and distance-based operators. The egalitarian operators we will define do not satisfy all the usual IC postulates. In fact the usual agregation postulates **(IC5)** and **(IC6)** are not satisfied. So we define a general family of belief merging operators, called pre-IC merging operators; where these Pareto-related conditions are replaced by unanimity conditions. Then we show how Sen-Hammond equity condition, and Pigou-Dalton property can be expressed in the belief merging setting. Then, we define the family of median distance-based merging operators. We show that the operators of this family based on the $leximed^k$ aggregation functions are pre-IC operators, and those for which $k \geq 0.5$ satisfy also the arbitration postulate **(Arb)**, but not the Pigou/Dalton property. Finally we introduce the family of cumulative sum distance-based merging operators; we identify in this family some pre-IC operators, and among them an operator satisfying the Pigou-Dalton property.

On Propositional Belief Merging

We consider a propositional language $\mathcal{L}$ defined from a finite set of propositional variables $\mathcal{P}$ and the usual connectives.

An interpretation (or state of the world) ω is a total function from $\mathcal{P}$ to $\{0,1\}$. Ω is the set of all interpretations. An interpretation is usually denoted by a bit vector whenever a strict total order on $\mathcal{P}$ is specified. An interpretation ω is a model of a formula $\phi \in \mathcal{L}$ if and only if it makes it true in the usual truth functional way. $\models$ and $\equiv$ denote logical entailment and equivalence, respectively. $[\phi]$ denotes the set of models of a formula ϕ, i.e., $[\phi] = \{\omega \in \Omega \mid \omega \models \phi\}$.

A *base* K denotes the set of beliefs of an agent, it is a finite set of propositional formulae, interpreted conjunctively (i.e., viewed as the conjunction of its elements).

A *profile* E denotes a group of n agents that are involved in the merging process; formally E is given by a muti-set $\{K_1, \ldots, K_n\}$ of bases. $\bigwedge E$ denotes the conjunction of all elements of E, and $\sqcup$ denotes the multi-set union. Two multi-sets $E = \{K_1, \ldots, K_n\}$ and $E' = \{K'_1, \ldots, K'_n\}$ are equivalent, noted $E \equiv E'$, iff there exists a permutation π over $\{1, \ldots, n\}$ s.t. for each $i \in 1, \ldots, n$, we have $K_i \equiv K'_{\pi(i)}$.

An *integrity constraint* μ is a formula restricting the possible results of the merging process.

A *merging operator* $\triangle$ is a function which associates with a profile E and an integrity constraint μ a *merged* base $\triangle_\mu(E)$.

The logical properties given in (Konieczny and Pino Pérez 2002a) for characterizing IC belief merging operators are:

Definition 1 *A merging operator $\triangle$ is an* IC merging operator *iff it satisfies the following properties:*

(IC0) $\triangle_\mu(E) \models \mu$
(IC1) *If* $\mu \not\models \bot$ *, then* $\triangle_\mu(E) \not\models \bot$
(IC2) *If* $\bigwedge E \wedge \mu \not\models \bot$, *then* $\triangle_\mu(E) \equiv \bigwedge E \wedge \mu$
(IC3) *If* $E_1 \equiv E_2$ *and* $\mu_1 \equiv \mu_2$, *then* $\triangle_{\mu_1}(E_1) \equiv \triangle_{\mu_2}(E_2)$
(IC4) *If* $K_1 \models \mu$ *and* $K_2 \models \mu$, *then* $\triangle_\mu(\{K_1, K_2\}) \wedge K_1 \not\models \bot$ *if and only if* $\triangle_\mu(\{K_1, K_2\}) \wedge K_2 \not\models \bot$
(IC5) $\triangle_\mu(E_1) \wedge \triangle_\mu(E_2) \models \triangle_\mu(E_1 \sqcup E_2)$
(IC6) *If* $\triangle_\mu(E_1) \wedge \triangle_\mu(E_2) \not\models \bot$, *then* $\triangle_\mu(E_1 \sqcup E_2) \models \triangle_\mu(E_1) \wedge \triangle_\mu(E_2)$
(IC7) $\triangle_{\mu_1}(E) \wedge \mu_2 \models \triangle_{\mu_1 \wedge \mu_2}(E)$
(IC8) *If* $\triangle_{\mu_1}(E) \wedge \mu_2 \not\models \bot$, *then* $\triangle_{\mu_1 \wedge \mu_2}(E) \models \triangle_{\mu_1}(E)$

See (Konieczny and Pino Pérez 2002a) for explanations on these properties. Two subclasses of IC merging operators are also defined in (Konieczny and Pino Pérez 2002a):

Definition 2 *An* IC majority operator *is an IC merging operator which satisfies the following majority property:*

(Maj) $\exists n \ \triangle_\mu (E_1 \sqcup \underbrace{E_2 \sqcup \ldots \sqcup E_2}_{n}) \models \triangle_\mu(E_2)$

An IC arbitration operator *is an IC merging operator which satisfies the following arbitration property:*[1]

(Arb) *If* $\left| \begin{array}{l} \triangle_{\mu_1}(K_1) \equiv \triangle_{\mu_2}(K_2) \\ \triangle_{\mu_1 \leftrightarrow \neg\mu_2}(\{K_1, K_2\}) \equiv (\mu_1 \leftrightarrow \neg\mu_2) \\ \mu_1 \not\models \mu_2 \\ \mu_2 \not\models \mu_1 \end{array} \right.$
then $\triangle_{\mu_1 \vee \mu_2}(\{K_1, K_2\}) \equiv \triangle_{\mu_1}(K_1)$

Majority operators solve conflicts using majority. **(Maj)** says that if one duplicates sufficiently many times a profile E_2, then the result of the merging of E_1 with the E_2 duplications will obey the choices of the profile E_2. Arbitration operators try to find a consensual result. See the corresponding condition 8 in Definition 3 and Example 1 which illustrates how this property gives a preference to consensual ("median") choices of interpretations.

The representation theorems enable to interpret these logical properties as constraints on the choice of interpretations for defining the models of the resulting base:

Definition 3 *A* syncretic assignment *is a function mapping each profile E to a total pre-order $\leq_E$[2] over Ω such that for*

[1] When $E = \{K\}$ we note $\triangle_\mu(K)$ instead of $\triangle_\mu(\{K\})$.

[2] For every pre-order $\leq$, $<$ denotes its strict part and $\simeq$ the corresponding indifference relation. Furthermore, we will use $\leq_K$ as a short for $\leq_{\{K\}}$, and $\leq_\omega$ as a short for any $\leq_{\{K_\omega\}}$ where ω is the unique model of K_ω.

any profiles E, E_1, E_2 and for any bases K, K' the following conditions hold:

1. *If $\omega \models \bigwedge E$ and $\omega' \models \bigwedge E$, then $\omega \simeq_E \omega'$*
2. *If $\omega \models \bigwedge E$ and $\omega' \not\models \bigwedge E$, then $\omega <_E \omega'$*
3. *If $E_1 \equiv E_2$, then $\leq_{E_1} = \leq_{E_2}$*
4. *$\forall \omega \models K \; \exists \omega' \models K' \; \omega' \leq_{\{K,K'\}} \omega$*
5. *If $\omega \leq_{E_1} \omega'$ and $\omega \leq_{E_2} \omega'$, then $\omega \leq_{E_1 \sqcup E_2} \omega'$*
6. *If $\omega <_{E_1} \omega'$ and $\omega \leq_{E_2} \omega'$, then $\omega <_{E_1 \sqcup E_2} \omega'$*

A majority syncretic assignment *is a syncretic assignment which satisfies the following condition:*

7. *If $\omega <_{E_2} \omega'$, then $\exists n \; \omega <_{E_1 \sqcup E_2^n} \omega'$*

A fair syncretic assignment *is a syncretic assignment which satisfies the following condition:*

8. *If $\omega <_{K_1} \omega'$, $\omega <_{K_2} \omega''$, and $\omega' \simeq_{\{K_1,K_2\}} \omega''$, then $\omega <_{\{K_1,K_2\}} \omega'$*

Proposition 1 ((Konieczny and Pino Pérez 2002a)) *A merging operator $\triangle$ is an IC merging operator (resp. an IC majority, an IC arbitration operator) iff there exists a syncretic assignment (resp. a majority syncretic assignment, a fair syncretic assignment) that maps each profile E to a total pre-order $\leq_E$ over Ω such that $[\triangle_\mu(E)] = \min([\mu], \leq_E)$.*

Let us now give some examples of IC merging operators using the family of distance-based merging operators (Konieczny, Lang, and Marquis 2004):

Definition 4 *A* distance[3] *between interpretations is a function $d : \Omega \times \Omega \to \mathbb{R}^+$ such that for any $\omega_1, \omega_2 \in \Omega$:*

- *$d(\omega_1, \omega_2) = d(\omega_2, \omega_1)$*
- *$d(\omega_1, \omega_2) = 0$ iff $\omega_1 = \omega_2$*

Usual distances considered in merging are the Hamming distance d_H: $d_H(\omega_1, \omega_2)$ is the number of propositional letters on which the two interpretations differ (this corresponds to the 1-norm distance, also referred to as the Manhattan distance) and the drastic distance d_D, defined as $d_D(\omega_1, \omega_2) = 0$ if $\omega_1 = \omega_2$, and $= 1$ otherwise (this corresponds to the infinity-norm distance, also known as Chebyshev distance).

Definition 5 *An* aggregation function *is a mapping[4] f from $\mathbb{R}^m$ to $\mathbb{R}$, which satisfies:*

- *if $x_i \geq x'_i$, then* **(non-decreasingness)** *$f(x_1, ..., x_i, ..., x_m) \geq f(x_1, ..., x'_i, ..., x_m)$*
- *$f(x_1, \ldots, x_m) = 0$ if $\forall i, \; x_i = 0$* **(minimality)**
- *$f(x) = x$* **(identity)**
- *If σ is a permutation over $\{1, \ldots, m\}$, then $f(x_1, \ldots, x_m) = f(x_{\sigma(1)}, \ldots, x_{\sigma(m)})$* **(symmetry)**

Some additional properties can be considered for f, especially:

- *if $x_i > x'_i$, then* **(strict non-decreasingness)** *$f(x_1, ..., x_i, ..., x_m) > f(x_1, ..., x'_i, ..., x_m)$*

[3]More exactly pseudo-distances since triangular inequality is not required, but for the sake of simplicity we will abuse words in this way.

[4]Strictly speaking, it is a family of mappings, one for each m.

Definition 6 *Let d and f be respectively a distance between interpretations and an aggregation function. The* distance-based merging operator $\triangle^{d,f}$ *is defined by $[\triangle_\mu^{d,f}(E)] = \min([\mu], \leq_E)$, where the total pre-order $\leq_E$ on Ω is defined in the following way (with $E = \{K_1, \ldots, K_n\}$):*

- *$\omega \leq_E \omega'$ iff $d(\omega, E) \leq d(\omega', E)$*
- *$d(\omega, E) = f(d(\omega, K_1), \ldots, d(\omega, K_n))$*
- *$d(\omega, K) = \min_{\omega' \models K} d(\omega, \omega')$*

For usual aggregation functions, whatever the chosen distance, the corresponding distance-based operators exhibit good logical properties ([(Konieczny and Pino Pérez 2002b; Everaere, Konieczny, and Marquis 2010a)]):

Proposition 2 *For any distance d:*

- *if f is the sum Σ, leximin[5], or Σ^n (the sum of the nth powers), then $\triangle^{d,f}$ is an IC majority operator.*
- *if f is leximax, then $\triangle^{d,f}$ is an IC arbitration operator.*

Pre-IC Operators

We now define a general family of belief merging operators, called pre-IC merging operators, obtained by relaxing the two postulates **(IC5)** and **(IC6)** into two natural conditions used in other aggregation theories contexts.

Definition 7 *A merging operator $\triangle$ is* pre-IC merging operator *iff it satisfies* **(IC0)** *to* **(IC4)**, **(IC7)** *to* **(IC8)** *and the following properties:*

(IC5b) $\triangle_\mu(K_1) \wedge \ldots \wedge \triangle_\mu(K_n) \models \triangle_\mu(\{K_1, \ldots, K_n\})$

(IC6b) *If* $\triangle_\mu(K_1) \wedge \ldots \wedge \triangle_\mu(K_n) \not\models \bot$, *then* $\triangle_\mu(\{K_1, \ldots, K_n\}) \models \triangle_\mu(K_1) \wedge \ldots \wedge \triangle_\mu(K_n)$

Thus, switching from IC operators to pre-IC ones simply consists in replacing the postulates **(IC5)** and **(IC6)** postulates by the weaker postulates **(IC5b)** and **(IC6b)**. Indeed, it is easy to prove that **(IC5b)** (resp. **(IC6b)**) is implied by **(IC5)** (resp. **(IC6)**). As a consequence, we have:

Proposition 3 *Every IC merging operator is a pre-IC merging operator.*

Let us now give a representation theorem suited to the pre-IC family:

Definition 8 *A* pre-syncretic assignment *is a function mapping each profile E to a total pre-order $\leq_E$ over Ω such that for any profiles E, E_1, E_2 and for any bases K, K', the following conditions hold:*

1. *If $\omega \models E$ and $\omega' \models E$ then $\omega \equiv_E \omega'$*

2. *If $\omega \models E$ and $\omega' \not\models E$ then $\omega <_E \omega'$*

3. *If $E_1 \equiv E_2$ then $\leq_{E_1} = \leq_{E_2}$*

4. *$\forall \omega \models K$, $\exists \omega' \models K' \; \omega' \leq_{\{K,K'\}} \omega$*

5b. *If $\forall i \; \omega \leq_{K_i} \omega'$ then $\omega \leq_{\{K_1,\ldots,K_n\}} \omega'$*

6b. *If $\forall i \; \omega \leq_{K_i} \omega'$ and $\exists k \; \omega <_{K_k} \omega'$ then $\omega <_{\{K_1,\ldots,K_n\}} \omega'$*

[5]The leximin (resp. leximax) aggregation function selects the interpretations that are minimal for the lexicographic order, once the distances are sorted into the increasing (resp. decreasing) order.

Conditions 5b and 6b are direct translations of Pareto conditions, which are usual conditions in social choice, multicriteria decision making, etc. So they should be considered as minimal aggregation conditions to be satisfied. Conditions 5 and 6 (Definition 3) are much more demanding, since they constraint all unions of two profiles.

Proposition 4 *A merging operator Δ is a pre-IC merging operator iff there exists a pre-syncretic assignment that maps each profile E to a total pre-order $\leq_E$ over Ω such that*

$$[\Delta_\mu(E)] = min([\mu], \leq_E).$$

Proof: **Only If** Let Δ be a pre-IC merging operator. We associate with it a pre-syncretic assignment as follows: for any profile $E = \{K_1, \ldots, K_n\}$, we define $\leq_E$ by $\omega \leq_E \omega'$ if and only if $\omega \models \Delta_\mu(E)$ where $[\mu] = \{\omega, \omega'\}$. From (Konieczny and Pino Pérez 2002a), we know that $\leq_E$ is a total pre-order; furthermore, as Δ satisfies (IC0-IC4) and (IC7-IC8), conditions 1 to 4 are satisfied by the assignment. We have then only to check that conditions $5b$ and $6b$ are satisfied. Consider two interpretations ω and ω', and let μ be such that $[\mu] = \{\omega, \omega'\}$:

Condition $5b$: suppose that $\forall i \in \{1, \ldots, n\}, \omega \leq_{K_i} \omega'$. Then $\forall i \in \{1, \ldots, n\}$, $\omega \models \Delta_\mu(K_i)$. Stated otherwise, $\omega \models \Delta_\mu(K_1) \wedge \ldots \wedge \Delta_\mu(K_n)$. From (IC5b), we know that $\Delta_\mu(K_1) \wedge \ldots \wedge \Delta_\mu(K_n) \models \Delta_\mu(\{K_1, \ldots, K_n\})$, so $\omega \models \Delta_\mu(\{K_1, \ldots, K_n\})$. Therefore, $\omega \leq_E \omega'$, hence condition $5b$ is satisfied.

Condition $6b$: suppose that $\forall i \in \{1, \ldots, n\}$, $\omega \leq_{K_i} \omega'$ and $\exists k \in \{1, \ldots, n\}$, $\omega <_{K_k} \omega'$. Then $\forall i \in \{1, \ldots, n\}$, $\omega \models \Delta_\mu(K_i)$ and $\omega' \not\models \Delta_\mu(K_k)$. Thus we have $\omega \models \Delta_\mu(K_1) \wedge \ldots \wedge \Delta_\mu(K_n)$ and $\omega' \not\models \Delta_\mu(K_1) \wedge \ldots \wedge \Delta_\mu(K_n)$. Hence $[\Delta_\mu(K_1) \wedge \ldots \wedge \Delta_\mu(K_n)] = \{\omega\}$. From (IC6b), since $\Delta_\mu(K_1) \wedge \ldots \wedge \Delta_\mu(K_n)$ is consistent, it must be the case that $\Delta_\mu(\{K_1, \ldots, K_n\}) \models \Delta_\mu(K_1) \wedge \ldots \wedge \Delta_\mu(K_n)$. Since μ is consistent and Δ satisfies (IC1), $\Delta_\mu(\{K_1, \ldots, K_n\})$ must be consistent as well. As a consequence, we must have $[\Delta_\mu(\{K_1, \ldots, K_n\})] = \{\omega\}$. Therefore, $\omega \models \Delta_\mu(\{K_1, \ldots, K_n\})$ and $\omega' \not\models \Delta_\mu(\{K_1, \ldots, K_n\})$, showing that $\omega <_E \omega'$. Hence condition $6b$ is satisfied.

If Consider a pre-syncretic assignment mapping each belief set E to a total pre-order $\leq_E$ over interpretations. Consider the merging operator Δ defined as follows: $[\Delta_\mu(E)] = min([\mu], \leq_E)$. From (Konieczny and Pino Pérez 2002a), we know that Δ satisfies (IC0-IC4) and (IC7-IC8). Let us now show that Δ satisfies (IC5b-IC6b). Suppose that $\Delta_\mu(K_1) \wedge \ldots \wedge \Delta_\mu(K_n)$ is consistent (if not, (IC5b-IC6b) is trivially satisfied).

(IC5b) let ω be any model of $\Delta_\mu(K_1) \wedge \ldots \wedge \Delta_\mu(K_n)$. So $\forall \omega' \models \mu$, $\omega \leq_{K_i} \omega'$. From condition $5b$, we know that $\forall \omega' \models \mu$, $\omega \leq_{\{K_1, \ldots, K_n\}} \omega'$. Hence by definition of Δ, we have $\omega \models \Delta_\mu(\{K_1, \ldots, K_n\})$. Since this holds for any model ω of $\Delta_\mu(K_1) \wedge \ldots \wedge \Delta_\mu(K_n)$, we conclude that $\Delta_\mu(K_1) \wedge \ldots \wedge \Delta_\mu(K_n) \models \Delta_\mu(\{K_1, \ldots, K_n\})$ and (IC5b) is satisfied.

(IC6b) towards a contradiction, suppose that $\Delta_\mu(\{K_1, \ldots, K_n\}) \not\models \Delta_\mu(K_1) \wedge \ldots \wedge \Delta_\mu(K_n)$. So $\exists \omega$ s.t. $\omega \models \Delta_\mu(\{K_1, \ldots, K_n\})$ and $\omega \not\models \Delta_\mu(K_1) \wedge \ldots \wedge \Delta_\mu(K_n)$. Since $\Delta_\mu(K_1) \wedge \ldots \wedge \Delta_\mu(K_n)$ is consistent, there is an interpretation ω' which is a model of $\Delta_\mu(K_1) \wedge \ldots \wedge \Delta_\mu(K_n)$. Hence $\forall i \in \{1, \ldots, n\}, \omega' \leq_{K_i} \omega$. Since $\omega \not\models \Delta_\mu(K_1) \wedge \ldots \wedge \Delta_\mu(K_n)$, $\exists k \in \{1, \ldots, n\}$ s.t. $\omega \not\models \Delta_\mu(K_k)$, showing that $\omega' <_{K_k} \omega$. From condition $6b$, we conclude that $\omega' <_{\{K_1, \ldots, K_n\}} \omega$. This contradicts the fact that $\omega \models \Delta_\mu(\{K_1, \ldots, K_n\})$. Hence, $\Delta_\mu(\{K_1, \ldots, K_n\}) \models \Delta_\mu(K_1) \wedge \ldots \wedge \Delta_\mu(K_n)$, and (IC6b) is satisfied. □

As one can expect, it is much easier to satisfy the pre-IC merging conditions than IC merging ones. We can for instance show that:

Proposition 5 *If d is any distance and f is any aggregation function satisfying strict non-decreasingness, then the merging operator $\Delta^{d,f}$ is a pre-IC merging operator.*

One can compare this result with a corresponding one about distance-based IC merging operators, reported in (Konieczny, Lang, and Marquis 2004), and showing that the aggregation function f has to satisfy two additional conditions in order to guarantee that the distance-based merging operator given by d and f is an IC merging operator.

Conditions for Egalitarian Merging

The only egalitarian property that has been proposed so far for belief merging is the *arbitration* property, represented by the **(Arb)** postulate (or the corresponding semantic condition 8 on syncretic assignments). So a key issue we would like to address is to determine whether other egalitarian properties are possible in the belief merging framework, and, if so, how they relate with arbitration.

If one looks closely at condition 8 in Definition 3, it is clear that the arbitration property only imposes some constraints on the merging of profiles consisting of two bases. Then the IC properties **(IC5)** and **(IC6)** ensure the propagation of the constraints on profiles of any size.

We now propose a first alternative condition, coming from social choice theory, for characterizing egalitarian behaviour in belief merging. This condition, proposed by Hammond (1976) is known in the literature as the Sen-Hammond equity condition (Sen 1997; Suzumura 1983). This condition can be expressed in the following way:

Definition 9 (Sen97) *If person i is worse off than person j both in x and in y, and if i is better off himself in x than in y, while j is better off in y than in x, and if furthermore all others are just as well off in x as in y, then x is socially at least as good as y.*

It is translated in the belief merging setting as constraints on the total pre-orders associated with the input profiles. These constraints concern profiles of arbitrary size, and not only those consisting of two bases. Before doing it, we first need to define a notion of the respective "satisfaction" of two bases given an interpretation:

Definition 10 *Given a merging operator $\triangle$ defining an assignment which maps every profile E to a total pre-order $\leq_E$ over Ω, given an interpretation ω, and two bases K_1*

and K_2, we say that K_1 is better than K_2 *given ω, denoted $K_1 \prec_\omega K_2$, iff $\exists \omega_1 \models K_1, \forall \omega_2 \models K_2, \omega_1 <_\omega \omega_2$.*

We can now give the translation of the Sen-Hammond Equity (SHe) condition:

Definition 11 (Condition (SHe)) *Let $E = \{K_1, \ldots, K_n\}$.*

$$\left.\begin{array}{l} \omega <_{K_1} \omega' \\ \omega' <_{K_2} \omega \\ \forall i \neq 1,2\ \omega \simeq_{K_i} \omega' \\ K_1 \prec_\omega K_2 \\ K_1 \prec_{\omega'} K_2 \end{array}\right\} \Longrightarrow\ \omega' \leq_E \omega$$

When distance-based merging operators are considered, this condition is equivalent to:

Definition 12 (Condition (SHE))

$$\left.\begin{array}{l} d(\omega, K_1) < d(\omega', K_1) < d(\omega', K_2) < d(\omega, K_2) \\ \forall i \neq 1,2\ d(\omega, K_i) = d(\omega', K_i) \end{array}\right\} \Longrightarrow$$

$$f(d(\omega', K_1), d(\omega', K_2), \ldots, d(\omega', K_n)) \leq$$
$$f(d(\omega, K_1), d(\omega, K_2), \ldots, d(\omega, K_n))$$

Proposition 6 *A distance-based merging operator $\Delta^{d,f}$ satisfies* **(SHE)** *if and only if it satisfies* **(SHe)**.

Proof: We prove the equivalence between **(SHe)** and **(SHE)** by showing that those two implications have equivalent premises and equivalent conclusions.

By definition $K_1 \prec_\omega K_2$ iff $\exists \omega_1 \models K_1, \forall \omega_2 \models K_2, \omega_1 <_\omega \omega_2$. Then $\exists \omega_1 \models K_1, \forall \omega_2 \models K_2$, $d(\omega, \omega_1) < d(\omega, \omega_2)$: $\exists \omega_1 \models K_1$, $d(\omega, \omega_1) < min_{\omega_2 \models K_2} d(\omega, \omega_2) = d(\omega, K_2)$. Hence we have $d(\omega, K_1) < d(\omega, K_2)$.

$\omega <_{K_1} \omega' \Leftrightarrow d(\omega, K_1) < d(\omega', K_1)$
$\omega' <_{K_2} \omega \Leftrightarrow d(\omega', K_2) < d(\omega, K_2)$
$\forall i \neq 1,2\ \omega \simeq_{K_i} \omega' \Leftrightarrow \forall i \neq 1,2\ d(\omega, K_i) = d(\omega', K_i)$
$K_1 \prec_\omega K_2 \Leftrightarrow d(\omega, K_1) < d(\omega, K_2)$
$K_1 \prec_{\omega'} K_2 \Leftrightarrow d(\omega', K_1) < d(\omega', K_2)$

This shows the equivalence of the premises. Now, using transitivity, we get: $d(\omega, K_1) < d(\omega', K_1) < d(\omega', K_2) < d(\omega, K_2)$ and $\forall i \neq 1,2\ \omega \simeq_{K_i} \omega' \Leftrightarrow \forall i \neq 1,2\ d(\omega, K_i) = d(\omega', K_i)$. Hence $\omega' \leq_E \omega \Leftrightarrow f(d(\omega', K_1), d(\omega', K_2), \ldots, d(\omega', K_n)) \leq f(d(\omega, K_1), d(\omega, K_2), \ldots, d(\omega, K_n))$. □

This Sen-Hammond Equity condition expresses the following idea: compare two "situations" ω_1 and ω_2 that are equally good for all the agents except two of them. For these two agents one of them (K_1) is in the two situations better than the other agent (K_2). Then the fairer situation is the one that gives the more to the less satisfied agent (K_2).

This condition looks close to the arbitration condition (compare **(SHe)** with condition 8 of Definition 3), but the two conditions are logically independent. Let us now illustrate on a simple example how they differ:

Example 1 *Consider a propositional language over two variables and a distance-based merging operator $\triangle^{d,f}$. Suppose that the distance d on which $\triangle^{d,f}$ is built is the shortest path distance on the following graph:*

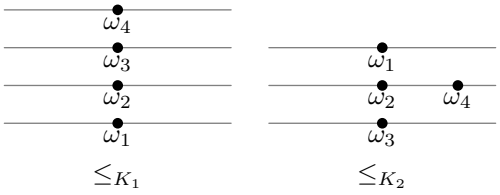

Figure 1: Egalitarian behaviour - (Arb)

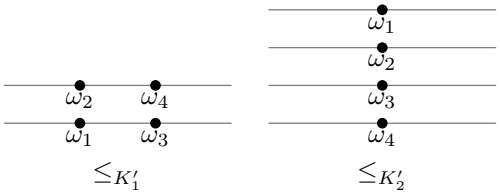

Figure 2: Egalitarian behaviour - (SHE)

$$\omega_1 \overset{1}{\text{——}} \omega_2 \overset{1}{\text{——}} \omega_3 \overset{1}{\text{——}} \omega_4.$$

Figure 1 illustrates the case when the unique model of K_1 is ω_1 and the unique model of K_2 is ω_3. It is clear here that ω_1 and ω_3 play symmetrical roles, so that they cannot be distinguished when K_1 and K_2 are merged. However, on this example, ω_2 appears as a more consensual choice than ω_1 and ω_3 for this merging. Accordingly, **(Arb)** *imposes that ω_2 is strictly preferred to ω_1 and to ω_3 w.r.t. $\leq_{\{K_1,K_2\}}$.*

Suppose now that we want to merge $E' = \{K'_1, K'_2\}$ where $[K'_1]$=$\{\omega_1, \omega_3\}$ and $[K'_2]$ =$\{\omega_4\}$, and that the choice to be made is between ω_1 and ω_2 (i.e., the integrity constraint μ satisfies $[\mu] = \{\omega_1, \omega_2\}$). This is illustrated by Figure 2. **(Arb)** *imposes no constraint on this choice. But clearly, whatever the choice (between $\{\omega_1\}$, $\{\omega_2\}$, or $\{\omega_1, \omega_2\}$), the result will be closer to K'_1 than to K'_2. So a simple equity argument is to commit to the choice that is the best for the furthest base K'_2, so to consider that ω_2 is strictly preferred to ω_1 in $\leq_{E'}$. This is what* **(SHe)** *gives.*

Unfortunately, the family of distance-based IC operators satisfying condition **(SHE)** looks rather limited:

Proposition 7 *Let d be any distance and f be any aggregation function satisfying strict non-decreasingness. The IC merging operator $\Delta^{d,f}$ satisfies condition* **(SHE)** *if and only if $f = leximax$.*

Proof: We know that $\Delta^{d,leximax}$ is an IC operator and that $leximax$ satisfies strict-decreasingness. It is easy to check that $\Delta^{d,leximax}$ satisfies **(SHE)**, so we have mainly to prove the converse implication.

Consider a distance d and an aggregation function f satisfying strict non-decreasingness, and suppose that $\Delta^{d,f}$ satisfies **(SHE)**.

Let $X = (x_1, \ldots, x_n)$ and $X' = (x'_1, \ldots, x'_n)$ be two vectors of distances to a profile E, ordered in the descending way ($\forall i$, $x_i = d(\omega, K_i)$ and $x_i \geq x_{i+1}$; $x'_i = d(\omega', K_i)$ and $x'_i \geq x'_{i+1}$). We have to show that:

$$X <_{leximax} X' \Leftrightarrow f(X) < f(X') \qquad (1)$$

and

$$X \simeq_{leximax} X'^{6} \Leftrightarrow f(X) = f(X') \quad (2)$$

We start with statement (1). Suppose that $X <_{leximax} X'$. We know that $\exists l$ s.t. $\forall i < l, x_i = x'_i$ and $x_l < x'_l$.

Case 1: $l = n$ or $\forall i > l$, $x_i = x'_i$: using strict non-decreasingness we get $f(X) < f(X')$.

Case 2: Suppose that $\exists k > l, x_k \neq x'_k$ and $\forall i \neq k, l, x_i = x'_i$.

- If $x_k \leq x'_k$, then using strict-decreasingness (as $x_l < x'_l$), we get $f(X) < f(X')$.
- If $x_k > x'_k$, then we have $x'_l > x_l \geq x_k > x'_k$. Consider a vector $Y = (y_1, \ldots, y_n)$ s.t. $\forall i \neq k, l$, $y_i = x'_i$ and y_k, y_l such that $x'_l > y_l > y_k > x_l$. As we have $\forall i \neq k, l$, $y_i = x'_i$ and $x'_l > y_l > y_k > x'_k$, because $\Delta^{d,f}$ satisfies **(SHE)**, we can conclude that $f(Y) \leq f(X')$. Furthermore $\forall i \neq k, l$, $y_i = x_i$ and $y_l > y_k > x_l \geq x_k$, using strict decreasingness, we get $f(Y) > f(X)$. By transitivity, we obtain $f(X) < f(X')$.

Case 3: Let us consider now the general case. $\forall i < l, x_i = x'_i$, $x_l < x'_l$ and $l < n$. We define $n - l + 1$ vectors $Y^r = (y^r_1, \ldots, y^r_n)$, for $r = 0$ to $n - l$:

$$y^r_i = \begin{cases} x_i \text{ if } i < l \\ x_l + \frac{r}{n-l}(x'_l - x_l) \text{ if } i = l \\ x_i \text{ if } l+1 \leq i \leq n-r \\ x'_i \text{ if } n-r+1 \leq i \leq n \end{cases}$$

We have $Y^0 = X$ and $Y^{n-l} = X'$, and any two consecutive vectors Y^r and Y^{r+1} differ only on two components, namely y^r_l and y^{r+1}_l on the one hand, and y^r_{n-r} and y^{r+1}_{n-r} on the other hand. Furthermore, $Y^r <_{leximax} Y^{r+1}$, because $\forall i < l, y^r_i = y^{r+1}_i$, $\forall i \leq l, y^r_i \geq y^r_{i+1}$, $\forall i \leq l, y^{r+1}_i \geq y^{r+1}_{i+1}$ and $y^r_l < y^{r+1}_l$. Using Case 2, we can conclude that $f(Y^r) < f(Y^{r+1})$. By transitivity we get $f(Y^0) = f(X) < f(Y^{n-l}) = f(X')$, and the conclusion follows.

Suppose now that $f(X) < f(X')$. If $X \simeq_{leximax} X'$, then $X = X'$ and $f(X) = f(X')$: contradiction. If $X >_{leximax} X'$, then taking advantage of the first part of the proof, we get $f(X) > f(X')$: contradiction. So $X <_{leximax} X'$.

Consider now statement (2).

If $X \simeq_{leximax} X'$, then $X = X'$ and $f(X) = f(X')$.

Suppose now $f(X) = f(X')$. If $X >_{leximax} X'$, then taking advantage of the first part of the proof, we get $f(X) > f(X')$: contradiction. If $X <_{leximax} X'$, then taking advantage of the first part of the proof, we get $f(X) < f(X')$: contradiction. So $X \simeq_{leximax} X'$. □

Let us stress here that the condition of strict non-decreasingness is quite natural and not very demanding. Actually all the aggregation functions giving rise to IC merging operators we are aware of (including Σ, $leximax$, $leximin$, Σ^n, etc.) satisfy non-decreasingness.

Given this proposition, defining other egalitarian distance-based merging operators requires to focus on other equity principles, or to weaken some IC postulates. We explore both ways in the following.

Thus, we first focus on another egalitarian condition from the social choice literature, namely Pigou-Dalton transfer principle (Dalton 1920). The idea underlying it is that every transfer from the most satisfied agent to the least satisfied one decreases the inequalities:

Definition 13 *Let f be an aggregation function. f satisfies* the Pigou-Dalton condition *if for all vectors $X = (x_1, \ldots, x_n)$ and $X' = (x'_1, \ldots, x'_n)$, if $x_1 < x'_1 \leq x'_2 < x_2$ and $x'_1 - x_1 = x_2 - x'_2$ and $\forall i \neq 1, 2$, $x_i = x'_i$ then $f(X) < f(X')$.*

This principle states that if X' can be obtained from X by just making some satisfaction transfer from a well-satisfied agent to a less satisfied one, without changing the fact that the first one is still more satisfied than the second one, then X' is fairer than X.

This principle can be translated as follows for distance-based merging:

Definition 14 (Condition (PD)) *If $\exists k$ and l s.t. $d(\omega, K_k) < d(\omega', K_k) \leq d(\omega', K_l) < d(\omega, K_l)$ and $d(\omega', K_k) - d(\omega, K_k) = d(\omega, K_l) - d(\omega', K_l)$ and $\forall i \neq k$ and $i \neq l, d(\omega, K_i) = d(\omega', K_i)$ then $\omega' <_E \omega$.*

Of course not all distance-based IC operators satisfy the **(PD)** condition. However, it is satisfied by the well-known arbitration operators based on $leximax$:

Proposition 8 *Let d be any distance.*

- $\Delta^{d,leximax}$ *satisfies the* **(PD)** *condition.*
- $\Delta^{d,\Sigma}$ *and* $\Delta^{d,leximin}$ *do not satisfy the* **(PD)** *condition.*

Median Operators

In this section we define a new family of merging operators using generalized median aggregation functions. Interestingly, some operators of this family are pre-IC merging operators and they satisfy **(Arb)**. The idea of using the median value is very motivated by trying to be as fair as possible. Instead of focusing on a unique aggregation function, we study a full family of k-median aggregation functions, inspired by the phantom voters voting rules of (Moulin 1988).

Definition 15 *Let $k \in]0, 1]$ be a real number, the $k-$*median $med^k(\{x_1, \ldots, x_n\})$ *of a multi-set $X = \{x_1, \ldots, x_n\}$ of values from a totally ordered set, is the value $m^k = x_{\sigma(\lceil n*k \rceil)}$ of X, where σ is a permutation of X where the x_i are sorted in ascending order ($\lceil . \rceil$ denotes the ceiling function).*

For $k = 0.5$, the usual notion of median is retrieved.

In many cases these $k-$median functions med^k are not discriminative enough, just like min and max functions. So, we can define k-leximedian operators, noted k-$leximed$, which are to med^k what $leximin$ (resp. $leximax$) is to min (resp. max).

[6] If $X \simeq_{leximax} X'$, then $\forall i, x_i = x'_i$, so $X = X'$.

	K_1	K_2	K_3	distance vector	$med^{0.5}$
000	0	1	1	(0, 1, 1)	1
001	1	0	2	(0, 1, 2)	1
010	1	2	2	(1, 2, 2)	2
011	2	1	3	(1, 2, 3)	2
100	**0**	**2**	**0**	**(0, 0, 2)**	**0**
101	1	1	1	(1, 1, 1)	1
110	1	3	1	(1, 1, 3)	1
111	2	2	2	(2, 2, 2)	2

Table 1: Merging with $\Delta^{d_H, med^{0.5}}$

Definition 16 *Let L_1 and L_2 be two multi-sets consisting of n elements from a totally ordered set:*
$L_1 \leq^k_{leximed} L_2$ *iff*

- $med^k(L_1) < med^k(L_2)$ *or*
- $med^k(L_1) = med^k(L_2)$ *and*
$L_1 \setminus \{med^k(L_1)\} \leq^k_{leximed} L_2 \setminus \{med^k(L_2)\}$

Let us define the k-median merging operators, and later the k-leximedian ones:

Definition 17 *Let $E = \{K_1, ..., K_n\}$ be a profile, d a distance between interpretations and $k \in]0, 1]$ a real number. Let $d^{d,k}_{med}(\omega, E) = med^k(d(\omega, K_1), d(\omega, K_2), \ldots, d(\omega, K_n))$. We define $[\Delta^{d,med^k}_\mu(E)]$ by*

$$[\Delta^{d,med^k}_\mu(E)] = \{\omega \models \mu \mid d^k_{med}(\omega, E) \text{ is minimal}\}.$$

Here is an example illustrating the behaviour of k-median operators:

Example 2 *We consider a profile E of three bases such that $[K_1] = \{000, 100\}$, $[K_2] = \{001\}$ and $[K_3] = \{100\}$. There is no integrity constraint ($\mu = \top$), we use the Hamming distance d_H and the value $k = 0.5$ for the "standard" median. The computations are presented in Table 1.*

We get $[\Delta^{d_H, med^{0.5}}_\top(E)] = \{100\}$. The only selected interpretation is 100, because the best vector is $(0, 0, 2)$, with a median value of 0.

Some specific values of k lead to well-known merging operators: given a profile E of n bases, Δ^{med^ϵ}, with $\epsilon \in]0, \frac{1}{n}]$ corresponds to the min operator, and Δ^{med^α}, with $\alpha \in]\frac{n-1}{n}, 1]$ to the max operator.

Let us now make precise the rationality postulates satisfied by these operators:

Proposition 9 *For any real number $k \in]0, 1]$ and any distance d, Δ^{d,med^k} satisfies* **(IC0)**, **(IC1)**, **(IC3)**, **(IC4)**, **(IC7)**, **(IC8)** *and* **(IC5b)**. **(IC2)**, **(IC5)**, **(IC6)**, **(IC6b)**, **(Maj)** *and* **(Arb)** *are not satisfied in general.*

Proof: For space reasons, we provide only the less obvious proofs.

(IC2) Suppose $k = 0.5$, $d = d_H$ and $[K_1] = \{00\}$, $[K_2] = \{00, 01\}$ and $[K_3] = \{00, 01\}$. We have $d^{d_H,0.5}_m(00, \{K_1, K_2, K_3\}) = 0$ and $d^{d_H,0.5}_m(01, \{K_1, K_2, K_3\}) = 0$: **(IC2)** is not satisfied. Note that for $k \in]\frac{n-1}{n}, 1]$ and any distance d, **(IC2)** is satisfied (the aggregation function max is retrieved).

(IC4) Suppose $K_1 \models \mu$, $K_2 \models \mu$ and $\Delta^{d,med^k}_\mu(\{K_1, K_2\}) \wedge K_1$ consistent.

Let $\omega_1 \models \Delta^{d,med^k}_\mu(\{K_1, K_2\}) \wedge K_1$. Then $d^{d,k}_m(\omega_1, \{K_1, K_2\}) = med^k(d(\omega_1, K_1), d(\omega_1, K_2)) = med^k(0, d(\omega_1, K_2)) = med^k(0, d(\omega_1, \omega_2))$, where $\omega_2 \models K_2$ s.t. $d(\omega_1, K_2) = d(\omega_1, \omega_2)$. Then $d(\omega_2, K_1) \leq d(\omega_1, \omega_2)$: $d^{d,k}_m(\omega_2, \{K_1, K_2\}) = med^k(d(\omega_2, K_1), 0) \leq d^{d,k}_m(\omega_1, \{K_1, K_2\})$. As a consequence ω_2 is selected.

(IC5) and **(IC6)** Suppose $k = 0.5$, and ω_1 s.t. $d^{d,0.5}_m(\omega_1, E_1) = med^{0.5}(0, 0) = 0$, $d^{d,0.5}_m(\omega_1, E_2) = med^{0.5}(3, 4, 4) = 4$ and accordingly $d^{d,0.5}_m(\omega_1, E_1 \sqcup E_2) = med^{0.5}(0, 0, 3, 4, 4) = 3$. Suppose ω_2 s.t. $d^{d,0.5}_m(\omega_2, E_1) = med^{0.5}(1, 1) = 1$, $d^{d,0.5}_m(\omega_2, E_2) = med^{0.5}(2, 6, 7) = 6$ and $d^{d,0.5}_m(\omega_2, E_1 \sqcup E_2) = med^{0.5}(1, 1, 2, 6, 7) = 2$. Then with $[\mu] = \{\omega_1, \omega_2\}$, $[\Delta^{d,med^{0.5}}_\mu(E_1)] = \{\omega_1\}$ and $[\Delta^{d,med^{0.5}}_\mu(E_2)] = \{\omega_1\}$ (and then $\Delta^{d,med^{0.5}}_\mu(E_1)$ and $\Delta^{d,med^{0.5}}_\mu(E_2)$ are jointly consistent), whereas $[\Delta^{d,med^{0.5}}_\mu(E_1 \sqcup E_2)] = \{\omega_2\}$. This example shows that neither **(IC5)** nor **(IC6)** is satisfied.

(Arb) Suppose $0 < k < 0.5$ (so that Δ^{d,med^k} is equivalent to $\Delta^{d,min}$). The following example shows that **(Arb)** is not satisfied. Let ω_1, ω_2, ω_3 be three interpretations s.t. $d(\omega_1, \omega_3) = 1$, $d(\omega_1, \omega_2) = 1$ and $d(\omega_2, \omega_3) = 2$. The bases K_1 and K_2 are defined by $K_1 = \{\omega_2\}$ and $K_2 = \{\omega_3\}$; and the constraints μ_1 and μ_2 are defined by $\mu_1 = \{\omega_1, \omega_3\}$, $\mu_2 = \{\omega_1, \omega_2\}$. Then we have:

$$\left.\begin{array}{c} [\Delta_{\mu_1}(K_1)] = [\Delta_{\mu_2}(K_2)] = \{\omega_1\} \\ [\Delta_{\mu_1 \leftrightarrow \neg\mu_2}(\{K_1, K_2\})] = [\mu_1 \leftrightarrow \neg\mu_2] = \{\omega_2, \omega_3\} \\ \mu_1 \not\models \mu_2 \text{ and } \mu_1 \not\models \mu_2 \end{array}\right\}$$

but $[\Delta_{\mu_1 \vee \mu_2}(\{K_1, K_2\}))] = \{\omega_2, \omega_3\}$ and $[\Delta_{\mu_1}(K_1)] = \{\omega_1\}$: contradiction . □

It turns out that k-median operators satisfy some but not all the expected rationality properties. In particular the very natural postulate **(IC2)**, asking that the result of the merging is just the conjunction of the bases when this conjunction is consistent, is not satisfied (except for values of k making the k-median identical to max). We also have:

Proposition 10 *If $k \geq 0.5$, then Δ^{d,med^k} satisfies* **(Arb)**.

No other equity condition is satisfied by such operators:

Proposition 11 *Whatever k, Δ^{d,med^k} does not satisfy* **(PD)** *or* **(SHE)**.

Proof: Consider the following counter-example, for $k < 0.5$: $med^k(1, 3) = 1$ and $med^k(2, 2) = 2$: $(1, 3) <_{med^k} (2, 2)$: none of **(PD)** or **(SHE)** is satisfied.

Consider the following counter-example, for $0.5 \leq k < 1$: $med^k(0, 4, 4, 7) = 4$ and $med^k(0, 4, 5, 6) = 5$ $(0, 4, 4, 7) <_{med^k} (0, 4, 5, 6)$: none of **(PD)** or **(SHE)** is satisfied.

Consider the following counter-example, for $k = 1$: $med^k(0, 4, 4, 7) = 7$ and $med^k(0, 3, 4, 8) = 8$

$(0,4,4,7) <_{med^k} (0,3,4,8)$: none of **(PD)** or **(SHE)** is satisfied. □

Let us now turn to the k-leximedian operators, that satisfy more expected properties:

Definition 18 *Let $E = \{K_1, ..., K_n\}$ be a profile, μ an integrity constraint, d a distance between interpretations and $k \in]0,1]$ a real number. Define $d^k_{leximed}(\omega, E) = leximed^k(d(\omega, K_1), d(\omega, K_2), \ldots, d(\omega, K_n))$. Then*

$[\Delta_\mu^{d,leximed^k}(E)] = \{\omega \models \mu \mid d_{leximed^k}(\omega, E)$ *is minimal*[7]$\}$

Again, some standard operators are recovered by considering specific values of k: $\Delta^{d,leximed^k}$ with $k \in]0, \frac{1}{n}[$ corresponds to the $leximin$ operator $\Delta^{d,leximin}$, and $\Delta^{d,leximed^1}$ to the $leximax$ operator $\Delta^{d,leximax}$.

As expected $\Delta^{d,leximed^k}$ operators satisfy more interesting properties than Δ^{d,med^k} ones:

Proposition 12 *For any distance d and any $k \in]0,1]$, $\Delta^{d,leximed^k}$ is a pre-IC merging operator.*

We do not have better than that. In particular, these operators are not IC merging ones in the general case:

Proposition 13 *$\Delta^{d,leximed^k}$ does not satisfy any of* **(IC5)**, **(IC6)**, **(Maj)** *and* **(Arb)** *in general.*

Concerning egalitarian properties, we reach the arbitration property, but not the other ones:

Proposition 14 *If $k \geq 0.5$, then $\Delta^{d,leximed^k}$ satisfies* **(Arb)** *but does not satisfy* **(PD)** *or* **(SHE)** *in general.*

It is easy to explain why the condition $k \geq 0.5$ is needed. Indeed, we know that when k goes towards 0 the $leximed^k$ function goes towards $leximin$, and that when k goes towards 1 $leximed^k$ goes towards $leximax$. So it is natural to obtain an egalitarian behaviour for values between "classical" median ($k = 0.5$) and $leximax$.

Considering Proposition 7, Proposition 14 shows that relaxing some IC postulates is a way for escaping from the $leximax$-based operators while satisfying some egalitarian condition.

Cumulative Sum Merging Operators

A very convenient representation of the inequalities of a distribution of income is the Lorenz curve (Lorenz 1905). The principle is to focus on the poorest (least satisfied) agents, by looking first as the utility of the poorest one, then at the sum of the utilities of the two poorest ones, etc. To be more precise, on a Lorenz curve, each element k of the x-axis corresponds to the k poorest agents and the value associated with it on the y-axis is the sum of the utilities of those agents.

This curve can be interpreted in different ways to measure how much a distribution is fair. In particular, the fairest distribution is when for any n, the $n\%$ poorest agents own $n\%$ of the income. The well-known Gini coefficient (Gini 1921; Sen 1973; Dutta 2002), one of the main inequality measures, is the (double of the) area between the Lorenz curve and the fairest distribution.

[7] w.r.t. the lexicographic order.

	K_1	K_2	K_3	Cum. Sat.	Σ
000	**3**	**2**	**2**	**(2, 4, 7)**	**13**
001	2	3	1	(1, 3, 6)	10
010	2	1	1	(1, 2, 4)	7
011	1	2	0	(0, 1, 3)	4
100	3	1	3	(1, 4, 7)	12
101	2	2	2	(2, 4, 6)	12
110	2	0	2	(0, 2, 4)	6
111	1	1	1	(1, 2, 3)	6

Table 2: Merging with $\Delta^{CS(d_H,\Sigma)}$

In the following, we adhere to the notion of cumulative sum for defining a new family of merging operators. We translate the distance between a base and an interpretation into a satisfaction value by reversing the scale. Then we compute the cumulative satisfaction vector and take advantage of an aggregation function on it.

Let us define formally the cumulative sum merging operators:

Definition 19 *Let d be a distance between interpretations, f an aggregation function, E a profile and μ an integrity constraint. Let $M = max(\{d(\omega, \omega') \mid \omega, \omega' \in \Omega\})$. For an interpretation ω, we consider the vector $(l_{\sigma(1)}, \ldots, l_{\sigma(n)})$ where $l_i = M - d(\omega, K_i)$ is the satisfaction value of agent i for the interpretation ω, and σ is the permutation of $\{1, \ldots, n\}$ sorting the l_i in ascending order (the less the least satisfied). Then we define the vector of cumulated satisfaction of μ, $W_d(\omega, E) = (W_1, \ldots, W_n)$, where $W_i = \Sigma_{k=1}^{i} l_{\sigma(k)}$. Finally, the selected interpretations are the ones which maximize the cumulated satisfaction $W_d(\omega, E)$:*

$$[\Delta_\mu^{CS(d,f)}(E)] = \{\omega \models \mu \mid f(W_d(\omega, E)) \text{ is maximal } \}.$$

Let us illustrate the behavior of a cumulative sum merging operator on a simple example:

Example 3 *We step back to Example 2. The computations are presented in Table 2, in which the values represent satisfaction values of the bases (the more the best), and not anymore distances (the less the best).*

We get $[\Delta_\top^{CS(d_H,\Sigma)}(E)] = \{000\}$. The selected interpretation is 000, because the sum of the cumulative satisfaction vector gives the maximal value of 13.

We recover some existing operators as cumulative sum ones:

Proposition 15 *Let d be any distance,*

- $\Delta^{CS(d,leximin)} = \Delta^{d,leximax}$.
- $\Delta^{CS(d,leximax)} = \Delta^{d,leximin}$.

Let us finally turn to the logical properties:

Proposition 16 • *If d is any distance, and f is an aggregation function satisfying strict non-decreasingness, then $\Delta^{CS(d,f)}$ is a pre-IC merging operator.*

$rank:$	$w(\omega, K_i):$	$w(\omega', K_i):$
1	x_1	x_1
$\dots$	$\dots$	$\dots$
$k-1$	x_{k-1}	x_{k-1}

$l+1$	x_{l+1}	x_{l+1}
$\dots$	$\dots$	$\dots$
n	x_n	x_n

- $\Delta^{CS(d,f)}$ *does not satisfy* **(Arb)** *and* **(Maj)** *in the general case.*
- $\Delta^{CS(d,f)}$ *does not satisfy* **(IC5)** *and* **(IC6)** *in the general case.*

While **(Arb)** is not satisfied in general, the Pigou-Dalton condition is ensured for instance when any sum of the m-powers, m varying, is used as aggregation function:

Proposition 17 *For any integer m, $\Delta^{CS(d,\Sigma^m)}$ satisfies* **(PD)***, but* **(SHE)** *is not satisfied.*

Proof:

$\Delta^{CS(d,\Sigma^m)}$ satifies **(PD)**.

Consider ω and ω' s.t. $\exists k$ and l s.t. $d(\omega, K_k) < d(\omega', K_k) \leq d(\omega', K_l) < d(\omega, K_l)$ and $d(\omega', K_k) - d(\omega, K_k) = d(\omega, K_l) - d(\omega', K_l)$ and $\forall i \neq k$ and $i \neq l, d(\omega, K_i) = d(\omega', K_i)$. We note g the value $d(\omega', K_k) - d(\omega, K_k)$, so we have $d(\omega', K_k) = d(\omega, K_k) + g$ and $d(\omega', K_l) = d(\omega, K_l) - g$. g is strictly positive.

We note $\forall i, x_i = n - d(\omega, K_i)$, $x'_k = n - d(\omega', K_k)$ and $x'_l = n - d(\omega', K_l)$. We suppose that the x_i are ordered in the ascending way: $x_1 \leq x_2 \leq \ldots \leq x_n$.

Let l' and k' be the relative ranks of x'_l and x'_k into the x_i-th. We suppose $l' \neq l$ and $k' \neq k$. As $x_l > x'_l \geq x'_k > x_k$, we know that if $l' \neq l$, $l' < l$ and if $k' \neq k$, $k' > k$. We have then the following table, if $k' \neq k$ and $l' \neq l$:

From rank 1 to rank $k-1$, the x_i-th are identical so the W_i^m also.

From rank k to rank $k'-1$, we have in $\Sigma^m(W_d(\omega, E))$:

$$\Sigma^m_{k\ldots(k'-1)}(W_d(\omega, E)) = (x_1 + \ldots + x_{k-1} + x_k)^m + \ldots + (x_1 + \ldots + x_{k-1} + x_k + \ldots + x_{k'-1})^m$$

and in $\Sigma^m(W_d(\omega', E))$:

$$\Sigma^m_{k\ldots(k'-1)}(W_d(\omega', E)) = (x_1 + \ldots + x_{k-1} + x_{k+1})^m + \ldots + (x_1 + \ldots + x_{k-1} + x_{k+1}) + (x_1 + \ldots + x_{k-1} + x'_k)^m \quad (3)$$

In Equation 3, the values from x_k to $x_{k'-1}$ are replaced by the values from x_{k+1} to $x_{k'}$. Since the x_i-th are increasing, we have $\Sigma^m_{k\ldots(k'-1)}(W_d(\omega, E)) \leq \Sigma^m_{k\ldots(k'-1)}(W_d(\omega', E))$.

From rank k' to rank $l'-1$, we have in $\Sigma^m(W_d(\omega, E))$:

$$\Sigma^m_{k'\ldots(l'-1)}(W_d(\omega, E)) = (x_1 + \ldots + x_{k-1} + x_k + \ldots + x_{k'})^m + \ldots + (x_1 + \ldots + x_{k-1} + x_k + \ldots + x_{l'-1})^m$$

and in $\Sigma^m(W_d(\omega', E))$:

$$\Sigma^m_{k'\ldots(l'-1)}(W_d(\omega', E)) = (x_1 + \ldots + x_{k-1} + x_{k+1} + \ldots + x_{k'-1} + x'_k)^m + \ldots + (x_1 + \ldots + x_{k-1} + x_{k+1} + \ldots + x'_k + x_{k'+1} + \ldots + x_{l'-1})^m = (x_1 + \ldots + x_{k-1} + x_{k+1} + \ldots + x_{k'-1} + x_k + g)^m + \ldots + (x_1 + \ldots + x_{k-1} + x_{k+1} + \ldots + x_k + g + x_{k'+1} + \ldots + x_{l'-1})^m$$

(because $x'_k = x_k + g$). Each term of $\Sigma^m(W_d(\omega', E))$ is equal to one term of $\Sigma^m(W_d(\omega, E))$ plus g. As $g > 0$, we have: $\Sigma^m_{k'\ldots(l'-1)}(W_d(\omega, E)) < \Sigma^m_{k'\ldots(l'-1)}(W_d(\omega', E))$.

From rank l' to rank l, we have in $\Sigma^m(W_d(\omega, E))$:

$$\Sigma^m_{l'\ldots l}(W_d(\omega, E)) = (x_1 + \ldots + x_k + x_{k+1} + \ldots + x_{l'-1} + x_{l'})^m + \ldots + (x_1 + \ldots + x_{l'-1} + x_{l'} + \ldots + x_{l-1} + x_l)^m$$

and in $\Sigma^m(W_d(\omega', E))$:

$$\Sigma^m_{l'\ldots l}(W_d(\omega', E)) = (x_1 + \ldots + x_k + g + x_{k+1} + \ldots + x_{l'-1} + x'_l)^m + \ldots + (x_1 + \ldots + x_k + g + x_{k+1} + \ldots + x'_l + x_{l'} + \ldots + x_{l-2} + x_{l-1})^m = (x_1 + \ldots + x_k + g + x_{k+1} + \ldots + x_{l'-1} + x_l - g)^m + \ldots + (x_1 + \ldots + x_k + g + x_{k+1} + \ldots + x_l - g + x_{l'} + \ldots + x_{l-1})^m$$

because $x'_l = x_l - g$, so:

$$\Sigma^m_{l'\ldots l}(W_d(\omega', E)) = (x_1 + \ldots + x_k + x_{k+1} + \ldots + x_{l'-1} + x_l)^m + \ldots + (x_1 + \ldots + x_k + x_{k+1} + \ldots + x_l + x_{l'} \ldots + x_{l-1})^m$$

In each term of $\Sigma^m_{l'\ldots l}(W_d(\omega', E))$, compared with $\Sigma^m_{l'\ldots l}(W_d(\omega, E))$, one element $x_{l'+i}$ with i varying from 0 to $l - l'$ of the sum W_j is remplaced by x_l. Since the x_i-th are increasing, $x_{l'+i} \leq x_l$ for $0 \leq i \leq l - l'$, so $\Sigma^m_{l'\ldots l}(W_d(\omega, E)) \leq \Sigma^m_{l'\ldots l}(W_d(\omega', E))$.

From rank $l+1$ to rank n, we have in $\Sigma^m(W_d(\omega, E))$:

$$\Sigma^m_{(l+1)\ldots n}(W_d(\omega, E)) = (x_1 + \ldots + x_{l'-1} + x_{l'} + \ldots + x_{l-1} + x_{l+1})^m + \ldots + (x_1 + \ldots + x_{l'-1} + x_{l'} + \ldots + x_{l-1} + x_l + x_{l+1} + \ldots + x_n)^m$$

and in $\Sigma^m(W_d(\omega', E))$:

$$\Sigma^m_{(l+1)\ldots n}(W_d(\omega', E)) = (x_1 + \ldots + x_k + x_{k+1} + \ldots + x_{l'-1} + x_{l+1})^m + \ldots + (x_1 + \ldots + x_k + x_{k+1} + \ldots + x'_l + x_{l'} + \ldots + x_n)^m$$

So $\Sigma^m_{(l+1)\ldots n}(W_d(\omega', E)) = \Sigma^m_{(l+1)\ldots n}(W_d(\omega, E))$.

Finally, we obtain $\Sigma^m(W_d(\omega, E)) < \Sigma^m(W_d(\omega', E))$, for all integer m, and ω' is selected : **(PD)** is satisfied.

For the other cases, when x'_l (resp. x'_k) has the same rank as x_l (resp. x_k), there are less cases to be studied, the table is simpler, but the result still holds. □

Conclusion

In this paper, we have investigated alternative egalitarian conditions to the arbitration postulate. Especially, we have translated to the belief merging framework two egalitarian conditions: Sen-Hammond equity, and Pigou-Dalton property.

We have shown that the distance-based merging operators satisfying Sen-Hammond equity are mainly those for which $leximax$ is the aggregation function. This led us to introduce a new family of belief merging operators, the pre-IC operators, which includes the family of IC merging operators as a specific case. We have pointed out a representation theorem for this family, which allows us to define easily some distance-based pre-IC operators. In order to enrich the family of egalitarian merging operators, we have considered two new families of belief merging operators, based respectively on the median and on an aggregated sum (Lorenz curves). We have shown that the operators based on the $leximed^k$ aggregation functions (with $k \geq 0.5$) are pre-IC operators which satisfy the arbitration postulate **(Arb)**. We have also proved that the $\Delta^{CS(d,\Sigma^n)}$ operators from the cumulative sum family are pre-IC operators satisfying **(PD)**.

Besides theory-oriented results, this work produced two interesting families of egalitarian operators: cumulative sum ones and $leximed^k$ ones. Before this work the only known egalitarian merging operators were the $leximax$-based ones. Egalitarian operators are significant for all applications where consensual results are expected, i.e., all agents are supposed to be satisfied in the best way, contrariwise to utilitarian/majority operators. Whereas utilitarian operators can be used when the information sources are sensors or databases, egalitarian operators are particularly important in applications where such sources are agents which are autonomous enough to reject the result of the merging if they consider that it is too far from their position.

Proceedings of the Fourteenth International Conference on Principles of Knowledge Representation and Reasoning

Justified Beliefs by Justified Arguments

Davide Grossi and Wiebe van der Hoek
University of Liverpool

Abstract

The paper addresses how the information state of an agent relates to the arguments that the agent endorses. Information states are modeled in doxastic logic and arguments by recasting abstract argumentation theory in a modal logic format. The two perspectives are combined by an application of the theory of product logics, delivering sound and complete systems in which the interaction of arguments and beliefs is investigated.

1 Introduction

Leaving probabilistic approaches aside, one can recognize in the KR tradition two main paradigms in the formal representation of the knowledge or, more generally, of the information state of an agent. One describes knowledge as what holds in all the situations the agent considers possible—the epistemic alternatives. That is the perspective of epistemic logic (Meyer and van der Hoek 1995; Fagin *et al.* 1995). The other describes knowledge as some form of 'stable' theory about the world the agent endorses in the face of conflicting information. This is the tradition of non-monotonic reasoning and of its most successful recent development, abstract argumentation theory (Dung 1995).

The paper combines these two dimensions in a unified framework where questions concerning the interaction of arguments and beliefs can be systematically addressed, such as: Is the set of arguments supporting an agent's doxastic state 'justifiable' from the point of view of abstract argumentation (e.g., conflict-free, admissible, stable, etc.)?

Technically, the combination of the two perspectives—epistemic and argumentation-theoretic—is achieved by deploying techniques and results from the theory of product modal logics (Gabbay *et al.* 2003). The key idea consists in taking states in a doxastic (Kripke) model and arguments in a (Dung) attack graph as two orthogonal dimensions for the description of the information state of an agent. This intuition suggests the use of bi-dimensional structures for the study of argument-based beliefs. The logics obtained are studied in their completeness and finite model properties.

More generally, the paper lays a bridge between epistemic logic and argumentation theory. We hope that the results presented can foster further interaction between the two fields.

Related work To the best of our knowledge, the only works to date attempting to interface argumentation with epistemic logic are (Grossi 2012) and (Schwarzentruber *et al.* 2012). The first is concerned with the analysis, in dynamic epistemic logic (van Ditmarsch *et al.* 2007), of the fixpoint behavior of some argumentation theoretic notions, and the second enriches the standard framework of abstract argumentation by enabling arguers to hold beliefs about other arguers' available arguments. In its broad purposes, the present paper can be related to recent work (in particular, (Artemov 2008; van Benthem and Pacuit 2011)) aiming at explicitly modeling the 'justifications' or 'reasons' upon which agents base their information state. Our paper shows the viability of using product logics for this type of analysis.

Outline of the paper The following section prepares the ground recapitulating some basic notions from both epistemic logic and abstract argumentation. We then proceed in a modular fashion. First (in Section 3) we introduce a logic that combines the simplest modal logic of argumentation (logic K, cf. (Grossi 2010)) and the simplest modal doxastic logic ($\mathsf{KD45}$). Argument-belief interaction properties are then formalized and discussed in Section 4. Then, we allow the agent to have preferences among the arguments. Finally, Section 6 then introduces and studies a more expressive logic, able to formalize ample fragments of Dung's argumentation theory as well as a rich set of doxastic attitudes based on the set of arguments that an agent endorses. We conclude by pointing at future research directions at the interface of abstract argumentation and epistemic logic. All proofs (or proof sketches) are provided in the appendix.

2 Preliminaries

We start by introducing the basic building blocks of our analysis: simple structures for representing beliefs and for representing arguments and their attacks. We then move to motivate a specific way of combining the two: products. Although we give all necessary definitions, space limitations demand we do this succinctly: the reader may wish to consult (Meyer and van der Hoek 1995) for more background on doxastic logic, (Baroni and Giacomin 2009;

Baroni *et al.* 2011) for abstract argumentation, and (Gabbay and Shehtman 1998; Gabbay *et al.* 2003) for products in modal logic.

Doxastic structures

Definition 1 (Doxastic frame). *A doxastic frame is a tuple $\mathcal{D} = \langle S, B\rangle$ where: i) S is a non-empty set of states; ii) $B \subseteq S$, s.t., $B \neq \varnothing$. The class of all doxastic frames is denoted $\mathfrak{D}$.*

A doxastic frame represents the non-empty set B of states that an agent holds as most plausible among the set of all states S. We will refer to elements of B as *doxastic alternatives* or *doxastically accessible states*.

Given a doxastic frame, a Kripke model is obtained by adding a valuation function $\mathcal{V} : \mathbf{P} \longrightarrow \wp(S)$ interpreting a set of atoms $\mathbf{P}$. A doxastic modality $\Diamond\!\!\!\!-_{\mathsf{B}}$ can then be interpreted as follows:

$$\langle \mathcal{D}, \mathcal{V}\rangle, s \vDash \Diamond\!\!\!\!-_{\mathsf{B}}\varphi \quad \text{iff} \quad \exists s' \in B : \langle \mathcal{D}, \mathcal{V}\rangle, s' \vDash \varphi \qquad (1)$$

For any diamond $\Diamond$ in this paper, we define an associated $\Box$ as $\Box\varphi = \neg \Diamond \neg\varphi$. So $\boxminus_{\mathsf{B}}\varphi$ means that the agent believes φ.

Doxastic frames are somewhat simpler than the structures typically used to study beliefs, namely relational frames where the accessibility relation is transitive and euclidean (cf. (Meyer and van der Hoek 1995)). The two, however, can be proven equivalent for the purpose of this paper, using some standard modal logic arguments:

Theorem 1. *On the basic modal language, the class of doxastic frames is modally equivalent to the class of serial, transitive and euclidean relational frames.*

So the logic of the class of doxastic frames is completely axiomatized by the standard axiom system for logic $\mathsf{KD45}$ containing: the rules Modus Ponens ($\mathbf{MP}$: form φ and $\varphi \rightarrow \psi$, infer ψ) and Necessitation ($\mathbf{Nec}$: from φ, infer $\boxminus_{\mathsf{B}}\varphi$); the axioms $\mathbf{K} : \boxminus_{\mathsf{B}}(\varphi \rightarrow \psi) \rightarrow (\boxminus_{\mathsf{B}}\varphi \rightarrow \boxminus_{\mathsf{B}}\psi)$ representing the agent's ability to reason propositionally, $\mathbf{D} : \neg \boxminus_{\mathsf{B}} \bot$ (beliefs are consistent) and the axioms $\mathbf{4} : \boxminus_{\mathsf{B}}\varphi \rightarrow \boxminus_{\mathsf{B}} \boxminus_{\mathsf{B}} \varphi$ and $\mathbf{5} : \neg\boxminus_{\mathsf{B}} \neg\varphi \rightarrow \boxminus_{\mathsf{B}}\neg\boxminus_{\mathsf{B}} \neg\varphi$ representing positive and negative introspection, respectively. For later reference, recall that $\mathsf{S5}$ is the logic $\mathsf{KD45} + \mathbf{T} : \boxminus_{\mathsf{B}}\varphi \rightarrow \varphi$.

Argumentative structures

We start by the key structure of abstract argumentation:

Definition 2 (Attack graphs (Dung 1995)). *An attack graph is a tuple $\mathcal{A} = \langle A, \rightarrow\rangle$ where: i) A is a non-empty set of arguments; ii) $\rightarrow \subseteq A^2$ is a binary relation ($a \rightarrow b$ stands for a attacks b). The class of all attack graphs is denoted $\mathfrak{A}$.*

These relational structures are the building blocks of abstract argumentation theory. Once A is taken to represent a set of arguments, and $\rightarrow$ an 'attack' relation between arguments, the study of these structures provides general insights on how competing arguments interact, and structural properties of subsets of A can be taken to formalize how collections of arguments form 'justifiable' positions in an argumentation ((Baroni and Giacomin 2009; Baroni *et al.* 2011)).

Conflict-free	$X \subseteq \{x \mid \nexists y \in X : x \leftarrow y\}$
Self-defended	$X \subseteq \{x \mid \forall y : x \leftarrow y \Rightarrow \exists z \in X, y \leftarrow z\}$
Admissible	X is conflict-free and self-defended
Complete extension	X is conflict-free &
	$X = \{x \mid \forall y : x \leftarrow y \Rightarrow \exists z \in X, y \leftarrow z\}$
Stable extension	$X = \{x \mid \nexists y \in X : x \leftarrow y\}$

Table 1: Properties of a set of arguments X in a given attack graph $\mathcal{A}$.

In this paper we will touch upon the argumentation-theoretic notions of conflict-freeness, self-defense, admissibility, complete and stable extensions. Table 1 recapitulates these notions for the ease of the reader.

A Kripke model $\mathcal{M} = \langle A, \leftarrow, \mathcal{V}\rangle$ can be obtained from an attack graph by inverting the attack relation ($a \leftarrow b$ denotes that a is attacked by b) and by adding a valuation function $\mathcal{V} : \mathbf{P} \longrightarrow \wp(A)$ interpreting a set of propositional atoms $\mathbf{P}$. Consider now a modality $\Diamond\!\!\!\!-_{\mathsf{A}}$ with the following semantics:

$$\langle \mathcal{A}, \mathcal{V}\rangle, a \vDash \Diamond\!\!\!\!-_{\mathsf{A}}\varphi \text{ iff } \exists b \in A : a \leftarrow b \;\&\; \langle \mathcal{A}, \mathcal{V}\rangle, b \vDash \varphi \quad (2)$$

An argument a satisfies $\Diamond\!\!\!\!-_{\mathsf{A}}\varphi$ iff some attacker b of a satisfies φ. The logic of $\Diamond\!\!\!\!-_{\mathsf{A}}$ defined by the class of attack graphs is, obviously, K. (Grossi 2010) shows that modal logic K can express a number of argumentation theoretic notions from (Dung 1995), such as: $\neg \Diamond\!\!\!\!-_{\mathsf{A}} p$, expressing that the current argument is not attacked by p; or $\boxdot_{\mathsf{A}} \Diamond\!\!\!\!-_{\mathsf{A}} p$ expressing that the current argument is 'defended' by p-arguments (i.e., its attackers are attacked by p-arguments). The logic K is axiomatized by rules $\mathbf{MP}$ and $\mathbf{Nec}$, and axiom $\mathbf{K}$.

Doxo-argumentative structures

Let us start with a simple motivating example:

Example 1 (After (Modgil 2009)). *Consider two individuals exchanging arguments about the weather forecast. Argument a: "Today will be dry in London since the BBC forecasts sunshine". And argument a': "Today will be wet in London since CNN forecasts rain". We have two arguments (a and a') concerned with whether the 'real' situation is a state s where the sun shines in London or in a state s' where it rains in London.*

In general, starting from a set of doxastic alternatives S and a set of 'arguments' A, we are after structures that can support the analysis of how elements of S interact with elements of A. We want to be able to express properties of state-argument pairs (s, a) such as, in particular, that "argument a supports state s" in the sense that a is ground for s or increases its likeliness.

Example 2 (After (Modgil 2009), continued). *Let then $S = \{s, s'\}$ and $A = \{a, a'\}$. We can represent the simple scenario of Example 1 by the model on the left of Figure 1, where the dark circles indicate that the pairs at issue have a property of interest (in this case the property of 'supporting'): a supports s and does not support s'; vice versa a' supports s' and does not support s.*

So our domain becomes the Cartesian product $S \times A$. Now,

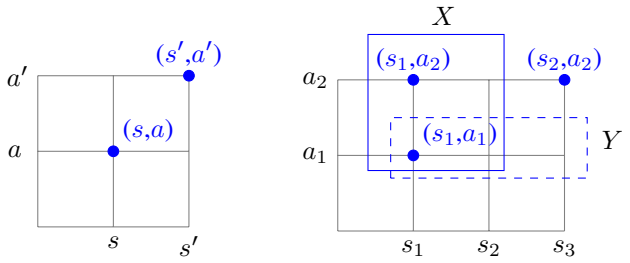

Figure 1: Two doxo-argumentative structures.

if S and A also come equipped with accessibility relations—the doxastic one in case of S and the attack one in case of A—then studying how the logics of these relations interact in $S \times A$ would allow one to talk about properties of state-argument pairs that are of a doxastic and argumentation-theoretic type in the same language. The paper takes this perspective and sets out to develop a formal theory of how arguments and their attacks relate to the doxastic state of an agent. The key tool in accomplishing this, is that of product logics.

Properties of states, arguments and their pairs

The above set up allows one to represent any property of state-argument pairs. In this paper, we will focus on one in particular, namely the property of *support* of an argument for a doxastic state. This will be denoted by symbol σ. Notice that the same argument can support several states and the same state can be supported by several arguments. If a set of states B is supported by a same argument a we say that a *supports* B.

Critically, the set up allows one to represent properties of states, or arguments alone. For instance, to express that a state s has a property X (e.g., 'the sun shines in London') it suffices for X to be true of all the state-argument pairs whose state is s, i.e., to be a set of columns in the Cartesian plane. Similarly, properties Y of arguments alone (e.g., 'being upheld by BBC') can be represented in the same fashion, i.e., by sets of rows of the Cartesian plane.[1]

Figure 1 (right) illustrates all these different properties. Dark circles indicate a relation (e.g., support) between arguments and states: a_2 supports both s_1 and s_3; s_1 is supported by both a_1 and a_2. Rectangle X represents a state-only property, of states s_1 and s_2, and rectangle Y (dashed line) represents an argument-only property, of argument a_1.

Product logics

The product of two (uni-)modal logics[2] is defined as follows (Gabbay and Shehtman 1998). The product $\mathcal{F} \times \mathcal{F}'$ between two frames $\mathcal{F} = \langle S, R\rangle$ and $\mathcal{F}' = \langle S', R'\rangle$ is the frame $\langle S \times S', H, V\rangle$ where:

$$\begin{array}{lll}(s,s')H(t,t') & \text{iff} & sRt \text{ AND } s' = t' \\ (s,s')V(t,t') & \text{iff} & s'R't' \text{ AND } s = t\end{array}$$

Intuitively, the product of two frames can be depicted as a Cartesian plane where H is the relation on the 'horizontal' dimension consisting of the set S and V is the relation on the the 'vertical' one consisting of set S'. Following (Marx 1999), we will use $\Diamond$ to denote the modality interpreted over H—'horizontal' modality—and $\Diamond$ the modality interpreted over V—'vertical' modality.

The product of two classes of frames $\mathfrak{F}$ and $\mathfrak{F}'$ is $\{\mathcal{F} \times \mathcal{F}' \mid \mathcal{F} \in \mathfrak{F} \text{ AND } \mathcal{F}' \in \mathfrak{F}'\}$. Now, given two logics L and L' the product $\mathsf{L} \times \mathsf{L}'$ is the logic of the class of frames defined by the product of the two largest classes $\mathfrak{F}$ and $\mathfrak{F}'$ for which the two logics are complete. For instance, $\mathsf{K} \times \mathsf{K}$ is the logic of the class of all frames consisting of the product of two frames. Here we study products between logics L and L' where L—the 'horizontal' logic—is a doxastic logic and L'—the 'vertical' logic—is a modal logic for argumentation.

3 A simple product logic: $\mathsf{KD45} \times \mathsf{K}$

As a first framework in which to investigate interaction principles between arguments and doxastic states we consider the product of the simplest doxastic logic, namely $\mathsf{KD45}$, with the simplest modal logic of attack graphs, i.e., K.

Syntax and semantics

The language $\mathcal{L}(\Diamond_{\mathsf{B}}, \Diamond_{\mathsf{A}})$, has the following BNF:

$$p \mid \bot \mid \neg\varphi \mid \varphi \wedge \varphi \mid \Diamond_{\mathsf{B}}\varphi \mid \Diamond_{\mathsf{A}}\varphi$$

where p belongs to the set of atoms $\mathbf{P}$. For any language $\mathcal{L}$ that we consider, the variant $\mathcal{L}^{\sigma}$ adds an atom σ to it, where σ intuitively says of (s,a) that s is supported by a. Semantics is given as follows. Let $\mathcal{D}$ be a doxastic frame on S and $\mathcal{A}$ an attack graph on A. A $\mathsf{KD45} \times \mathsf{K}$ model is a structure $\mathcal{M} = \langle \mathcal{D} \times \mathcal{A}, \mathcal{V}\rangle$ where $\mathcal{V} : \mathbf{P} \longrightarrow \wp(S \times A)$. The satisfaction relation is defined by the standard Boolean clauses plus the following clauses (cf. the expressions (1) and (2)):

$$\begin{array}{lll}\mathcal{M},(s,a) \vDash \Diamond_{\mathsf{A}}\varphi & \text{iff} & \exists a' \in A : a \leftarrow a' \;\&\; \mathcal{M},(s,a') \vDash \varphi \\ \mathcal{M},(s,a) \vDash \Diamond_{\mathsf{B}}\varphi & \text{iff} & \exists s' \in B : \mathcal{M},(s',a) \vDash \varphi\end{array}$$

As usual, we denote the truth-set of a formula φ by $[\![\varphi]\!]$.

The expression $\mathcal{M},(s,a) \vDash \varphi$ can be interpreted as: given the 'actual' state is s and the 'currently entertained' argument is a, φ holds. So $\boxminus_{\mathsf{B}}\varphi$ expresses the property that, by keeping fixed the current argument, all pairs consisting of the current argument and a doxastically accessible state, satisfy φ. Intuitively: it is believed that φ holds of the current argument. Similarly, modalities $\Diamond_{\mathsf{A}}$ and $\boxminus_{\mathsf{A}}$ express properties of the attack relation. So $\Diamond_{\mathsf{A}}\varphi$ expresses the property that, by keeping the current state fixed, there exists a pair consisting of the current state and an argument that attacks the current argument, and this pair satisfies φ.

Remark 1 (Satisfaction in products). *As customary in modal logic, formulae are interpreted on pointed models*

[1] Cf. (Sano 2011).

[2] The multi-modal case is a straightforward generalization. Cf. (Gabbay and Shehtman 1998).

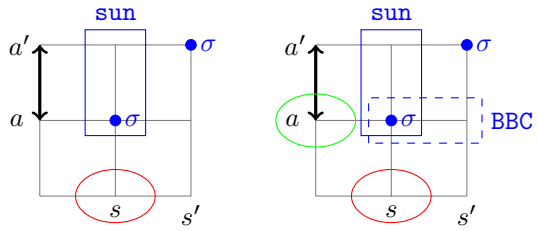

Figure 2: Rendering of Example 1 as a KD45×K model (left) and a DA model (right). Universal relations are not depicted.

"$\mathcal{M}, (s, a)$". So, when we interpret a formula we fix both an argument and a state and $\mathcal{M}, (s, a) \vDash \varphi$ can be interpreted as: given the 'actual' state is s and the 'currently entertained' argument is a, φ holds.

Example 3 (After (Modgil 2009), continued). *We extend Example 1 by making explicit that the two arguments a and a' attack one another, and that the agent believes the actual state is s (the only one supported by argument a), so that the set of doxastic alternatives B is $\{s\}$ (left of Figure 2, where the ellipsis encloses the set of doxastic alternatives). Dark circles denote the truth set of atom σ (representing 'support') and the rectangle denotes the truth set of an atom* sun *(for 'sunshine'). Notice that* sun *is here a 'column' property (Remark 2). Arrows on the vertical dimension denote attack.*

Here are some formulae true at (s, a): (i) $\boxminus_{\mathsf{B}}\sigma$; (ii) $\boxminus_{\mathsf{B}}(\sigma \wedge \boxplus_{\mathsf{A}}\neg\sigma)$. Intuitively: (i) says that my beliefs are supported by the current argument, in the sense that all my doxastic alternatives are supported by the current argument; (ii) says that all my doxastic alternatives are supported by the current argument and all its attackers are not supported by my doxastic alternatives. Here are some of the formulae true at (s', a'): (i) $\neg$sun $\wedge \boxminus_{\mathsf{B}}$sun; (ii) $\boxminus_{\mathsf{B}}\neg\sigma$; (iii) $\boxminus_{\mathsf{B}} \Diamond_{\mathsf{A}} \sigma$. Intuitively: (i) expresses a standard false belief property 'I believe sun *of the current argument but* sun *is false'; (ii) expresses that no doxastic alternative is supported by the current argument; (iii) states that for all doxastic alternatives, the current argument is attacked by an argument supporting that alternative.*

Metalogical results

Axiomatization Logic KD45 × K is the logic on $\mathcal{L}$ of the class of frames consisting of the product of one single-agent doxastic frame and one attack frame. It is axiomatized by taking KD45 for $\Diamond_{\mathsf{B}}$, and K for $\Diamond_{\mathsf{A}}$, plus the two following axioms:

Com	$\Diamond_{\mathsf{A}} \Diamond_{\mathsf{B}} \varphi \leftrightarrow \Diamond_{\mathsf{B}} \Diamond_{\mathsf{A}} \varphi$
Con	$\Diamond_{\mathsf{B}} \boxplus_{\mathsf{A}} \varphi \rightarrow \boxplus_{\mathsf{A}} \Diamond_{\mathsf{B}} \varphi$

We will come back later to the intuitive meaning of these.

The completeness of this axiom system is established as a corollary of known general theorems (Gabbay and Shehtman 1998, Theorem 7.12) or (Gabbay *et al.* 2003, Theorem 5.9): we only need to check that the axioms for K and KD45 are either without atoms (i.e., frame formulae), or else have a specific syntactic form (called *pseudo-transitivity*), which is the case.[3]

Decidability & Complexity A logic has the *product finite model property* w.r.t. class $\mathfrak{F}\times\mathfrak{F}'$ iff every satisfiable formula on that class can be satisfied on a model built on the product of finite frames in $\mathfrak{F}$ and $\mathfrak{F}'$.

Logic KD45 × K has the (strong) product finite model property as every φ can be satisfied on a finite model of size exponential in the length of φ (Gabbay *et al.* 2003, Theorem 6.56). Logic KD45 × K is therefore decidable and its satisfiability problem is NEXPTIME-complete (Gabbay *et al.* 2003, Theorem 6.57).

4 Interaction of attacks and beliefs

We now turn to the sort of insights that we gain by modeling the interaction of doxastic structures (Kripke frames) and argument structures (attack graphs) as a product, and what logic KD45 × K allows us to say about such interaction.

Beliefs

Let us first define formally the classes of state- and argument-properties we have informally introduced in an earlier section. A state-property (column property) is expressed by a formula $\sigma \in \mathcal{L}(\Diamond_{\mathsf{B}}, \Diamond_{\mathsf{A}})$ such that the following equation holds:

$$[\![\sigma]\!] = \{(s, a) \in S \times A \mid \exists a' \in A : (s, a') \in [\![\sigma]\!]\}\,.$$

Similarly, an argument-property (row property) is expressed by a formula $\gamma \in \mathcal{L}(\Diamond_{\mathsf{B}}, \Diamond_{\mathsf{A}})$ such that the following equation holds:

$$[\![\alpha]\!] = \{(s, a) \in S \times A \mid \exists s' \in A : (s', a) \in [\![\alpha]\!]\}\,.^4$$

In the remaining of the paper we will denote state-properties by a variable σ and argument properties by a variable α.

Logic KD45 × K supports the representation of two types of beliefs: the beliefs an agent can entertain about an 'external' state-of-affairs, and the beliefs an agent can entertain about how the states it considers possible interact with available arguments.

Beliefs of the first type concern state-properties: $\boxminus_{\mathsf{B}}\sigma$. Notice that beliefs of state-properties are themselves state-properties. That is, formulae $\boxminus_{\mathsf{B}}\sigma$ are independent of the vertical coordinate, so we have $\mathcal{M}, (s, a) \vDash \boxminus_{\mathsf{B}}\sigma$ iff $\mathcal{M}, (s, a') \vDash \boxminus_{\mathsf{B}}\sigma$ for any $a' \in A$. Put differently: the equivalence $\boxminus_{\mathsf{B}}\sigma \leftrightarrow \boxplus_U \boxminus_{\mathsf{B}} \sigma$ is valid.

Beliefs of the second type concern properties φ expressing some kind of relation between doxastic states and arguments. Both kinds of beliefs behave according to logic

[3] More precisely, the theorem states that the product $\mathsf{L}_H \times \mathsf{L}_V$ of two logics L_H and L_V whose axioms are either formulae from the frame language (i.e., without atoms, like $\Diamond\top$) or have the form $\bigtriangledown \Box p \rightarrow \bigtriangleup p$ where $\bigtriangledown$ is a sequence of possibly different diamonds and $\bigtriangleup$ a sequence of possibly different boxes (so-called *pseudo-transitive formulae*), is completely axiomatized by the axioms of L_H, the axioms of L_V, plus the **Com** and **Con** axioms for each pairs of modalities in the combined language. Notice that pseudo-transitive formulae are Sahlqvist formulae.

[4] Cf. Remark 2 below.

KD45, therefore validating the standard doxastic principles (e.g., positive and negative introspection). To this type of beliefs we turn in the next section.

Interaction properties

Example 3 has already shown interaction properties expressible in KD45 × K. Here are a few more examples, which we illustrate using the designated atom σ:

$$(a)\quad \Box_{\mathsf{A}} \Diamond_{\mathsf{A}} \top \qquad (b)\quad \sigma \wedge \Diamond_{\mathsf{A}} \top \wedge \Box_{\mathsf{A}} \sigma$$
$$(c)\quad \Diamond\!\!\!\!-_{\mathsf{B}} \sigma \qquad (d)\quad \sigma \wedge \Box_{\mathsf{A}} \neg \Diamond\!\!\!\!-_{\mathsf{B}} \sigma$$

To understand these properties, let us see what they express once evaluated at a pointed model $\mathcal{M}, (s, a)$, where s denotes the current state and a the argument currently entertained. Formula (a) expresses that all attackers of a have an attacker, i.e., a is *defended* by some argument. Formula (b) states that the current argument a supports the current alternative s, but a has attackers and indeed all attackers of a support s. Intuitively, a is therefore a 'weak' argument for s. Formula (c) expresses that some doxastically accessible alternatives are supported by the current argument a and hence the beliefs of the agent are supported by that argument. Formula (d) states again that the current argument is supported by the current alternative and that all attackers of the current argument do not support any alternative. This property expresses a form of *safety* of a state-argument pair: the argument supports the alternative but there is no other alternative which is supported by an argument attacking the current one.

It is worth observing that that the latter property generalises a purely argumentative notion of safety as non-existence of attackers ($\Box_{\mathsf{A}} \bot$), by requiring that if there are attackers, then these are not effective as they rule out any doxastic alternative. So it makes the requirement of not having attackers relative to whether they support any further doxastic alternatives. The formula $\boxminus_{\mathsf{B}}(\sigma \rightarrow \Box_{\mathsf{A}} \neg \Diamond\!\!\!\!-_{\mathsf{B}} \sigma)$ would then express the agent's belief of safety of the current argument, across the set of doxastic alternatives.

Validities of KD45 × K and their interpretation

Let us move to the interpretation of **Com** and **Con**.[5]

Intuitively, $\Diamond_{\mathsf{A}} \Diamond\!\!\!\!-_{\mathsf{B}} \varphi \leftrightarrow \Diamond\!\!\!\!-_{\mathsf{B}} \Diamond_{\mathsf{A}} \varphi$ states that the property 'there is an attacker of the argument I'm currently entertaining, and a state I consider doxastically possible, such that the first is in a relation φ with the latter' can be formulated independently of the order of the diamonds involved. The order of quantification over attacks and over doxastic alternatives does not matter.

As to $\Diamond\!\!\!\!-_{\mathsf{B}} \Box_{\mathsf{A}} \varphi \rightarrow \Box_{\mathsf{A}} \Diamond\!\!\!\!-_{\mathsf{B}} \varphi$, it expresses that, if I hold a state as doxastically possible which is in relation φ with all the attackers of an argument I currently entertain, then all the attackers of that argument I currently entertain are in relation φ with one of my doxastic alternatives.

We conclude this section by listing some further validities of KD45 × K. They concern the interaction properties of arguments and doxastic states and can all be proven by applications of axioms **Com** and **Con**.

[5] **Con** is also known as the Church-Rosser property.

Proposition 1. *The following are validities of* KD45 × K*:*

$$\boxminus_{\mathsf{B}} \Diamond_{\mathsf{A}} \varphi \rightarrow \Diamond\!\!\!\!-_{\mathsf{B}} \Diamond_{\mathsf{A}} \boxminus_{\mathsf{B}} \varphi \tag{3}$$
$$\Diamond_{\mathsf{A}} \Diamond\!\!\!\!-_{\mathsf{B}} \varphi \rightarrow \boxminus_{\mathsf{B}} \Diamond_{\mathsf{A}} \Diamond\!\!\!\!-_{\mathsf{B}} \varphi \tag{4}$$

Again, to interpret these formulae it is useful to remember that they are evaluated at a given state and argument. Let us comment on the Formula (3): if all the states I hold possible are such that they are in relation φ (e.g., 'support') with an attacker of the argument I currently entertain, then I hold it possible that some attacker is in relation φ (e.g., 'support') with all the states I consider possible.

Neighborhoods

We conclude this section with a comment on related work. Evidence and justification for doxastic attitudes have been studied within neighborhood semantics (Chellas 1980) in (van Benthem and Pacuit 2011). It is worth, albeit only in passing, to notice a straightforward formal link between our two-dimensional models and neighborhood frames. The intuition is that the set of states supported by each argument can be viewed as the element of a neighborhood. So, any doxo-argumentative model $\mathcal{M} = \langle \mathcal{D} \times \mathcal{A}, \mathcal{V} \rangle$, where $\mathcal{V}$ evaluates a designated constant σ, induces a static neighborhood frame $\langle S, \mathcal{N} \rangle$ where: $\mathcal{N} = \{\{s \in S \mid \exists a \in A : \mathcal{M}, (s, a) \vDash \sigma\}\}_{a \in A}$ Vice versa, any static neighborhood frame $\langle S, \mathcal{N} \rangle$ induces a class of doxo-argumentative models such $\mathcal{M} = \langle \mathcal{D} \times \mathcal{A}, \mathcal{V} \rangle$ such that: the support of $\mathcal{D}$ is S; the support of $\mathcal{A}$ is $\mathcal{N}$; $\mathcal{V}$ is such that $\mathcal{M}, (s, a) \vDash \sigma$ iff $s \in a \in \mathcal{N}$. With respect to neighborhood frames, doxo-argumentative models contain extra structural information encoded in the attack relation.

5 Believing & endorsing

We now want to express properties about the interaction of a given set of doxastic alternatives and a given set of arguments representing the arguments the agent *endorses*. Logic KD45 × K lacks this expressivity. So, to do this, we enrich the K component of the logic. We move from simple attack graphs $\langle A, \rightarrow \rangle$ to attack graphs designating a non-empty set E of 'endorsed arguments': $\mathcal{E} = \langle A, \rightarrow, E \rangle$. We call these frames *enriched attack graphs* and we denote their class by $\mathfrak{E}$. In this section we study the logic of the products of doxastic frames with enriched attack graphs and discuss the sort of insights the logic enables on the interaction between arguments and beliefs.

Syntax and semantics

The language $\mathcal{L}^E$ is defined by the following BNF:

$$p \mid \bot \mid \neg\varphi \mid \varphi \wedge \varphi \mid \Diamond\!\!\!\!-_{\mathsf{B}} \varphi \mid \Diamond_{\mathsf{E}} \varphi \mid \Diamond_{\mathsf{A}} \varphi \mid \Diamond\!\!\!\!-_{\mathsf{U}} \varphi \mid \Diamond_{\mathsf{U}} \varphi$$

with $p \in \mathbf{P}$. As before, $\mathcal{L}^{E,\sigma}$ extends $\mathcal{L}^E$ with the designated atom σ. Modalities $\Diamond\!\!\!\!-_{\mathsf{B}}$ and $\Diamond_{\mathsf{A}}$ are as above. As to the others: $\Diamond_{\mathsf{E}}$ means 'for some endorsed argument by keeping fixed the current state'; $\Diamond\!\!\!\!-_{\mathsf{U}}$ means 'for some state by keeping fixed the current argument'; $\Diamond_{\mathsf{U}}$ means 'for some argument by keeping fixed the current state'. Notice that $\Diamond\!\!\!\!-_{\mathsf{U}}$ and $\Diamond_{\mathsf{U}}$ are nothing but universal modalities for the horizontal and, vertical dimensions, respectively. We refer to the fragment

of $\mathcal{L}^E$ containing only $\Diamond\!\!\!\!-_{\mathsf{B}}$, $\Diamond\!\!\!\!-_{\mathsf{U}}$ modalities as its *horizontal fragment*, and to the fragment of $\mathcal{L}^E$ containing only $\Diamond_{\mathsf{E}}$, $\Diamond_{\mathsf{A}}$ and $\Diamond_{\mathsf{U}}$ modalities as its *vertical fragment*.

The semantics for $\mathcal{L}^E$ is defined as follows. Let $\mathcal{F}$ be a doxastic frame on S and $\mathcal{A}$ an enriched attack graph on A. A model is a structure $\mathcal{M} = \langle \mathcal{D} \times \mathcal{E}, \mathcal{V} \rangle$ where $\mathcal{V} : \mathbf{P} \longrightarrow \wp(S \times A)$. The satisfaction relation is defined as follows (clauses are limited to the newly introduced operators):

$$\begin{array}{lll} \mathcal{M}, (s,a) \vDash \Diamond_{\mathsf{E}}\varphi & \text{iff} & \exists a' \in E : \mathcal{M}, (s,a') \vDash \varphi \\ \mathcal{M}, (s,a) \vDash \Diamond\!\!\!\!-_{\mathsf{U}}\varphi & \text{iff} & \exists s' \in S : \mathcal{M}, (s',a) \vDash \varphi \\ \mathcal{M}, (s,a) \vDash \Diamond_{\mathsf{U}}\varphi & \text{iff} & \exists a' \in A : \mathcal{M}, (s,a') \vDash \varphi \end{array}$$

We call the logic on $\mathcal{L}^E$ defined by the class of the above models DA *doxastic argument logic*.

Remark 2 ('Column' and 'row' properties). *Modalities $\Diamond\!\!\!\!-_{\mathsf{U}}$ and $\Diamond_{\mathsf{U}}$ make it possible to express that given properties are state- or argument-properties. A state- or 'column' property is a formula σ that satisfies (in the given model) the equation: $\sigma \leftrightarrow \Box\!\!\!\!-_{\mathsf{U}}\sigma$ (i.e., σ holds of the current pair independently of the argument). Similarly, an argument- or 'row' property is expressed by a formula α that satisfies the equation: $\alpha \leftrightarrow \boxminus_{\mathsf{U}}\alpha$ (i.e., α holds of the current pair independently of the state). Examples are, in the right model of Figure 2: $\Box\!\!\!\!-_{\mathsf{U}}\mathtt{sun}$ of state s, and $\boxminus_{\mathsf{U}}\mathtt{BBC}$ of argument a. We can then express that the agent* believes *φ, in the sense that all its doxastc alternatives have column property φ by $\boxminus_{\mathsf{B}} \Box\!\!\!\!-_{\mathsf{U}} \varphi$ (in the example: $\boxminus_{\mathsf{B}} \Box\!\!\!\!-_{\mathsf{U}} \mathtt{sun}$). Similarly, we can express that all the arguments endorsed by the agent have row property φ by $\Box_{\mathsf{E}} \boxminus_{\mathsf{U}} \varphi$ (in the example: $\Box_{\mathsf{E}} \boxminus_{\mathsf{U}} \mathtt{BBC}$).*

Example 4 (After (Modgil 2009), continued). *We expand Example 3 by recasting it as a* DA *model and making thus explicit that the agent endorses argument a, that is: $E = \{a\}$. The new model is depicted on the right of Figure 2 where the ellipsis on the vertical axis encloses the set of endorsed arguments. The following are validities of the above model (thus independent of the point of evaluation):*

$$\begin{array}{ll} (a) & \boxminus_{\mathsf{B}} \Diamond_{\mathsf{E}} \sigma \\ (b) & \Box_{\mathsf{E}} \boxminus_{\mathsf{B}} (\sigma \rightarrow \neg \Diamond_{\mathsf{A}} \Diamond\!\!\!\!-_{\mathsf{B}} \sigma) \\ (c) & \boxminus_{\mathsf{B}} \Box\!\!\!\!-_{\mathsf{U}} \mathtt{sun} \\ (d) & \Box\!\!\!\!-_{\mathsf{U}} \boxminus_{\mathsf{U}} ((\sigma \wedge \mathtt{sun}) \rightarrow \neg \Diamond_{\mathsf{A}} \Diamond\!\!\!\!-_{\mathsf{U}} (\sigma \wedge \mathtt{sun})) \end{array}$$

Intuitively: (a) expresses that the agent's beliefs are supported by arguments it endorses; (b) that for all pairs of endorsed arguments and doxastic alternatives, if the argument supports the alternative, then there is no attacker of that argument which supports some other alternative; (c) that all doxastic alternatives satisfy sun*—i.e., the agent believes* sun *(cf. Remark 2); (d) that the state-argument pairs satisfying $\sigma \wedge$ sun do not contain any attack between their arguments, that is, their arguments ar* conflict-free.[6] *Notice that none of these properties was expressible in the simpler language $\mathcal{L}(\Diamond\!\!\!\!-_{\mathsf{B}}, \Diamond_{\mathsf{A}})$.*

[6] We come back to a general formalization of conflict-freeness and the other properties of Table 1 below.

Remark 3 (On the 'support' relation between states and arguments). *We have taken a liberal view on the notion of support of a state by an argument. We have treated support as just one of the possible relations between arguments and states (others can be 'incompatibility', 'weak support', etc. depending on the application domain) and modeled it through a dedicated atom σ, whose interpretation has not been constrained. It is important to notice that meaningful classes of* DA *models can be isolated by strengthening our axiom system with axioms enforcing desirable properties on σ, such as: $\Diamond\!\!\!\!-_{\mathsf{U}}\sigma$ (every argument supports some state); $\boxminus_{\mathsf{B}} \Diamond_{\mathsf{E}} \sigma$ (the agent considers possible only states that are supported by some argument).*

Metalogical results

We provide here a sound and complete axiom system for DA. The axiomatization is built from axiom systems for the horizontal and vertical components of the logic. We then establish the decidability of the logic and sample a few results on its expressivity.

Axiomatization: horizontal logic Let us first concern ourselves with axiomatizing the logic determined by the class of doxastic frames on the horizontal fragment of $\mathcal{L}^E$. Consider the logic—call it DA^H—defined by the rules and axioms of KD45 for modality $\Diamond\!\!\!\!-_{\mathsf{B}}$, the rules and axioms of S5 for modality $\Diamond\!\!\!\!-_{\mathsf{U}}$ plus:

$\mathbf{Inc}_{\mathsf{BU}}$	$\Diamond\!\!\!\!-_{\mathsf{B}}\varphi \rightarrow \Diamond\!\!\!\!-_{\mathsf{U}}\varphi$	$\mathbf{4}_{\mathsf{BU}}$	$\boxminus_{\mathsf{B}}\varphi \rightarrow \boxminus_{\mathsf{U}} \boxminus_{\mathsf{B}} \varphi$
$\mathbf{5}_{\mathsf{BU}}$	$\Diamond\!\!\!\!-_{\mathsf{B}}\varphi \rightarrow \boxminus_{\mathsf{U}} \Diamond\!\!\!\!-_{\mathsf{B}} \varphi$		

Lemma 1. *DA^H is sound and complete for class $\mathfrak{D}$.*

Axiomatization: vertical logic As to the logic determined by the class of enriched attack graphs on the vertical fragment of $\mathcal{L}^E$ we can proceed in a similar fashion. Notice that an enriched attack graph $\mathcal{E} = \langle A, \rightarrow, E \rangle$ can be viewed as a doxastic frame to which a binary relation $\rightarrow$ is added. So, consider the logic—call it DA^V—defined by: the rules and axioms of KD45 for modality $\Diamond_{\mathsf{E}}$, the rules and axioms of K for modality $\Diamond_{\mathsf{A}}$ and the rules and axioms of S5 for modality $\Diamond\!\!\!\!-_{\mathsf{U}}$, plus:

$\mathbf{Inc}_{\mathsf{AU}}$	$\Diamond_{\mathsf{A}}\varphi \rightarrow \Diamond_{\mathsf{U}}\varphi$	$\mathbf{Inc}_{\mathsf{EU}}$	$\Diamond_{\mathsf{E}}\varphi \rightarrow \Diamond_{\mathsf{U}}\varphi$
$\mathbf{4}_{\mathsf{EU}}$	$\Box_{\mathsf{E}}\varphi \rightarrow \Box_{\mathsf{U}} \Box_{\mathsf{E}} \varphi$	$\mathbf{5}_{\mathsf{EU}}$	$\Diamond_{\mathsf{E}}\varphi \rightarrow \Box_{\mathsf{U}} \Diamond_{\mathsf{E}} \varphi$

Lemma 2. *DA^V is sound and complete for class $\mathfrak{E}$.*

The proof proceeds as for Lemma 1.

An axiom system for DA Everything is now in place to prove the following result:

Theorem 2 (Completeness of DA**).** *The logic defined by the axioms and rules of DA^H and of DA^V plus the following instances of* **Com** *and* **Con***:*

Com	$\Diamond \Diamond \varphi \leftrightarrow \Diamond \Diamond \varphi$
Con	$\Diamond \Box \varphi \rightarrow \Box \Diamond \varphi$

where $\Diamond \in \{\Diamond\!\!\!\!-_{\mathsf{B}}, \Diamond\!\!\!\!-_{\mathsf{U}}\}$, and $\Diamond \in \{\Diamond_{\mathsf{E}}, \Diamond_{\mathsf{A}}, \Diamond\!\!\!\!-_{\mathsf{U}}\}$, is sound and complete for the class $\mathfrak{D} \times \mathfrak{E}$ consisting of products of doxastic frames and enriched attack graphs.

(Product) Finite model property & decidability We finally establish the two following results concerning the decidability of DA:

Theorem 3. *Logic* DA *does not have the product finite model property.*

Theorem 4. *Logic* DA *is decidable.*

Expressivity on frames We conclude with some technical considerations about the expressivity of DA. The previous subsection has shown how basic notions from argumentation theory can be characterized at the level of models in DA. We now look at the feasibility of characterizations at frame level: are there formulae which characterize whether the set of endorsed arguments E is conflict-free and self-defended? This is a novel application of frame correspondence theory (van Benthem 1983) to abstract argumentation. We start by the following:

Proposition 2. *Let $\mathcal{F} = \mathcal{D} \times \mathcal{E}$. If $\mathcal{F} \vDash \Box_{\mathsf{E}}(\boxminus_{\mathsf{U}} p \rightarrow \neg \Diamond_{\mathsf{A}} \boxminus_{\mathsf{U}} p)$ then E in $\mathcal{E}$ is conflict free.*

We next show that Proposition 2 cannot be strengthened to a *characterization* of conflict-freeness:

Theorem 5. *There exists no formula φ of* DA *s.t.: $\mathcal{F} \vDash \varphi$ iff E is conflict-free, for $\mathcal{F} \in \mathfrak{D} \times \mathfrak{E}$.*

However, a characterization *does* exists for self-defense:

Proposition 3 (Characterization of self-defense of E). *Let $\mathcal{F} = \mathcal{D} \times \mathcal{E}$. Then $\mathcal{F} \vDash (\Box_{\mathsf{E}} p \wedge \Diamond_{\mathsf{E}} \Diamond_{\mathsf{A}} q) \rightarrow \Diamond_{\mathsf{U}}(q \wedge \Diamond_{\mathsf{A}} p)$ if and only if E in $\mathcal{E}$ is self-defended.*

6 Justified beliefs & arguments in DA

This section concludes by showcasing DA as a rich framework for the study of argument-based beliefs.

From beliefs to argument-based beliefs

In standard doxastic logic beliefs are properties that are true of all (doxastically) accessible states. In DA, beliefs are properties that are true of all (doxastically) accessible state-argument pairs, *independently of the argument*. So, "I believe that φ" is formalized by $\boxminus_{\mathsf{B}} \Box_{\mathsf{U}} \varphi$ (cf. Remark 2). But now, the argumentative structure available in DA allows us to differentiate between beliefs based on how they relate to underlying arguments, for instance by being supported by some such arguments. The following definitions illustrate the interaction between beliefs and endorsed arguments:

$$SB\varphi := \boxminus_{\mathsf{B}}(\Box_{\mathsf{U}}\varphi \wedge \Diamond_{\mathsf{U}}\sigma) \quad (5)$$

$$EB\varphi := \boxminus_{\mathsf{B}}(\Box_{\mathsf{U}}\varphi \wedge \Diamond_{\mathsf{E}}\sigma) \quad (6)$$

$$JB(\varphi,\psi) := \boxminus_{\mathsf{B}}(\Box_{\mathsf{U}}\varphi \wedge \Diamond_{\mathsf{E}}(\sigma \wedge \boxminus_{\mathsf{U}}\psi)) \quad (7)$$

The formulae appear in the order from logically weaker to logically stronger and may be taken as definitions of different types of argument-based beliefs in φ: supported belief (SB), endorsed supported belief (EB), and justified belief (JB) where the type of justification is expressed by ψ. Formula (5) expresses that the agent believes φ and its beliefs are supported by arguments—each doxastic alternative is supported by some argument. Formula (6) expresses that the agent believes φ and its beliefs are supported by arguments it endorses. Finally, Formula (7) states that the agent believes φ and its beliefs are supported by arguments it endorses and which have property ψ (notice again the use of $\boxminus_{\mathsf{U}}$ to express that such ψ is a 'row' property, *independent of the doxastic state*). In particular, such ψ can be chosen to express properties such as: "the argument belongs to a given conflict-free set", "the argument belongs to a given stable extension" and the like, to which we now turn.

Dung's argumentation theory in DA We show now how DA can capture some fundamental argumentation-theoretic properties (Table 1). These properties are properties of sets of arguments, that is, row properties (cf. Remark 2). For instance, we want to formalize the property that says that a given row property $\boxminus_{\mathsf{U}}\varphi$ identifies a set of admissible arguments. The strategy for obtaining these formalizations is based on (Grossi 2010). Let $\blacksquare := \boxminus_{\mathsf{U}}\Box_{\mathsf{U}}$:

(i)	φ is a conflict free set	$\blacksquare(\boxminus_{\mathsf{U}}\varphi \rightarrow \neg \Diamond_{\mathsf{A}} \boxminus_{\mathsf{U}}\varphi)$
(ii)	φ is a self-defended set	$\blacksquare(\boxminus_{\mathsf{U}}\varphi \rightarrow \Box_{\mathsf{A}} \Diamond_{\mathsf{A}} \boxminus_{\mathsf{U}}\varphi)$
(iii)	φ is a fixpoint of $\Box_{\mathsf{A}}\Diamond_{\mathsf{A}}$	$\blacksquare(\boxminus_{\mathsf{U}}\varphi \leftrightarrow \Box_{\mathsf{A}} \Diamond_{\mathsf{A}} \boxminus_{\mathsf{U}}\varphi)$
(iv)	φ is an admissible set	$(i) \wedge (ii)$
(v)	φ is a complete extension	$(i) \wedge (iii)$
(vi)	φ is a stable extension	$\blacksquare(\boxminus_{\mathsf{U}}\varphi \leftrightarrow \neg \Diamond_{\mathsf{A}} \boxminus_{\mathsf{U}}\varphi)$

We comment on (i) and (ii). Formula (i) says that if an argument satisfies row property $\boxminus_{\mathsf{U}}\varphi$, then no attacker of that argument exists which also satisfies the same property. Formula (ii) states that all arguments satisfying row property $\boxminus_{\mathsf{U}}\varphi$ are such that all their attackers are defended by some argument satisfying the same property.

Example 5 (After (Modgil 2009), continued). *Let us go back to the model on the right of Figure 2. It is a validity of the model that: the agent believes that* sun *is the case; that it has arguments for that belief, which it endorses; and that those arguments also have the property of belonging to the conflict-free set of arguments specified by property* BBC*. That is, the agent holds a belief to the effect that* sun *is the case and such belief is justified by the set of conflict-free* BBC *arguments. Formally: $JB(\mathtt{sun}, \psi)$ where $\psi := \mathtt{BBC} \wedge \blacksquare(\boxminus_{\mathsf{U}}\mathtt{BBC} \rightarrow \neg \Diamond_{\mathsf{A}} \boxminus_{\mathsf{U}}\mathtt{BBC})$. It is also a validity of the model that the set of arguments supporting the agent's doxastic alternatives is an admissible set, that is:*

$$\blacksquare(\Diamond\!\!\!\!-_{\mathsf{B}}\sigma \rightarrow \neg \Diamond_{\mathsf{A}} \Diamond\!\!\!\!-_{\mathsf{B}}\sigma) \wedge \blacksquare(\Diamond\!\!\!\!-_{\mathsf{B}}\sigma \rightarrow \Box_{\mathsf{A}} \Diamond_{\mathsf{A}} \Diamond\!\!\!\!-_{\mathsf{B}}\sigma)$$

where, notice, $\Diamond\!\!\!\!-_{\mathsf{B}}\sigma$ is a row property ($\Diamond\!\!\!\!-_{\mathsf{B}}\sigma \leftrightarrow \boxminus_{\mathsf{U}} \Diamond\!\!\!\!-_{\mathsf{B}} \sigma$).

Properties of argument-based beliefs

Having interfaced beliefs with properties of supporting arguments, the natural question arising is: how do the argument-based beliefs we have introduced in Formulae (5)-(7) behave with respect to standard principles of doxastic logic? In this final subsection we set out to provide a first answer to this question, and show that argument-based beliefs offer interesting insights into the failure of controversial principles such as, in particular, negative introspection.

All the above types of argument-based beliefs—viz., supported beliefs, endorsed beliefs and justified beliefs—obey the standard distribution and positive introspection principles, while they fail the negative introspection principle.

Proposition 4. *The following formulae are valid on* $\mathfrak{D} \times \mathfrak{E}$*:*

$$SB(\varphi \to \psi) \to (SB\varphi \to SB\psi) \quad (8)$$
$$EB(\varphi \to \psi) \to (EB\varphi \to EB\psi) \quad (9)$$
$$JB(\varphi \to \psi, \chi) \to (JB(\varphi, \chi) \to JB(\psi, \chi)) \quad (10)$$
$$SB\varphi \to SBSB\varphi \quad (11)$$
$$EB\varphi \to EBEB\varphi \quad (12)$$
$$JB(\varphi, \psi) \to JB(JB(\varphi, \psi), \psi) \quad (13)$$

Proposition 5 (Negative introspection failure). *The following formulae are* not *valid on* $\mathfrak{D} \times \mathfrak{E}$*:*

$$\neg SB\varphi \to SB\neg SB\varphi \quad (14)$$
$$\neg EB\varphi \to EB\neg EB\varphi \quad (15)$$
$$\neg JB(\varphi, \psi) \to JB(\neg JB(\varphi, \psi), \psi) \quad (16)$$

A simple inspection of the proof (in the appendix) shows that negative introspection fails only in one specific case, namely when it is not the case that all doxastic states are supported by some argument (resp., supported by endorsed arguments, or supported by endorsed arguments with property ψ). That is, negative introspection for argument-based beliefs does not go through only when the to-be-introspected belief itself is not supported by arguments.

This suggests that, although negative introspection fails in its full form, it still holds in a restricted one:

Proposition 6. *The following formulae are valid on* $\mathfrak{D} \times \mathfrak{E}$*:*

$$(\neg SB\varphi \wedge \boxminus_{\mathsf{B}} \Diamond_{\mathsf{U}} \sigma) \to SB\neg SB\varphi \quad (17)$$
$$(\neg EB\varphi \wedge \boxminus_{\mathsf{B}} \Diamond_{\mathsf{E}} \sigma) \to EB\neg EB\varphi \quad (18)$$
$$(\neg JB\varphi \wedge \boxminus_{\mathsf{B}} \Diamond_{\mathsf{E}} (\sigma \wedge \boxminus_{\mathsf{U}} \psi)) \to JB\neg JB\varphi \quad (19)$$

In other words, if I do not believe (with justification) that φ, but my beliefs are justified then I believe (with justification) that I do not believe (with justification) that φ.

7 Concluding remarks

Summary We proposed an approach based on product logics to study the interaction between the information state of an agent and the arguments the agent endorses. The approach has been illustrated by two product logics, which have been studied from a logical point of view, and have been used to model simple scenarios and formalize a number of interaction properties between beliefs and arguments.

Justification logic A related framework to the one we presented is *justification logic* (Artemov 2008), which formalizes the logic of statements of the type "t is a justification for φ", where t is called a, possibly complex, term. Justification logic provides an articulated solution to the logical omniscience problem of standard epistemic logic. In our framework arguments can well be seen as (atomic) terms but, unlike in justification logic, they are reified in the semantics of the logic and obtain the same 'ontological' status as doxastic states. While on the one hand this reintroduces logical omniscience, on the other hand it enables a classical modal approach for the study of (atomic) justifications viewed as arguments, which was our primary aim with this paper. Whether the reification of arguments/justifications in the semantics can be reconciled with a solution to the logical omniscience problem is an interesting open question.

Future work We point to three more research directions we consider especially worth pursuing. First, in our analysis we have assumed a primitive relation of 'support' between doxastic alternatives and arguments. This relation enabled us to say that a set of states (e.g., the truth-set of a column formula) was supported by a set of arguments whenever each state had an argument which was ground for it. Hence an argument can support a set of states only if it supports each alternative taken in isolation. This is clearly a strong requirement and is in part related to the logical omniscience issue just mentioned. Arguments might be thought of supporting sets of states without needing to support any of the states in the set taken in isolation. How to achieve this weakening while remaining within the set up of product logics is an interesting open question.

Second, we believe that studying our proposal in a multi-agent context would be another prominent venue for further research. For the beliefs, this would require that the alternatives for agents are modelled through a relation, rather than just identifying one set of states that are deemed doxastically possible. For the dimension representing the arguments, there is a range of possibilities one can consider. Are the arguments commonly known by all agents? Note that in our set-up, it is valid that $\blacklozenge \boxminus_{\mathsf{U}} \varphi \leftrightarrow \boxminus_{\mathsf{B}} \blacklozenge \boxminus_{\mathsf{U}} \varphi$ (with $\blacklozenge := \Diamond_{\mathsf{U}} \Diamond_{\mathsf{U}}$): there is an argument with row property φ if and only if the agent believes that. For the single agent-case this seems reasonable, but when reasoning about other agents' beliefs and justifications, there may be reasons to assume (we order them from weak to stronger) that (1) not all agents endorse the same arguments; (2) not all agents agree on the attack relation between arguments, and (3) not all agents need to be aware of the same arguments.[7] Once one agrees on some of those assumptions, one also needs to take into account that agents make such assumptions about each other (e.g., agent a believes that b's beliefs are justified by b's arguments, but not by arguments that a endorses).

Third, the paper has started from the simplest possible doxastic logic, KD45. Incorporating more sophisticated logics of belief constitutes another natural avenue of research. Apart from our interest to look at ways to cover the multi-agent case, other options that present themselves are incorporating richer order-theoretic models for doxastic logic (Baltag and Smets 2008); and studying the dyanmics supported by the horizontal and vertical dimensions with tools from dynamic epistemic logic (van Ditmarsch *et al.* 2007).

A Appendix: proofs

Proof of Theorem 1. Let $\mathfrak{F}$ the class of transitive and euclidian frames and $\mathfrak{F}_g$ the class of point-generated transitive and euclidean frames. We know that $\mathfrak{F}$ and $\mathfrak{F}_g$ are modally equivalent (Blackburn *et al.* 2001). [LEFT TO RIGHT] Assume $\mathfrak{D} \vDash \varphi$. Let $\mathcal{F}_s = \langle S_s, R_s \rangle \in \mathfrak{F}_g$ and $s \in S_s$. Define $B = \{x \mid sR_sx\}$ and notice that $\mathcal{D}_s = \langle S_s, B \rangle \in \mathfrak{D}$ and hence $\mathcal{D}_s \vDash \varphi$. An easy induction shows that $\mathcal{D}_s$ and $\mathcal{F}_s$ are modally equivalent and thus $\mathfrak{F} \vDash \varphi$ [RIGHT TO LEFT] Assume $\mathfrak{F} \vDash \varphi$. Let $\mathcal{D} = \langle S, B \rangle \in \mathfrak{D}$. Define a relation R on S

[7] Cf. (Schwarzentruber *et al.* 2012).

by xRy iff $y \in B$. It is easy to see that R is transitive and euclidean and hence $\mathcal{F} = \langle S, R\rangle \in \mathfrak{F}$. An easy induction proves that $\mathcal{D}$ and $\mathcal{F}$ are modally equivalent, entailing $\mathfrak{D} \vDash \varphi$. □

Proof sketch of Theorem 2. The result follows from Lemmata 1 and 2 by (Gabbay and Shehtman 1998, Theorem 7.12) (cf. our comment on completeness of $\mathsf{KD45} \times \mathsf{K}$). □

Proof sketch of Theorem 3. We exhibit a satisfiable formula from $\mathcal{L}^E$ which cannot be satisfied on a finite product model. Consider the following formula ψ from $\mathcal{L}^E$:

$$\Box_{\mathsf{U}} \Diamond\!\!\!-_{\mathsf{B}} p \wedge \Box_{\mathsf{U}} \boxminus_{\mathsf{B}} (p \rightarrow \Diamond_{\mathsf{A}} \neg p) \wedge \Box_{\mathsf{U}} \boxminus_{\mathsf{B}} (\neg p \rightarrow \Box_{\mathsf{A}} \neg p).$$

Let $\mathcal{E} = \langle A, E, \rightarrow\rangle$ be such that $\langle A, \rightarrow\rangle$ consists of an infinite $\leftarrow$-ascending chain of elements $\langle x_n \mid 0 \leq n < \omega\rangle$ such that $a_i \not\rightarrow a_j$ for $i < j$. For any choice of E, this is clearly a frame in $\mathfrak{E}$. Let then $\mathcal{D}$ consist of a point s_0 accessing all other states (except itself) in the frame. Take an enumeration $s_0, s_1, \ldots$ of these states. This is clearly a frame in $\mathfrak{D}$. Set $\mathcal{V}(p) = \{(s_{n+1}, a_n) \mid 0 \leq n < \omega\}$. We have $\langle \mathcal{D} \times \mathcal{E}, \mathcal{V}\rangle, (s_0, a_0) \vDash \psi$. Clearly, no model on a finite frame in $\mathfrak{D} \times \mathfrak{E}$ satisfies ψ.[8] □

Proof sketch of Lemma 1. Soundness is straightforward. As to completeness, the axiom system can be shown to be complete with respect to the class of frames $\mathcal{F} = \langle S, R_{\mathsf{B}}, R_{\mathsf{U}}\rangle$ consisting of one equivalence relation R_{U} (axiomatized by S5) which, within each of its equivalence classes, contains (containment is enforced by $\mathbf{Inc}_{\mathsf{BU}}$) a transitive and euclidean relation R_{B} (axiomatized by KD45) with the additional property (enforced by axioms $\mathbf{4}_{\mathsf{BU}}$ and $\mathbf{5}_{\mathsf{BU}}$) that within each equivalence class all states have access to the same set of states: $\forall x, y, z$ (in each equivalence class): $xR_{\mathsf{B}}y$ iff $zR_{\mathsf{B}}y$ (in other words, there exists a set of states B all of which elements are R_{B}-accessible by all states in the class, cf. Definition 1). The latter property is a consequence of the fact that R_{B} is a subrelation of R_{U} (by $\mathbf{Inc}_{\mathsf{BU}}$) and that axioms $\mathbf{4}_{\mathsf{BU}}$ and $\mathbf{5}_{\mathsf{BU}}$—which, notice, are Sahlqvist—correspond to the following properties: $\forall x, y, z$ if $xR_{\mathsf{U}}y$ and $yR_{\mathsf{B}}z$ then $xR_{\mathsf{B}}z$; $\forall x, y, z$ if $xR_{\mathsf{U}}y$ and $xR_{\mathsf{B}}z$ then $yR_{\mathsf{B}}z$. Call now this class $\mathfrak{F}$ and consider the class $\mathfrak{F}_g$ of frames in $\mathfrak{F}$ which are point-generated by the equivalence relation R_{U}. Any $\mathcal{F} \in \mathfrak{F}_g$ is thus such that R_{U} is the universal relation on $\mathcal{F}$ and $\mathcal{F}$ contains one unique set B R_{B}-accessible by all elements of the frame. $\mathcal{F}$ is therefore modally equivalent (on the horizontal fragment of $\mathcal{L}^E$) to a $\mathcal{D} \in \mathfrak{D}$. Vice versa, any $\mathcal{D} \in \mathfrak{D}$ is modally equivalent to a $\mathcal{F} \in \mathfrak{F}_g$ (cf. proof of Theorem 1). So $\mathfrak{D}$ is modally equivalent to $\mathfrak{F}_g$ which is, by general results (Blackburn *et al.* 2001), modally equivalent to $\mathfrak{F}$. Therefore, the axiom system is complete for $\mathfrak{D}$. □

Proof sketch of Theorem 4. We provide a reduction of DA^H to S5 and of DA^V to K^{U}, proving that the satisfiability of DA is reducible to the satisfiability of $\mathsf{S5} \times \mathsf{K}^{\mathsf{U}}$, which is decidable (Gabbay *et al.* 2003, Theorem 6.58). [DA^H to S5]. Take a fresh atom p and define a translation (Boolean clauses omitted): $t(\Diamond\!\!\!-_{\mathsf{U}}\varphi) = \Diamond t(\varphi)$; $t(\Diamond\!\!\!-_{\mathsf{B}}\varphi) = \Diamond(p \wedge t(\varphi))$. We prove: φ is satisfiable in $\mathfrak{D}$ iff $t(\varphi)$ is satisfiable in the class

[8] The proof goes through also for the weaker logic $\mathsf{KD45} \times \mathsf{K}^{\mathsf{U}}$.

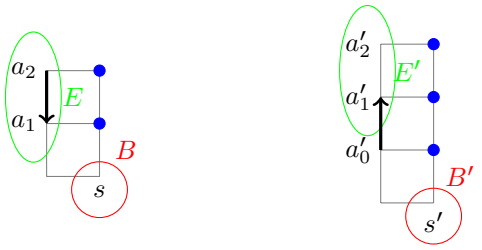

Figure 3: Two frames $\mathcal{F}$ and $\mathcal{F}'$ for the proof of Theorem 5.

of universal frames. [LEFT TO RIGHT] Assume $\mathcal{M}, x \vDash \varphi$. Build $\mathcal{M}' = \langle S', \mathcal{V}'\rangle$ with an extra atom p where: $S' = S$ and $\mathcal{V}' = \mathcal{V} \cup \{\langle p, S\rangle\}$. A simple induction shows that: $\mathcal{M}, x \vDash \varphi$ iff $\mathcal{M}', x \vDash t(\varphi)$. [RIGHT TO LEFT] Assume $\mathcal{M}, x \vDash t(\varphi)$. Build $\mathcal{M}' = \langle S', B, \mathcal{V}'\rangle$ where: $S' = S$, $B = \mathcal{V}(p)$ and $\mathcal{V}' = \mathcal{V} - \{\langle p, S\rangle\}$. A simple induction shows that: $\mathcal{M}, x \vDash t(\varphi)$ iff $\mathcal{M}' \vDash \varphi$. [$\mathsf{DA}^V$ to K^{U}] Similar. □

Proof sketch of Theorem 5. Consider the frames $\mathcal{F}$ and $\mathcal{F}'$ of Figure 3. We have that $\forall \psi \in \mathcal{L}^E$ $\mathcal{F}' \vDash \psi \Rightarrow \mathcal{F} \vDash \psi$, while at the same time, E' in $\mathcal{F}'$ is conflict free. □

Proof sketch of Proposition 4. Simple semantic arguments can be used to prove the claims. We do it for Formulae (8) and (13). [Formula (8)] Assume $\mathcal{M}, (s, a) \vDash \boxminus_{\mathsf{B}}(\Box_{\mathsf{U}}(\varphi \rightarrow \psi) \wedge \Diamond_{\mathsf{U}}\sigma)$. It follows, by the semantics of $\boxminus_{\mathsf{B}}$ and $\Box_{\mathsf{U}}$ that $\mathcal{M}, (s, a) \vDash \boxminus_{\mathsf{B}} \Box_{\mathsf{U}} (\varphi \rightarrow \psi) \wedge \boxminus_{\mathsf{B}} \Diamond_{\mathsf{U}} \sigma$ and then, by propositional reasoning, $\mathcal{M}, (s, a) \vDash \boxminus_{\mathsf{B}}(\Box_{\mathsf{U}}\varphi \wedge \Diamond_{\mathsf{U}}\sigma) \rightarrow \boxminus_{\mathsf{B}}(\Box_{\mathsf{U}}\psi \wedge \Diamond_{\mathsf{U}}\sigma)$, which proves the claim. [Formula (13)] Assume $\mathcal{M}, (s, a) \vDash \boxminus_{\mathsf{B}}(\Box_{\mathsf{U}}\varphi \wedge \Diamond_{\mathsf{E}}(\sigma \wedge \boxminus_{\mathsf{U}}\psi))$. It follows, by the semantics of $\boxminus_{\mathsf{B}}$ and $\Box_{\mathsf{U}}$ and propositional reasoning, that $\mathcal{M}, (s, a) \vDash \Box_{\mathsf{U}} \boxminus_{\mathsf{B}} (\Box_{\mathsf{U}}\varphi \wedge \Diamond_{\mathsf{E}}(\sigma \wedge \boxminus_{\mathsf{U}}\psi)) \wedge \boxminus_{\mathsf{B}} \Diamond_{\mathsf{E}} (\sigma \wedge \boxminus_{\mathsf{U}}\psi))$. From this, by again the semantics of $\boxminus_{\mathsf{B}}$ we conclude $\mathcal{M}, (s, a) \vDash \boxminus_{\mathsf{B}}(\Box_{\mathsf{U}}(\boxminus_{\mathsf{B}}(\Box_{\mathsf{U}}\varphi \wedge \Diamond_{\mathsf{E}}(\sigma \wedge \boxminus_{\mathsf{U}}\psi))) \wedge \Diamond_{\mathsf{E}}(\sigma \wedge \boxminus_{\mathsf{U}}\psi))$, which proves the claim. □

Proof sketch of Proposition 5. It suffices to exhibit some counterexamples. We do that for Formula (14). Consider the model $\mathcal{M} = \langle\langle \{s\}, \{s\}\rangle \times \langle \{a\}, \varnothing, \varnothing\rangle, \mathcal{V}\rangle$ consisting of one pair (s, a) s.t. $(s, a) \in \mathcal{V}(p)$ and $(s, a) \notin \mathcal{V}(\sigma)$. We have that $\mathcal{M}, (s, a) \vDash \neg \boxminus_{\mathsf{B}} (\Box_{\mathsf{U}}\varphi \wedge \Diamond_{\mathsf{U}}\sigma)$ and $\mathcal{M}, (s, a) \nvDash \boxminus_{\mathsf{B}}(\Box_{\mathsf{U}}(\neg \boxminus_{\mathsf{B}} (\Box_{\mathsf{U}}\varphi \wedge \Diamond_{\mathsf{U}}\sigma)) \wedge \Diamond_{\mathsf{U}}\sigma)$. □

Proof sketch of Proposition 6. We prove the claim of Formula (17). The other two are analogous. Assume $\mathcal{M}, (s, a) \vDash \neg SB\varphi \wedge \boxminus_{\mathsf{B}} \Diamond_{\mathsf{U}} \sigma$. It follows by Formula (5) that $\mathcal{M}, (s, a) \vDash \neg \boxminus_{\mathsf{B}} \Box_{\mathsf{U}}\varphi \wedge \boxminus_{\mathsf{B}} \Diamond_{\mathsf{U}} \sigma$, from which by the semantics of $\boxminus_{\mathsf{B}}$ we obtain $\mathcal{M}, (s, a) \vDash \boxminus_{\mathsf{B}}(\Box_{\mathsf{U}}(\neg \boxminus_{\mathsf{B}} \Box_{\mathsf{U}}\varphi \wedge \Diamond_{\mathsf{U}}\sigma) \wedge \boxminus_{\mathsf{B}} \Diamond_{\mathsf{U}} \sigma)$. Hence $\mathcal{M}, (s, a) \vDash SB\neg SB\varphi$. □

Belief Change Operations: A Short History of Nearly Everything, Told in Dynamic Logic of Propositional Assignments

Andreas Herzig
Université de Toulouse, CNRS, IRIT
http://www.irit.fr/~Andreas.Herzig

Abstract

We examine several belief change operations in the light of Dynamic Logic of Propositional Assignments DL-PA. We show that we can encode in a systematic way update operations (such as Winslett's 'Possible Models Approach') and revision operations (such as Dalal's) as particular DL-PA programs. Every DL-PA formula being equivalent to a boolean formula, we obtain syntactical counterparts for all these belief change operations.

Introduction

When a belief base B is modified in order to take into account a new piece of information A then we want to build a new belief base $B \circ A$. In that enterprise at least two reasoning problems are interesting.

- The *belief change problem* is a function problem: find a logical formula representing the modified base $B \circ A$.
- The *belief change consequence problem* (called implication problem in (Eiter and Gottlob 1992)) is a decision problem: for a given formula C, decide whether C is a consequence of $B \circ A$, i.e., decide whether the implication $(B \circ A) \rightarrow C$ is valid.

These problems are omnipresent in computer science, e.g. in databases, reasoning about actions, planning, logic programming, and in semantic web ontologies.

Many belief change operations can be found in the literature. Among the most prominent are Dalal's revision operation (Dalal 1988), Winslett's 'Possible Models Approach' (PMA) (Winslett 1988; 1990), Forbus's update operation (Forbus 1989), and Winslett's Standard Semantics (WSS) (Winslett 1995). We refer to (Herzig and Rifi 1999) for a detailed overview and comparison. According to Katsuno and Mendelzon's classical distinction between update and revision operations, the first three are update operations, while Dalal's is a revision operation (Katsuno and Mendelzon 1992). A recent discussion of the distinction between the two concepts and their relationship can be found in (Lang 2007).

Beyond the above concrete belief change operations, there exist more abstract frameworks. Alchourrón, Gärdenfors and Makinson (AGM) studied the properties that 'good' revision operations should have (Alchourrón, Gärdenfors, and Makinson 1985). Similarly, Katsuno and Mendelzon (KM) studied the properties 'good' update operations should have (Katsuno and Mendelzon 1992). The difference between revision and update can be illustrated by the example of a new edition of a dictionary that is advertised as being 'updated and revised': revision corrects information that turned out to be wrong (about a static world), while update takes into account new usages of words, i.e., the dynamics of the world.

Dalal's operation satisfies the AGM postulates for revision, and Winslett's and Forbus's operations satisfy the KM postulates for update. This is however not enough to *characterise* these operations: they validate properties beyond the AGM/KM postulates, such as Parikh's relevance postulate that is based on language splitting (Parikh 1999; Kourousias and Makinson 2007). Only few papers investigated this issue. Similarly, the related problem of syntactically constructing the new belief base $B \circ A$ has only received little attention. Indeed, the above concrete belief change operations were almost exclusively studied from a semantical perspective: instead of viewing $B \circ A$ as a formula, it is viewed as a set of models of classical propositional logic, alias a set of valuations. Therefore $\circ$ is not part of the object language but is in the metalanguage. We call $\circ$ a metalanguage operat*ion*, as opposed to object language operat*or*, i.e., a logical connective.

If the set of propositional variables $\mathbb{P}$ is finite then there is an easy recipe to construct a formula representing $B \circ A$: describe each valuation $v \in B \circ A$ by the conjunction of literals $\mathsf{Fml}(v) = \left(\bigwedge_{p \in v} p \right) \wedge \left(\bigwedge_{p \in \mathbb{P} \setminus v} \neg p \right)$ and take the disjunction of these big conjunctions $\mathsf{Fml}(v)$: the set of models of $\bigvee_{v \in B \circ A} \mathsf{Fml}(v)$ equals $B \circ A$, and therefore the former is the syntactical counterpart of the latter.

Is there a better, syntactic procedure building the new belief base? The answer is positive for WSS, which is the simplest update operation: an update procedure based on variable forgetting is in (Herzig and Rifi 1999) and its generalisation to literal forgetting is in (Herzig, Lang, and Marquis 2013). As to the PMA, there is an axiomatisation in (Herzig 1996) that can be turned into a decision procedure for the belief change consequence problem; it is however based on formulas in disjunctive normal form and is as such very close to the semantics. Finally, there

are syntactical belief change operations that are based on the computation of prime implicants and prime implicates and do not have semantics (Bienvenu, Herzig, and Qi 2008; Marchi, Bittencourt, and Perrussel 2010).

In this paper we propose a powerful yet simple logical framework for belief change: Dynamic Logic of Propositional Assignments, abbreviated DL-PA (Herzig et al. 2011; Balbiani, Herzig, and Troquard 2013). DL-PA is a simple instantiation of Propositional Dynamic Logic PDL (Harel 1984; Harel, Kozen, and Tiuryn 2000): instead of PDL's abstract atomic programs, its atomic programs are assignments of propositional variables to either true or false, written $p{\leftarrow}\top$ and $p{\leftarrow}\bot$. Just as in PDL, these atomic programs can be combined by means of program operators: sequential and nondeterministic composition, finite iteration, and test. In the present paper we moreover make use of a program operator that is less frequently considered in PDL, namely the converse operator. While DL-PA programs describe the evolution of the world, DL-PA formulas describe the state of the world. In particular, formulas of the form $\langle\pi\rangle\varphi$ express that φ is true after *some* possible execution of π, and $[\pi]\varphi$ expresses that φ is true after *every* possible execution of π.

The models of DL-PA are considerably simpler than PDL's Kripke models: valuations of classical propositional logic are enough. The assignment $p{\leftarrow}\top$ updates the current valuation by p, while the assignment $p{\leftarrow}\bot$ updates it by $\neg p$. For example, the program $\mathsf{emp}_{\mathsf{Ann,CS}}{\leftarrow}\bot$ updates the current valuation by the fact that Ann is not an employee of the CS department. The other way round, the program $(\mathsf{emp}_{\mathsf{Ann,CS}}{\leftarrow}\bot)^-$ undoes that update. Consider the formula

$$\langle \mathsf{emp}_{\mathsf{Ann,CS}}{\leftarrow}\bot^-\rangle(\mathsf{emp}_{\mathsf{Ann,CS}} \wedge \mathsf{emp}_{\mathsf{Bob,CS}})$$

It says that possibly, before Ann was fired from the CS department, both she and Bob were employees there. This means that it is possible that the belief base $\mathsf{emp}_{\mathsf{Ann,CS}} \wedge \mathsf{emp}_{\mathsf{Bob,CS}}$ has been updated by $\neg\mathsf{emp}_{\mathsf{Ann,CS}}$, resulting in the current belief base. The current base is therefore nothing but

$$(\mathsf{emp}_{\mathsf{Ann,CS}} \wedge \mathsf{emp}_{\mathsf{Bob,CS}}) \circ \neg\mathsf{emp}_{\mathsf{Ann,CS}}$$

This can be generalised: we have

$$B \circ p = \|\langle (p{\leftarrow}\top)^-\rangle B\|$$
$$B \circ \neg p = \|\langle (p{\leftarrow}\bot)^-\rangle B\|$$

for every propositional variable p and each of the update operations among PMA, WSS, and Forbus, where the function $\|.\|$ associates to each formula the set of valuations where it is true. (The corresponding equality for Dalal's revision operation is a bit more involved and will be given later.)

The first contribution of the present paper is to go beyond such updates by literals and to associate to every input formula A a program π_A implementing the update by A. Precisely, these programs π_A depend on the belief change operation under concern, and WSS, PMA and Forbus's operation will be implemented by different programs π_A^{wss}, π_A^{forbus}, and π_A^{pma}. For instance, we will show that the WSS update by the disjunction $p{\vee}q$ is captured by the program

$$\pi^{\mathsf{wss}}_{p\vee q} = (p{\leftarrow}\top \cup p{\leftarrow}\bot); (q{\leftarrow}\top \cup q{\leftarrow}\bot); p{\vee}q?$$

which is equivalent to

$$(p{\leftarrow}\top; q{\leftarrow}\top) \cup (p{\leftarrow}\top; q{\leftarrow}\bot) \cup (p{\leftarrow}\bot; q{\leftarrow}\top).$$

We establish that being in a state where B was updated by A is the same as being in a state where B was true before the update program π_A was executed. Formally, we prove that

$$B \circ A \;=\; \|\langle(\pi_A)^-\rangle B\|$$

for each of the belief change operations $\circ$ and associated family of programs π_A that we consider: WSS, PMA, Forbus, and Dalal.[1]

It is shown in (Herzig et al. 2011; Balbiani, Herzig, and Troquard 2013) that every DL-PA formula can be reduced to an equivalent propositional formula. It is shown in the latter paper that the reduction can be extended to the converse operator. We thereby obtain a syntactical representation of the modified belief base in terms of a boolean formula. This is the second contribution of our paper.

In the next two sections we settle some notations and introduce DL-PA. In the remaining sections we embed several belief change semantics into DL-PA: Winslett's WSS, Winslett's PMA, and Forbus's update operation, and finally Dalal's belief revision operation.

Background: propositional logic

Here are some notations and conventions for propositional logic, as well as the definitions of symmetric difference and Hamming distance between propositional valuations.

A *valuation* associates a truth value to each propositional variable in the countable set $\mathbb{P} = \{p, q, \ldots\}$. We identify valuations with subsets of $\mathbb{P}$ and use v, v_1, v_2, etc. to denote them. The set of all valuations is $\mathbb{V} = 2^{\mathbb{P}}$. Sometimes we write $v(p) = 1$ when $p \in v$ and $v(p) = 0$ when $p \notin v$.

The *symmetric difference* between two valuations v_1 and v_2 is the set of all those p such that $v_1(p) \neq v_2(p)$. Formally, it is defined as

$$v_1 \dot{-} v_2 = (v_1 \setminus v_2) \cup (v_2 \setminus v_1)$$

For example, $\{p, q\} \dot{-} \{q, r, s\} = \{p, r, s\}$.

The *Hamming distance* between v_1 and v_2 is is the number of all those p such that $v_1(p) \neq v_2(p)$. Formally, it is defined to be $\mathsf{card}(v_1 \dot{-} v_2)$, i.e., the cardinality of the symmetric difference between v_1 and v_2. For example, the Hamming distance between $\{p, q\}$ and $\{q, r, s\}$ is $\mathsf{card}(\{p, r, s\}) = 3$. Note that the Hamming distance might be infinite: for instance, $\mathsf{card}(\emptyset \dot{-} \mathbb{P}) = \infty$.

Boolean formulas (also called *propositional formulas*) are built from propositional variables by means of the standard boolean connectives. We will in particular make use of the exclusive disjunction, denoted by $\oplus$. Boolean formulas are denoted by A, B, C, etc. Contrasting with that, *modal formulas*—to be defined in the next section—will be denoted by φ, ψ, etc. For a given boolean formula A, the set of variables occurring in A is denoted by $\mathbb{P}_A$. For example, $\mathbb{P}_{p\vee\neg q} = \{p, q\}$.

A given valuation determines the truth value of each boolean formula. An *A-valuation* is a valuation where the boolean formula A is true.

[1] In the case of Dalal's revision operation, the program actually also depends on the base B. This is as it should be, because AGM revision operations involve checking whether $A{\wedge}B$ is satisfiable.

Dynamic Logic of Propositional Assignments

In this section we define syntax and semantics of Dynamic Logic of Propositional Assignments DL-PA and state decidability and complexity results. Based on earlier work by Tiomkin and Makowski and by van Eijck (Tiomkin and Makowsky 1985; van Eijck 2000), star-free DL-PA was studied in (Herzig et al. 2011) and full DL-PA in (Balbiani, Herzig, and Troquard 2013).

Language The language of DL-PA is defined by the following grammar:

$$\begin{array}{lll} \varphi & ::= & p \mid \top \mid \bot \mid \neg\varphi \mid \varphi \vee \varphi \mid \langle\pi\rangle\varphi \\ \pi & ::= & p{\leftarrow}\top \mid p{\leftarrow}\bot \mid \pi;\pi \mid \pi \cup \pi \mid \pi^* \mid \pi^- \mid \varphi? \end{array}$$

where p ranges over $\mathbb{P}$. So the *atomic programs* of the language of DL-PA are of the form $p{\leftarrow}\top$ and $p{\leftarrow}\bot$. The operators of sequential composition (";"), nondeterministic composition ("$\cup$"), finite iteration ("$(.)^*$", the so-called Kleene star), and test ("$(.)?$") are familiar from PDL. The operator "$(.)^-$" is the converse operator. The *star-free fragment* of DL-PA is the subset of the language made up of formulas without the Kleene star "$(.)^*$".

The set of variables occurring in φ is denoted by $\mathbb{P}_\varphi$, just as for boolean formulas. The *length* of a formula φ, denoted by $|\varphi|$, is the number of symbols used to write down φ, without "$\langle$", "$\rangle$", and parentheses. For example, $|\langle q{\leftarrow}\top\rangle(q \vee r)| = 3{+}3 = 6$. The length of a program π, denoted by $|\pi|$, is defined in the same way. For example, $|p{\leftarrow}\bot; p?| = 6$. We have $\mathsf{card}(\mathbb{P}_\varphi) \leq |\varphi|$ for every φ.

We abbreviate the logical connectives $\wedge$, $\rightarrow$, $\leftrightarrow$, and $\oplus$ in the usual way. Moreover, $[\pi]\varphi$ abbreviates $\neg\langle\pi\rangle\neg\varphi$. Several program abbreviations are familiar from PDL. First, skip abbreviates $\top?$ ("nothing happens"). Second, the conditional "if φ then π_1 else π_2" is expressed by $(\varphi?;\pi_1) \cup (\neg\varphi?;\pi_2)$. Third, the loop "while φ do π" is expressed by $(\varphi?;\pi)^*;\neg\varphi?$. Let us moreover recursively define the n-th iteration of π and the iteration up to n of π, for $n \geq 0$:

$$\pi^n = \begin{cases} \mathsf{skip} & \text{if } n = 0 \\ \pi;\pi^{n-1} & \text{if } n \geq 1 \end{cases}$$

$$\pi^{\leq n} = \begin{cases} \mathsf{skip} & \text{if } n = 0 \\ (\mathsf{skip} \cup \pi);\pi^{\leq n-1} & \text{if } n \geq 1 \end{cases}$$

Finally, we introduce assignments of literals to variables by means of the following two abbreviations:

$$\begin{array}{rl} p{\leftarrow}q = & \text{if } q \text{ then } p{\leftarrow}\top \text{ else } p{\leftarrow}\bot \\ = & (q?; p{\leftarrow}\top) \cup (\neg q?; p{\leftarrow}\bot) \\ p{\leftarrow}\neg q = & \text{if } q \text{ then } p{\leftarrow}\bot \text{ else } p{\leftarrow}\top \\ = & (q?; p{\leftarrow}\bot) \cup (\neg q?; p{\leftarrow}\top) \end{array}$$

The former assigns to p the truth value of q, while the latter assigns to p the truth value of $\neg q$. In particular, the program $p{\leftarrow}\neg p$ flips the truth value of p. Note that the abbreviations $p{\leftarrow}q$ and $p{\leftarrow}\neg q$ have constant length (namely 14).

Semantics DL-PA programs are interpreted by means of a (unique) *relation between valuations*. The atomic programs $p{\leftarrow}\top$ and $p{\leftarrow}\bot$ update valuations in the obvious way, and complex programs are interpreted just as in PDL by mutual recursion. Table 1 gives the interpretation of the DL-PA connectives.

$$\begin{array}{rcl} \|p\| & = & \{v \ : \ p \in v\} \\ \|\top\| & = & \mathbb{V} \ = \ 2^{\mathbb{P}} \\ \|\bot\| & = & \emptyset \\ \|\neg\varphi\| & = & 2^{\mathbb{P}} \setminus \|\varphi\| \\ \|\varphi \vee \psi\| & = & \|\varphi\| \cup \|\psi\| \\ \|\langle\pi\rangle\varphi\| & = & \{v \ : \ \text{there is } v_1 \text{ s.t. } (v, v_1) \in \|\pi\| \text{ and } v_1 \in \|\varphi\|\} \\ \|p{\leftarrow}\top\| & = & \{(v_1, v_2) \ : \ v_2 = v_1 \cup \{p\}\} \\ \|p{\leftarrow}\bot\| & = & \{(v_1, v_2) \ : \ v_2 = v_1 \setminus \{p\}\} \\ \|\pi;\pi'\| & = & \|\pi\| \circ \|\pi'\| \\ \|\pi \cup \pi'\| & = & \|\pi\| \cup \|\pi'\| \\ \|\pi^*\| & = & \bigcup_{k \in \mathbb{N}_0} (\|\pi\|)^k \\ \|\pi^-\| & = & \|\pi\|^{-1} \\ \|\varphi?\| & = & \{(v, v) \ : \ v \in \|\varphi\|\} \end{array}$$

Table 1: Interpretation of the DL-PA connectives.

Two formulas φ_1 and φ_2 are *formula equivalent* if $\|\varphi_1\| = \|\varphi_2\|$. Two programs π_1 and π_2 are *program equivalent* if $\|\pi_1\| = \|\pi_2\|$. For example, $\mathsf{skip};\pi$ is program equivalent to π, and $\mathsf{skip} \cup p{\leftarrow}\neg p$ is program equivalent to $p{\leftarrow}\top \cup p{\leftarrow}\bot$. We write $\pi_1 \equiv \pi_2$ when π_1 and π_2 are progam equivalent.

Proposition 1 (Proposition 10 in (Balbiani, Herzig, and Troquard 2013)). *The following program equivalences are* DL-PA *valid:*

$$\begin{array}{rll} p?; p{\leftarrow}\top & \equiv & p? \\ \neg p?; p{\leftarrow}\bot & \equiv & \neg p? \\ p{\leftarrow}\tau; p{\leftarrow}\top & \equiv & p{\leftarrow}\top \\ p{\leftarrow}\tau; p{\leftarrow}\bot & \equiv & p{\leftarrow}\bot \\ p{\leftarrow}\tau; q{\leftarrow}\top & \equiv & q{\leftarrow}\top; p{\leftarrow}\tau \qquad \textit{if } p \neq q \\ p{\leftarrow}\tau; q{\leftarrow}\bot & \equiv & q{\leftarrow}\bot; p{\leftarrow}\tau \qquad \textit{if } p \neq q \end{array}$$

where τ is a placeholder for either true or false.

An *expression* is a formula or a program. When we say that two expressions are equivalent we mean program equivalence if we are talking about programs, and formula equivalence otherwise. Equivalence is preserved under replacement of a sub-expression by an equivalent expression (Balbiani, Herzig, and Troquard 2013, Proposition 7).

A formula φ is DL-PA *valid* if it is formula equivalent to $\top$, i.e., if $\|\varphi\| = 2^{\mathbb{P}}$. It is DL-PA *satisfiable* if it is not formula equivalent to $\bot$, i.e., if $\|\varphi\| \neq \emptyset$. For example, the formulas $\langle p{\leftarrow}\bot\rangle\top$ and $\langle p{\leftarrow}\top\rangle\varphi \leftrightarrow \neg\langle p{\leftarrow}\top\rangle\neg\varphi$ are DL-PA valid. Other examples of DL-PA validities are $\langle p{\leftarrow}\top\rangle p$ and $\langle p{\leftarrow}\bot\rangle\neg p$. The valid schemas $\varphi \rightarrow [\pi]\langle\pi^-\rangle\varphi$ and $\varphi \rightarrow [\pi^-]\langle\pi\rangle\varphi$ are inherited from converse PDL; they are called the *conversion axioms*. Moreover, $\varphi \rightarrow [\pi]\varphi$ is valid if and only if $\langle\pi^-\rangle\varphi \rightarrow \varphi$ is valid. The two senses of the "if and only if" correspond to the two so-called *conversion rules*.

$$

\end{aligned}
$$

Table 2: Reduction axioms for the converse operator.

Observe that if p does not occur in φ then both $\varphi \to \langle p{\leftarrow}\top\rangle\varphi$ and $\varphi \to \langle p{\leftarrow}\bot\rangle\varphi$ are valid. This is due to the following semantical property that is instrumental in the proof of several results in the rest of the paper.

Proposition 2. *Suppose $\mathbb{P}_\varphi \cap P = \emptyset$, i.e., none of the variables in P occurs in φ. Then $v \cup P \in \|\varphi\|$ iff $v \setminus P \in \|\varphi\|$.*

Reduction to propositional logic In PDL, all program operators but the Kleene star can be eliminated. In contrast, *all* program operators can be eliminated in DL-PA. We describe this in detail now.

The first step is to eliminate the converse operator. Table 2 lists the program equivalences by means of which we can eliminate the converse operator with only linear increase in program length.[2]

Proposition 3. *For every program π there is an equivalent π' such that no converse operator occurs in π' and such that the length of π' is linear in the length of π.*

For example, the converse of assignments of literals to variables are reduced as follows:

$$
p{\leftarrow}q^- \equiv \begin{cases} \mathsf{skip} & \text{if } q = p\\ p{\leftrightarrow}q?;(p{\leftarrow}\top \cup p{\leftarrow}\bot) & \text{otherwise}\end{cases}
$$

$$
p{\leftarrow}\neg q^- \equiv \begin{cases} p{\leftarrow}\neg p & \text{if } q = p\\ p{\oplus}q?;(p{\leftarrow}\top \cup p{\leftarrow}\bot) & \text{otherwise}\end{cases}
$$

The second step is to eliminate the Kleene star.

[2]This simplifies the original proof of (Balbiani, Herzig, and Troquard 2013, Section VII.B), which instead of directly stating a reduction axiom for the Kleene star rather relies on its preliminary elimination.

We might as well apply de Giacomo's general elimination technique(de Giacomo 1996). It is however more complicated than ours. He proceeds by first applying the four last reduction axioms of Table 2 to the original formula φ_0 in order to push down the converse operator. For the resulting formula φ_1, a theory Γ_{φ_1} is built that is made up of instances of the conversion axioms for all symbols occurring in φ and that are prefixed by a master modality relative to the symbols of φ. Finally, it is proved that the original φ_0 is a theorem if and only if $\Gamma \models \varphi_1'$, where φ_1' is obtained from φ_1 by considering the converse of atomic programs as new program names (so φ_1' is without converse operators). Overall, this is less direct and not as simple as the present reduction axioms.

$$
\begin{aligned}
\mathsf{flip}^1(P) &= p_1{\leftarrow}\neg p_1 \cup \cdots \cup p_n{\leftarrow}\neg p_n\\
\mathsf{flip}^{\geq 0}(P) &= (p_1{\leftarrow}\top \cup p_1{\leftarrow}\bot);\cdots;(p_n{\leftarrow}\top \cup p_n{\leftarrow}\bot)\\
\mathsf{store}(P) &= p_1'{\leftarrow}p_1;\cdots;p_n'{\leftarrow}p_n\\
\mathsf{restore}^1(P) &= (p_1{\oplus}p_1'?;p_1{\leftarrow}p_1') \cup \cdots \cup (p_n{\oplus}p_n'?;p_n{\leftarrow}p_n')\\
\mathsf{restore}^{\geq 0}(P) &= (\mathsf{skip} \cup p_1{\leftarrow}p_1');\cdots;(\mathsf{skip} \cup p_n{\leftarrow}p_n')
\end{aligned}
$$

Table 3: Some useful DL-PA programs, where $P = \{p_1,\ldots,p_n\}$. For $n = 0$ all programs are supposed to equal skip. In $\mathsf{store}(P)$, $\mathsf{restore}^1(P)$, and $\mathsf{restore}^{\geq 0}(P)$, the p_i' are supposed to be fresh.

Proposition 4 (Theorem 1 of (Balbiani, Herzig, and Troquard 2013)). *For every converse-free π there is an equivalent π' such that no Kleene star occurs in π'.*

The resulting formula is in star-free PDL, for which it is known that all the program operators can be eliminated. Once this has been done, modal operators only contain atomic programs. Such modal operators are both serial and deterministic and therefore distribute over negation and disjunction: $\langle p{\leftarrow}\bot\rangle\neg\varphi$ is equivalent to $\neg\langle p{\leftarrow}\bot\rangle\varphi$, and $\langle p{\leftarrow}\bot\rangle(\varphi_1 \vee \varphi_2)$ is equivalent to $\langle p{\leftarrow}\bot\rangle\varphi_1 \vee \langle p{\leftarrow}\bot\rangle\varphi_2$. They can finally be eliminated when they face a propositional variable, according to the following formula equivalences:

$$
\langle p{\leftarrow}\top\rangle q \leftrightarrow \begin{cases}\top & \text{if } q = p\\ q & \text{otherwise}\end{cases}
$$

$$
\langle p{\leftarrow}\bot\rangle q \leftrightarrow \begin{cases}\bot & \text{if } q = p\\ q & \text{otherwise}\end{cases}
$$

For example, $\langle p{\leftarrow}\bot\rangle p \vee \langle p{\leftarrow}\bot\rangle\neg r$ is equivalent to $\bot \vee \neg r$.

Together, these three steps make up a complete set of reduction axioms: for every formula there is an equivalent boolean formula.

Complexity In this paper we only need complexity results for star-free DL-PA. The complexity of both model checking and satisfiability checking for the converse-free and star-free fragment of the language of DL-PA is shown to be PSPACE complete in (Herzig et al. 2011). By Proposition 3 these results transfer to star-free DL-PA with the converse operator.

Some useful DL-PA programs Table 3 collects some DL-PA programs that are going to be convenient in our enterprise. In that table, P is the set of variables $\{p_1,\ldots,p_n\}$, and P' is the set of variables p_k' such that p_k is in P and p_k' is *fresh*: we suppose that p_k' does not occur in P (or rather, in the formula under consideration). In order to alleviate notation we drop set parentheses and write $\mathsf{flip}^1(p)$ instead of $\mathsf{flip}^1(\{p\})$, etc. Note that the length of each program of Table 3 is linear in the cardinality of the set P.

The first two programs of Table 3 change the truth values of some of the variables in the set P. The program $\mathsf{flip}^1(P)$ flips some nondeterministically chosen variable of P. So the iteration $\mathsf{flip}^1(P)^n$ does this n times and $\mathsf{flip}^1(P)^{\leq n}$ does this

at most n times. For example, we have

$$\begin{aligned}\mathsf{flip}^1(p)^1 &= p{\leftarrow}\neg p;\mathsf{skip}\\ &\equiv p{\leftarrow}\neg p\\ \mathsf{flip}^1(p)^{\leq 1} &= (\mathsf{skip}\cup p{\leftarrow}\neg p);\mathsf{skip}\\ &\equiv p{\leftarrow}\top\cup p{\leftarrow}\bot\\ &= \mathsf{flip}^{\geq 0}(p)\end{aligned}$$

The program $\mathsf{flip}^{\geq 0}(P)$ nondeterministically changes the truth value of some of the variables in P. It is program equivalent to $\mathsf{flip}^1(P)^{\leq n}$ while being shorter.[3] It actually implements the operation of *forgetting* the values of the variables in P (Lang, Liberatore, and Marquis 2003). Note that $\mathsf{flip}^{\geq 0}(\mathbb{P}_\varphi);\varphi?$ relates any valuation v to all φ-valuations where the variables outside φ have the same truth values.

The last three programs of Table 3 store or restore some of the values of the variables of P. The program $\mathsf{store}(P)$ stores the truth value of each variable p_k of P by means of a fresh variable p'_k. When the truth values of p_k and p'_k differ then we say that p_k is marked; else we say that p_k is unmarked. The program $\mathsf{restore}^1(P)$ restores one of the marked variables p_k of P: after it, some p_k has the truth value of p'_k. Finally, $\mathsf{restore}^{\geq 0}(P)$ restores zero or more marked variables of P.

Proposition 5. *The following hold:*

1. $(v_1, v_2) \in \|\mathsf{flip}^1(p)\|$ *iff* $\mathsf{card}(v_1 \dot{-} v_2) = 1$.
2. $(v_1, v_2) \in \|\mathsf{flip}^1(P)^{\leq n}\|$ *iff* $\mathsf{card}(v_1 \dot{-} v_2) \leq n$.
3. $(v_1, v_2) \in \|\mathsf{flip}^{\geq 0}(P)\|$ *iff* $v_1 \dot{-} v_2 \subseteq P$.
4. $(v_1, v_2) \in \|\mathsf{store}(P)\|$ *iff* $v_2 = (v_1 \setminus P') \cup \{p' \,:\, p \in v_1 \cap P\}$.
5. $(v_1, v_2) \in \|\mathsf{restore}^1(P)\|$ *iff there is* $p_k \in P$ *such that* $v_1 \dot{-} v_2 = \{p_k\}$ *and* $v_1(p_k) \neq v_1(p'_k)$.
6. $(v_1, v_2) \in \|\mathsf{restore}^{\geq 0}(P)\|$ *iff there is* $S \subseteq P$ *such that* $v_1 \dot{-} v_2 = S$ *and* $v_1(p_k) \neq v_1(p'_k)$ *for every* $p_k \in S$.

Note that $\mathsf{flip}^1(P)^n$ may flip less than exactly n variables: for example, $\mathsf{flip}^1(P)^2$ may flip the same variable twice and in that case has the same effect as skip. So $(v_1, v_2) \in \|\mathsf{flip}^1(P)^n\|$ does not imply that the Hammming distance between v_1 and v_2 is n. But what matters is that in Proposition 8 below (and Theorem 3 that is based on it), the occurrence of $\mathsf{flip}^1(\mathbb{P}_A)^m$ is preceded by the test $\mathsf{H}(A, \geq m)?$, which when successfully executed guarantee that the Hamming distance is n.

Proposition 6. *The following programs are equivalent:*

$$\begin{aligned}(\mathsf{flip}^{\geq 0}(P))^- &\equiv \mathsf{flip}^{\geq 0}(P)\\ (\mathsf{flip}^1(P)^n)^- &\equiv \mathsf{flip}^1(P)^n\\ (\mathsf{flip}^1(P)^{\leq n})^- &\equiv \mathsf{flip}^1(P)^{\leq n}\end{aligned}$$

Some useful DL-PA formulas Table 4 collects some interesting DL-PA formulas: $\mathsf{Valid}(\varphi)$ expresses that the formula φ is valid and $\mathsf{Sat}(\varphi)$ expresses that φ is satisfiable. The former is equivalent to $[\mathsf{flip}^{\geq 0}(\mathbb{P}_\varphi);\varphi?]\top$ and the latter is equivalent to $\langle\mathsf{flip}^{\geq 0}(\mathbb{P}_\varphi);\varphi?\rangle\top$. The formula $\mathsf{D}(\varphi, P)$ is true at a valuation v exactly when there is a closest φ-valuation whose symmetric difference with v is P. The formula $\mathsf{H}(\varphi, \geq m)$ is true at a valuation v exactly when the closest φ-valuations in the sense of the Hamming distance differ in at least m variables from v. For example:

$$\begin{aligned}\mathsf{Valid}(\varphi) &= [\mathsf{flip}^{\geq 0}(\mathbb{P}_\varphi)]\varphi\\ \mathsf{Sat}(\varphi) &= \langle\mathsf{flip}^{\geq 0}(\mathbb{P}_\varphi)\rangle\varphi\\ \mathsf{D}(\varphi, P) &= \langle\mathsf{flip}^{\geq 0}(P)\rangle\varphi \wedge \neg\langle\bigcup_{p\in P}\mathsf{flip}^{\geq 0}(P\setminus\{p\})\rangle\varphi\\ \mathsf{H}(\varphi, \geq m) &= \begin{cases}\top & \text{if } m = 0\\ \neg\langle\mathsf{flip}^1(\mathbb{P}_\varphi)^{\leq m-1}\rangle\varphi & \text{if } m \geq 1\end{cases}\end{aligned}$$

Table 4: Some useful DL-PA formulas, where φ is a formula, $P \subseteq \mathbb{P}_\varphi$ is a nonempty set of propositional variables, and $m \leq \mathsf{card}(\mathbb{P}_\varphi)$ is a non-negative integer.

$$\begin{aligned}\mathsf{H}(p, \geq 1) &= \neg\langle\mathsf{flip}^1(p)^{\leq 0}\rangle p\\ &= \neg\langle\mathsf{skip}\rangle p\\ &\leftrightarrow \neg p\\ \mathsf{H}(p\vee q, \geq 1) &= \neg\langle\mathsf{flip}^1(p, q)^{\leq 0}\rangle(p\vee q)\\ &\leftrightarrow \neg p \wedge \neg q\\ \mathsf{H}(p\vee q, \geq 2) &= \neg\langle\mathsf{flip}^1(p, q)^{\leq 1}\rangle(p\vee q)\\ &\leftrightarrow \neg\langle\mathsf{skip}\cup p{\leftarrow}\neg p\cup q{\leftarrow}\neg q\rangle(p\vee q)\\ &\leftrightarrow \neg(p\vee q \vee \langle p{\leftarrow}\neg p\rangle(p\vee q) \wedge \langle q{\leftarrow}\neg q\rangle(p\vee q))\\ &\leftrightarrow \neg((p\vee q) \vee (\neg p\vee q) \vee (p \vee \neg q))\\ &\leftrightarrow \bot\end{aligned}$$

The first two items of the next proposition show that both validity checking and satisfiability checking can both be reduced to model checking.

Proposition 7. *Let v a valuation and φ a formula.*

1. $v \in \|\mathsf{Valid}(\varphi)\|$ *iff φ is valid.*
2. $v \in \|\mathsf{Sat}(\varphi)\|$ *iff φ is satisfiable.*
3. $v \in \|\mathsf{D}(\varphi, P)\|$ *iff there is a valuation* $v_1 \in \|\varphi\|$ *such that* $v \dot{-} v_1 = P$ *and there is no valuation* $v_2 \in \|\varphi\|$ *such that* $v \dot{-} v_2 \subset P$.
4. $v \in \|\mathsf{H}(\varphi, \geq m)\|$ *iff there is no valuation* $v_1 \in \|\varphi\|$ *such that* $\mathsf{card}(v \dot{-} v_1) < m$.

The length of each formula of Table 4 is polynomial in the length of φ. (For $\mathsf{Sat}(\varphi)$ it is linear, for $\mathsf{D}(\varphi, P)$ and $\mathsf{H}(\varphi, \geq m)$ it is quadratic.)

From the above programs we can build a program which checks whether the Hamming distance to the closest A-valuation is m.

Proposition 8. *Let $m \leq \mathsf{card}(\mathbb{P}_A)$. Then*

$$(v_1, v_2) \in \|\mathsf{H}(A, \geq m)?;\mathsf{flip}^1(\mathbb{P}_A)^m;A\|$$

[3] The length of $\mathsf{flip}^1(P)^n$ and $\mathsf{flip}^1(P)^{\leq n}$ is quadratic in n. The length of the latter would have been cubic had we adopted the somewhat more natural definition $\bigcup_{k\leq n}\mathsf{flip}^1(P)^k$.

if and only if $v_2 \in \|A\|$, $\mathsf{card}(v_1 \dot{-} v_2) = m$, *and there is no* $v_2' \in \|A\|$ *such that* $\mathsf{card}(v_1 \dot{-} v_2') < m$.

WSS

Winslett's standard semantics (WSS) (Winslett 1995) is a syntax-dependent update operation that is less conservative than the other operations that we are going to examine, in the sense that each of the other operations preserves at least as much information of the original knowledge base as the WSS.

Semantics of the WSS Let v be a valuation and A be a propositional formula. The *WSS update of v by A* is

$$\begin{aligned} v \diamond^{\mathsf{wss}} A &= \{v_1 \in \|A\| \ : \ v \dot{-} v_1 \subseteq \mathbb{P}_A\} \\ &= \{v_1 \in \|A\| \ : \ \text{for every } p \notin \mathbb{P}_A, v(p) = v_1(p)\} \end{aligned}$$

So the set $v \diamond^{\mathsf{wss}} A$ is the set of A-valuations that agree with v on all the variables that do not occur in A. For example,

$$\emptyset \diamond^{\mathsf{wss}} p \vee q \ = \ \{\{p\}, \{q\}, \{p, q\}\}$$

The WSS update operation is syntax-dependent: depending on their language, logically equivalent formulas A_1 and A_2 may update the same valuation v in different ways.

Let A and B be propositional formulas. The *WSS update of B by A* is obtained by collecting the updates of every B-valuation by A:

$$B \diamond^{\mathsf{wss}} A = \bigcup_{v \in \|B\|} v \diamond^{\mathsf{wss}} A$$

The operation $\diamond^{\mathsf{wss}}$ therefore takes two propositional formulas and returns a set of valuations. For example:

$$\begin{aligned} \neg p \wedge \neg q \diamond^{\mathsf{wss}} p &= \|p \wedge \neg q\| \\ \neg p \wedge \neg q \diamond^{\mathsf{wss}} p \vee q &= \|p \vee q\| \\ \neg q \diamond^{\mathsf{wss}} p &= \|p \wedge \neg q\| \\ \neg p \vee \neg q \diamond^{\mathsf{wss}} p &= \|p\| \end{aligned}$$

Expressing the WSS operation in DL-PA Let us turn to the problem of expressing WSS updates in DL-PA.

Theorem 1. *Let A, B be propositional formulas. Let π_A^{wss} be the* DL-PA *program*

$$\mathsf{flip}^{\geq 0}(\mathbb{P}_A); A?$$

Then $B \diamond^{\mathsf{wss}} A = \|\langle (\pi_A^{\mathsf{wss}})^- \rangle B\|$.

Via the program equivalences for the converse operator of Proposition 6, it follows that $B \diamond^{\mathsf{wss}} A = \|\langle A?; \mathsf{flip}^{\geq 0}(\mathbb{P}_A) \rangle B\|$.

For example, consider the input formula $A = p$. Then

$$\begin{aligned} \pi_p^{\mathsf{wss}} &= \mathsf{flip}^{\geq 0}(P); p? \\ &= (p \leftarrow \top \cup p \leftarrow \bot); p? \\ &\equiv (p \leftarrow \top; p?) \cup (p \leftarrow \bot; p?) \\ &\equiv p \leftarrow \top \\ (\pi_p^{\mathsf{wss}})^- &\equiv (p \leftarrow \top)^- \\ &\equiv p? \cup (p?; p \leftarrow \bot) \end{aligned}$$

For the base $B = \neg p \wedge q$ and the input $A = p$ we have:

$$\begin{aligned} \langle (\pi_A^{\mathsf{wss}})^- \rangle B &\leftrightarrow \langle p?; (p \leftarrow \top \cup p \leftarrow \bot) \rangle (\neg p \wedge q) \\ &\leftrightarrow p \wedge (\langle p \leftarrow \top \rangle (\neg p \wedge q) \vee \langle p \leftarrow \bot \rangle (\neg p \wedge q)) \\ &\leftrightarrow p \wedge (\bot \vee (\top \wedge q)) \\ &\leftrightarrow p \wedge q \end{aligned}$$

So the update of $\neg p \wedge q$ by p is equivalent to $p \wedge q$, as expected.

Observe that the length of π_A^{wss} is linear in the length of A.

PMA

Winslett's possible models approach (PMA) operation (Winslett 1988; 1990) is the belief update operation that is most cited and used, e.g. in database theory (Winslett 1995; Chomicki and Marcinkowski 2004), reasoning about actions and planning (Baral 1995), logic programming (Slota and Leite 2010) and in description logics and the semantic web (Baader et al. 2005; Liu et al. 2006; 2011).

The PMA is more conservative than the WSS, in the sense that it preserves more information from the base B. This is achieved by a principle of minimal change.

Semantics of the PMA operation Let v be a valuation and A be a propositional formula. The *PMA update of v by a formula A* is

$$v \diamond^{\mathsf{pma}} A = \{v_1 \in \|A\| \ : \ \text{there is no } v_2 \in \|A\| \text{ s.t. } v \dot{-} v_2 \subset v \dot{-} v_1\}$$

So the set $v \diamond^{\mathsf{pma}} A$ is the set of A-valuations that are closest to v w.r.t. symmetric difference. For example,

$$\begin{aligned} \emptyset \diamond^{\mathsf{pma}} p \vee q &= \{\{p\}, \{q\}\} \\ \emptyset \diamond^{\mathsf{pma}} (p \wedge q) \vee r &= \{\{p, q\}, \{r\}\} \end{aligned}$$

Let A and B be propositional formulas. Just as all the update operations *à la* Katsuno-Mendelzon (Katsuno and Mendelzon 1992), the *PMA update of B by A* collects the updates of each B-valuation by A:

$$B \diamond^{\mathsf{pma}} A = \bigcup_{v \in \|B\|} v \diamond^{\mathsf{pma}} A$$

For example:

$$\begin{aligned} \neg p \wedge \neg q \diamond^{\mathsf{pma}} p &= \|p \wedge \neg q\| \\ \neg q \diamond^{\mathsf{pma}} p &= \|p \wedge \neg q\| \\ \neg p \wedge \neg q \diamond^{\mathsf{pma}} p \vee q &= \|p \oplus q\| \\ \neg p \wedge \neg q \wedge \neg r \diamond^{\mathsf{pma}} (p \wedge q) \vee r &= \|(p \wedge q) \oplus r\| \end{aligned}$$

Expressing the PMA operation in DL-PA We now polynomially translate the update problem $B \diamond^{\mathsf{pma}} A$ into DL-PA: we define a family of update programs π_A^{pma} whose length is linear in the length of A.

It is tempting to define π_A^{pma} to be the program $\mathsf{while}\ \neg A\ \mathsf{do}\ \mathsf{flip}^1(\mathbb{P}_A)$, where while is as defined above. However, it does not have the exact behaviour of $\diamond^{\mathsf{pma}}$. Indeed, the interpretation of

$$\mathsf{while}\ \neg((p \wedge q) \vee r)\ \mathsf{do}\ \mathsf{flip}^1(\{p, q, r\})$$

relates the empty valuation to the four valuations $\{p, q\}$, $\{r\}$,

$\{p, r\}$, and $\{q, r\}$, while we have seen above that the PMA update of the empty valuation only outputs the first two of these valuations. Actually the above program defines an update operation with strength between WSS and PMA; it seems that it has not been considered in the literature up to now.

The exact DL-PA counterpart of the PMA updates is a bit more involved. The most straightforward way is to define π_A^{pma} to be the program

$$A?\ \cup\ \left(\neg A?;\ \bigcup_{\emptyset \subset P \subseteq \mathbb{P}_A} \mathsf{D}(A,P)?\ ;\ \mathsf{flip}^{\geq 0}(P)\ ;\ A?\right)$$

where $\mathsf{D}(A,P)$ is defined in Table 4. While it does the same job as $\diamond^{\mathsf{pma}}$, its length is exponential in the length of A due to the nondeterministic choice in the powerset of $\mathbb{P}_A$.

Our polynomial embedding of the PMA involves storing the values of variables as defined in Table 3.

Theorem 2. *Let A, B be propositional formulas. Let $\mathbb{P}_A = \{p_1, \ldots, p_n\}$ be set of variables occurring in A. Let $\mathbb{P}'_A = \{p'_1, \ldots, p'_n\}$ be such that the p'_k neither occur in A nor in B. Let π_A^{pma} be the following program:*

$$\begin{aligned}&\mathsf{store}(\mathbb{P}_A); \mathsf{flip}^{\geq 0}(\mathbb{P}_A); A?;\\ &[\mathsf{restore}^1(\mathbb{P}_A); \mathsf{restore}^{\geq 0}(\mathbb{P}_A)]\neg A?;\\ &\mathsf{flip}^{\geq 0}(\mathbb{P}'_A)\end{aligned}$$

Then $B \diamond^{\mathsf{pma}} A = \|\langle(\pi_A^{\mathsf{pma}})^-\rangle B\|$ for every valuation v.

The length of the program π_A^{pma} is linear in the length of A. It starts by saving the truth values of the variables of A by means of $\mathsf{store}(\mathbb{P}_A)$. It then goes to an A-valuation by $\mathsf{flip}^{\geq 0}(\mathbb{P}_A); A?$. The next step is to check whether all the ways one can get there are exclusively made up of $\neg A$-valuations: an A-valuation is disregarded if another A-valuation can be attained by fewer changes. Finally the copies p'_k of the variable p_k of A are forgotten by $\mathsf{flip}^{\geq 0}(\mathbb{P}'_A)$. For example,

$$\begin{aligned}\pi_p^{\mathsf{pma}} &= p'{\leftarrow}p; (p{\leftarrow}\top \cup p{\leftarrow}\bot); p?;\\ &\quad [p{\oplus}p'?; p{\leftarrow}p'; (\mathsf{skip} \cup p{\leftarrow}p')]\neg p?; (p'{\leftarrow}\top \cup p'{\leftarrow}\bot)\\ &\equiv p'{\leftarrow}p; p{\leftarrow}\top; [p{\oplus}p'?; p{\leftarrow}p']\neg p?; (p'{\leftarrow}\top \cup p'{\leftarrow}\bot)\\ &\equiv p'{\leftarrow}p; p{\leftarrow}\top; [p{\oplus}p'?]\neg p'?; (p'{\leftarrow}\top \cup p'{\leftarrow}\bot)\\ &\equiv p'{\leftarrow}p; p{\leftarrow}\top; (p'{\leftarrow}\top \cup p'{\leftarrow}\bot)\\ &\equiv p{\leftarrow}\top; (p'{\leftarrow}\top \cup p'{\leftarrow}\bot)\end{aligned}$$

As p' is fresh, the 'net effect' of the update program π_p^{pma} is just $p{\leftarrow}\top$, as expected. (Observe that while the programs π_p^{pma} and $p{\leftarrow}\top$ are not equivalent; what matters to us is that the formulas $\langle(\pi_p^{\mathsf{pma}})^-\rangle B$ and $\langle p{\leftarrow}\top^-\rangle B$ are so.)

Just as for the other update operators, the converse operator can be eliminated from π_A^{pma}. We do not state it because we were not able to simplify it further.

Forbus

Forbus's update operation (Forbus 1989) is even more conservative than Winslett's. It is based on minimisation of the Hamming distance between valuations.

Semantics of Forbus's operation *Forbus's update of v by A* is defined as:

$$v \diamond^{\mathsf{forbus}} A = \{v_1 \in \|A\| \ : \text{there is no } v_2 \in \|A\| \text{ such that } \mathsf{card}(v \dot{-} v_2) < \mathsf{card}(v \dot{-} v_1)\}$$

So the set $v \diamond^{\mathsf{forbus}} A$ is the set of A-valuations that are closest to v w.r.t. the Hamming distance. For example,

$$\begin{aligned}\emptyset \diamond^{\mathsf{forbus}} p \vee q &= \{\{p\}, \{q\}\}\\ \emptyset \diamond^{\mathsf{forbus}} (p \wedge q) \vee r &= \{\{r\}\}\end{aligned}$$

The last example illustrates the difference with the PMA update operation.

Let A and B be propositional formulas. Just as WSS and PMA updates, *Forbus's update of B by A* is the pointwise update of the B-valuations by A:

$$B \diamond^{\mathsf{forbus}} A = \bigcup_{v \in \|B\|} v \diamond^{\mathsf{forbus}} A$$

For example:

$$\begin{aligned}\neg p \wedge \neg q \diamond^{\mathsf{forbus}} p \vee q &= \|p \oplus q\|\\ \neg p \wedge \neg q \wedge \neg r \diamond^{\mathsf{forbus}} (p \wedge q) \vee r &= \|\neg p \wedge \neg q \wedge r\|\end{aligned}$$

Expressing Forbus's operation in DL-PA We polynomially transform update problems of the form $B \diamond^{\mathsf{forbus}} A$ into DL-PA: we define a family of update programs π_A^{forbus} whose length is cubic in the length of A.

Theorem 3. *Let A, B be propositional formulas. Let π_A^{forbus} be the following program:*

$$\left(\bigcup_{0 \leq m \leq \mathsf{card}(\mathbb{P}_A)} \mathsf{H}(A, \geq m)?; \mathsf{flip}^1(\mathbb{P}_A)^m\right); A?$$

Then $B \diamond^{\mathsf{forbus}} A = \|\langle(\pi_A^{\mathsf{forbus}})^-\rangle B\|$.

The length of the program π_A^{forbus} is cubic in the length of A. It nondeterministically selects an integer m, checks whether the Hamming distance to A is at least m, flips m variables, and checks whether A is true. For example:

$$\begin{aligned}\pi_p^{\mathsf{forbus}} &= \Big((\mathsf{H}(p, \geq 0)?; \mathsf{flip}^1(p)^0) \cup (\mathsf{H}(p, \geq 1)?; \mathsf{flip}^1(p)^1)\Big); p?\\ &\equiv \Big((\top?; \mathsf{skip}) \cup (\neg\langle \mathsf{flip}^1(p)^{\leq 0}\rangle p?; p{\leftarrow}\neg p)\Big); p?\\ &\equiv \Big(\mathsf{skip} \cup (\neg p?; p{\leftarrow}\neg p)\Big); p?\\ &\equiv p? \cup (\neg p?; p{\leftarrow}\neg p; p?)\\ &\equiv p{\leftarrow}\top\end{aligned}$$

Therefore $B \diamond^{\mathsf{forbus}} p = \|\langle p{\leftarrow}\top^-\rangle B\|$. Here is another example:

$$\begin{aligned}\pi_{p \vee q}^{\mathsf{forbus}} \equiv\ & (\mathsf{H}(p \vee q, \geq 0)?; \mathsf{flip}^1(p,q)^0; p \vee q?) \cup\\ & (\mathsf{H}(p \vee q, \geq 1)?; \mathsf{flip}^1(p,q)^1; p \vee q?) \cup\\ & (\mathsf{H}(p \vee q, \geq 2)?; \mathsf{flip}^1(p,q)^2; p \vee q?)\\ \equiv\ & (\top?; \mathsf{skip}; p \vee q?) \cup\\ & (\neg(p \vee q)?; (p{\leftarrow}\neg p \cup q{\leftarrow}\neg q); p \vee q?) \cup\\ & (\bot?; \mathsf{flip}^1(p,q)^2; p \vee q?)\\ \equiv\ & p \vee q? \cup (\neg(p \vee q)?; (p{\leftarrow}\neg p \cup q{\leftarrow}\neg q))\end{aligned}$$

The identity can be simplified by means of the program equivalences for the converse operator:

$$B\diamond^{\mathsf{forbus}}A = \|\langle A?; \Big(\bigcup_{0\le m\le \mathsf{card}(\mathbb{P}_A)} \mathsf{flip}^1(\mathbb{P}_A)^m; \mathsf{H}(A,\ge m)?\Big)\rangle B\|.$$

Dalal

According to Katsuno and Mendelzon's distinction (Katsuno and Mendelzon 1992), Dalal's belief change operation (Dalal 1988) is not an update operation but rather a revision operation. We follow the usage in the literature and denote it by $*^{\mathsf{dalal}}$ (and not by $\diamond^{\mathsf{dalal}}$).

We are going to capture $*^{\mathsf{dalal}}$ by a DL-PA program $\pi^{\mathsf{dalal}}_{A,B}$ which depends not only on the input A, but also on the base B. One of the reasons for that is that Dalal's definition distinguishes two cases: when B is satisfiable and when it is unsatisfiable. In the latter case the result of the update by A is stipulated to be $\|A\|$. This guarantees that the revised base is satisfiable as soon as the input formula A is so. This however does not square well with our embedding into DL-PA: in modal logic, when B is unsatisfiable then $\langle(\pi^{\mathsf{dalal}}_{A,B})^-\rangle B$ is unsatisfiable, too. We therefore consider a variant where the revision of an unsatisfiable base is unsatisfiable, too. In the end of the section we embed Dalal's original operation.

Semantics of Dalal's operation Just as Forbus's update operation, Dalal's revision operation is based on minimisation of the Hamming distance between valuations. However, as Dalal's is a revision operator we minimise globally instead of valuation-wise.

Let A and B be propositional formulas. *Dalal's revision of B by A* is defined as:

$$\begin{aligned} B*^{\mathsf{dalal}}A = \{v_A \in \|A\| \ &: \text{there is } v_B \in \|B\| \text{ such that} \\ &\mathsf{card}(v_A \dot{-} v_B) \le \mathsf{card}(v'_A \dot{-} v'_B) \\ &\text{for all } v'_A \in \|A\|, v'_B \in \|B\| \ \} \end{aligned}$$

It follows that when B is unsatisfiable then $B*^{\mathsf{dalal}}A$ is unsatisfiable. As mentioned above, our definition differs from Dalal's original definition in this point.

Here is an example:

$$\neg p\vee\neg q *^{\mathsf{dalal}} p \ = \ \|p\wedge\neg q\|$$

It illustrates that revision operations satisfy the preservation postulate, which says that when $B\wedge A$ is satisfiable then $B * A = \|B\wedge A\|$. This is the main difference with update operations: WSS, PMA, and Forbus's operation all agree that the update of $\neg p\vee\neg q$ by p should equal $\|p\|$.

Expressing Dalal's operation in DL-PA We polynomially transform revision problems of the form $B*^{\mathsf{dalal}}A$ into DL-PA: we define a family of revision programs $\pi^{\mathsf{dalal}}_{A,B}$ whose length is cubic in the length of A and B.

Theorem 4. *Let A, B be propositional formulas. Let $\pi^{\mathsf{dalal}}_{A,B}$ be the following program:*

$$\mathsf{flip}^{\ge 0}(\mathbb{P}_B)\ ;\ B?\ ;\ \left(\bigcup_{0\le m\le \mathsf{card}(\mathbb{P}_A)} [\mathsf{flip}^{\ge 0}(\mathbb{P}_B)\ ;\ B?]\mathsf{H}(A,\ge m)?\ ;\mathsf{flip}^1(\mathbb{P}_A)^m\right); A?$$

Then $B*^{\mathsf{dalal}}A = \|\langle(\pi^{\mathsf{dalal}}_{A,B})^-\rangle\top\|$.

The length of the program $\pi^{\mathsf{dalal}}_{A,B}$ is cubic in the sum of $|A| + |B|$. It visits all the B-valuations v_B via the program $\mathsf{flip}^{\ge 0}(\mathbb{P}_B); B?$, failing if there is no such valuation. It then nondeterministically selects an integer m such that the Hamming distance between the B-valuations and the A-valuations is at least m, flips m such variables, and checks whether A is true.

When the input is a literal then we obtain:

$$\begin{aligned} \pi^{\mathsf{dalal}}_{p,B} &= \mathsf{flip}^{\ge 0}(\mathbb{P}_B); B?\ ; \\ &\quad \Big(([\mathsf{flip}^{\ge 0}(\mathbb{P}_B); B?]\mathsf{H}(p,\ge 0)?\ ; \mathsf{flip}^1(p)^0) \cup \\ &\quad\ ([\mathsf{flip}^{\ge 0}(\mathbb{P}_B); B?]\mathsf{H}(p,\ge 1)?\ ; \mathsf{flip}^1(p)^1)\Big); p? \\ &= \mathsf{flip}^{\ge 0}(\mathbb{P}_B); B?\ ; \\ &\quad \Big([\mathsf{flip}^{\ge 0}(\mathbb{P}_B); B?]\top?; \mathsf{skip} \cup \\ &\quad\ ([\mathsf{flip}^{\ge 0}(\mathbb{P}_B); B?]\neg p?\ ; p{\leftarrow}\neg p)\Big); p? \\ &\equiv \mathsf{flip}^{\ge 0}(\mathbb{P}_B); B?\ ; \ \Big(p?\ \cup ([\mathsf{flip}^{\ge 0}(\mathbb{P}_B); B?]\neg p?\ ; p{\leftarrow}\top)\Big) \end{aligned}$$

and likewise for $B*^{\mathsf{dalal}}\neg p$. So when $B\wedge p$ is consistent then $\pi^{\mathsf{dalal}}_{p,B}$ goes to a $B\wedge p$-valuation, and updates by p otherwise.

The proof of Theorem 4 is in two steps: first we prove that $B*^{\mathsf{dalal}}A = \|\langle(\pi^{\mathsf{dalal}}_{A,B})^-\rangle B\|$, and then that $\|\langle(\pi^{\mathsf{dalal}}_{A,B})^-\rangle B\| = \|\langle(\pi^{\mathsf{dalal}}_{A,B})^-\rangle\top\|$. The second step relies on the validity of the equivalence $\langle B?; \mathsf{flip}^{\ge 0}(\mathbb{P}_B)\rangle\top \leftrightarrow \langle B?; \mathsf{flip}^{\ge 0}(\mathbb{P}_B)\rangle B$.

Finally, we note that we can also capture Dalal's original definition where the revision of an unsatisfiable B by A equals $\|A\|$ (instead of being unsatisfiable as with our definition). The modified identity which does the job is

$$B*^{\mathsf{dalal}}A = \|(\neg\mathsf{Sat}(B)\wedge A)\vee\langle(\pi^{\mathsf{dalal}}_{A,B})^-\rangle\top\|$$

Discussion

Let us come back to the belief change consequence problem. This is a decision problem, and tight complexity bounds are known for each of the operations that we have considered: the belief change consequence problem is

- NP complete for the WSS update operation (Herzig and Rifi 1999),
- $\mathrm{P}^{\mathrm{NP}[O(\log(n))]}$ for Dalal's belief revision operation, i.e., polynomial with $\log(n)$ calls to an NP oracle (Eiter and Gottlob 1992), and
- Π^2_p complete for Winslett's PMA update and Forbus's update (Eiter and Gottlob 1992).

Our embeddings are in the star-free fragment of the language of DL-PA. We therefore obtain a PSPACE upper bound for the complexity of deciding whether $(B\circ A)\to C$ is the case. So this is clearly suboptimal. However, the nesting of modal operators in our decision problems $B\to[\pi_A]C$ is bounded: for the WSS, there is a single $\forall$ quantification and for the PMA, $[\pi_A]C$ is of the form

$$[\pi_1; \mathsf{flip}^{\ge 0}(\mathbb{P}_A); \pi_2; [\pi_3; \mathsf{restore}^{\ge 0}(\mathbb{P}_A)]\neg A?]C$$

where π_1, π_2, π_3 are deterministic programs, which is equivalent to

$$[\pi_1; \mathsf{flip}^{\ge 0}(\mathbb{P}_A); \pi_2](\langle\pi_3; \mathsf{restore}^{\ge 0}(\mathbb{P}_A)\rangle A\vee C)$$

The latter makes the ∀-∃-quantification obvious. For Forbus's operator, $[\pi_A]C$ is basically of the form

$$\Big[\Big(\bigcup_{0\le m\le \mathsf{card}(\mathbb{P}_A)} \neg\langle \mathsf{flip}^1(\mathbb{P}_A)^{\le m-1}\rangle A?; \mathsf{flip}^1(\mathbb{P}_A)^m\Big); A\Big]C$$

which is again a ∀-∃-quantification. The argument for Dalal's operation is similar. By Proposition 7, checking the validity of $B \to [\pi_A]C$ can be done by checking whether $v \in \|\mathsf{flip}^{\ge 0}(\mathbb{P}_A)(B \to [\pi_A]C)\|$. The latter can be checked by an alternating algorithm, and as the alternation-depth is 2 for PMA and Forbus's update and for Dalal's revision, we obtain a Π^2_p upper bound for the respective belief change decision problems.

We leave to future work the implementation of decision procedures for DL-PA and its fragments.

Up to now, complexity characterisations of belief change operations often resorted to translations from or to QBF (see e.g. (Eiter and Gottlob 1992)). Our logic DL-PA is clearly at least as expressive as QBF: the QBF formula $\exists p\varphi$ is equivalent to the DL-PA formula $\langle p{\leftarrow}\top \cup p{\leftarrow}\bot\rangle\varphi$, which is exploited in (Herzig et al. 2011) to show PSPACE hardness of satisfiability and model checking. We believe that the richer language of programs of DL-PA provides a more natural tool to capture domains involving action and change. The present paper is part of a research program demonstrating the applicability of DL-PA to problems involving dynamics in finite domains. In other papers we have embedded several frameworks: Coalition Logic of Propositional Control and its extension by delegation programs (van der Hoek, Walther, and Wooldridge 2010) in (Herzig et al. 2011), equilibrium logic underlying ASP and its extension by update operations in (Fariñas del Cerro, Herzig, and Su 2013), a simple version of separation logic in (Herzig 2013), belief merging operations in (Herzig, Pozos Parra, and Schwarzentruber 2014), and Dung's argumentation frameworks and their update in (Doutre, Herzig, and Perrussel 2014).

Conclusion

We have given polynomial embeddings of several prominent belief change operations into a single framework: Dynamic Logic of Propositional Assignments DL-PA. Within that framework, we have given syntactic counterparts to the most popular semantically defined belief change operations: Winslett's update operations WSS and PMA, Forbus's operation operation, and Dalal's revision operation. The reduction of the DL-PA formula representing the updated belief base can be exponentially longer than the original formula; however, our examples illustrate that sometimes our syntactic representation of the updated belief base can be substantially reduced.

As an aside, we have also defined a new update operation when discussing the program $\mathsf{while}\ \neg A\ \mathsf{do}\ \mathsf{flip}^1(\mathbb{P}_A)$ as a candidate for the update program implementing the PMA. The corresponding update operation is a bit more conservative than the WSS and less than the PMA. It seems that it was not studied in the literature up to now.

Our approach can be extended to cover other concrete belief change operations. For example, the program implementing Satoh's revision operation (Satoh 1988) combines the search of a 'good starting point' as performed by the prefix $\mathsf{flip}^{\ge 0}(\mathbb{P}_B); B?$ of the revision program $\pi^{\mathsf{dalal}}_{A,B}$ with the copy-based change minimisation of the program π^{pma}_A for the PMA.

Abstract

A strong intuition for AGM belief change operations, Gärdenfors suggests, is that formulas that are independent of a change should remain intact. Based on this intuition, Farias and Herzig axiomatize a *dependence* relation w.r.t. a belief set, and formalize the connection between dependence and belief change. In this paper, we introduce *base dependence* as a relation between formulas w.r.t. a *belief base*. After an axiomatization of base dependence, we formalize the connection between base dependence and a particular belief base change operation, saturated kernel contraction. Moreover, we prove that base dependence is a *reversible generalization* of Farias and Herzig's dependence. That is, in the special case when the underlying belief base is deductively closed (i.e., it is a belief set), base dependence reduces to dependence. Finally, an intriguing feature of Farias and Herzig's formalism is that it meets other criteria for dependence, namely, Keynes' conjunction criterion for dependence (CCD) and Grdenfors' conjunction criterion for independence (CCI). We show that our base dependence formalism also meets these criteria. More interestingly, we offer a more specific criterion that implies both CCD and CCI, and show our base dependence formalism also meets this new criterion.

Introduction

Belief Change

The *AGM* paradigm of *belief change* studies the dynamics of belief states in light of new information (Alchourrn, GŁrdenfors, and Makinson 1985). For theoretical simplification, AGM idealizes a belief state as a *belief set* or a *theory*: a set of logical formulas that is closed under implication.

An important variant of the original AGM approach uses *belief bases* instead of using belief sets. Belief bases are not necessarily deductively closed, and they are usually *finite*. Thus, they are more suitable to be represented in finite machines. Also, many authors have argued that, compared to belief sets, belief bases are more expressive (Hansson 2003), and they are more tolerant of inconsistency (Hansson and Wassermann 2002). Therefore, belief bases can be more useful in practice than belief sets.

Belief Change and Dependence

A long standing intuition concerning belief change is that formulas independent of a change should remain intact (GŁrdenfors 1990). In *Belief Change and Dependence*, Farias del Cerro and Herzig (1996) (FH) attempt to ground this intuition by axiomatizing a particular *dependence* relation in a close relationship to belief change. FH's work is particularly interesting and unique in the sense that it fits the original AGM model of belief change. Their stated aim is both "to give a formal account of the notion of dependence, and to employ it in belief change." This deep integration into the AGM model sets apart their work from other works on relevance or dependence in the context of belief change.

Belief Change and Base Dependence

A natural next step is to find a similar connection between dependence and *belief base contraction*. We call such a dependence (or relevance) relation *base dependence* (or *base relevance*). In this work, we provide an axiomatization of base dependence, and establish its relation to belief base contraction. Interestingly, base dependence turns out to be a *reversible generalization* of FH's dependence. That is, in the special case that a belief base is deductively closed (i.e., it is a belief set), the base dependence relation reduces to FH's original dependence relation.

Composite Dependence

One interesting aspect of FH's work is that some of the axioms that they use to capture the concept of dependence come from intuitions put forward previously. For example, Keynes (1921) holds that there is an intuitive relationship between relevance (dependence) and logical conjunction that should stay valid for any reasonable definition of relevance. Calling it the *Conjunction Criterion for Dependence*, CCD, FH

formulate it as follows:

> If δ depends on α and δ depends on β then δ depends on $\alpha \wedge \beta$. (CCD)

Moreover, Gärdenfors (1978) puts forward another principle that he believes should hold for relevance/dependence relations, the *Conjunction Criterion for Independence*, CCI.

> If δ is independent of α and δ is independent of β then δ is independent of $\alpha \wedge \beta$.

It maintains its intuitive appeal in its contrapositive form:

> If δ depends on $\alpha \wedge \beta$ then δ depends on α or δ depends on β. (CCI)

Notably, our formalism preserves both CCD and CCI. Furthermore, we offer a new and more specific criterion for dependence, which we call the *Conjunction Criterion of Dependence Factoring*, CCDF. We show that CCDF implies both CCD and CCI, and that our base dependence formalism meets the three criteria: CCDF and so CCD and CCI.

Contributions

The contributions in this work are as follows. We offer an axiomatization of base dependence for belief base formulas, and we provide characterization theorems relating base dependence to belief base contraction. We then show that base dependence is a reversible generalization of FH's dependence relation. We also show that while generalizing the dependence relation, base dependence preserves some of the most interesting properties of dependence, particularly, Keynes' CCD, and Grdenfors' CCI. Finally we put forward a more specific conjunction criterion of dependence, CCDF, that implies both CCD and CCI, and show that this new criterion is also met by base dependence.

Background

Formal Preliminaries

We assume $\mathcal{L}$ to be a propositional language defined on a finite set of propositional variables or atoms $\mathcal{V}$ with the usual Boolean operators negation $\neg$, conjunction $\wedge$, disjunction $\vee$, and implication $\rightarrow$. We will use lower case Greek letters α, β, δ, etc. as meta variables over sentences in $\mathcal{L}$. For convenience, we introduce the sentential constants $\top$ and $\bot$ representing truth and falsity respectively. A logical consequence α of a set of formulas B is represented by $B \vdash \alpha$. Also Cn is a consequence operator, a total function taking sets of formulas to sets of formulas, defined as $\mathrm{Cn}(B) = \{\alpha \mid B \vdash \alpha\}$.

For the proofs of theorems in this paper, please refer to (Oveisi 2013).

Belief Contraction

To model rational belief change, AGM uses *rationality postulates* to describe what constitute operators for belief change and it also specifies how to *construct* such operators. The belief contraction postulates are as follows:

$(\div 1)$ $K \div \alpha$ is a belief set (closure)

$(\div 2)$ $K \div \alpha \subseteq K$ (inclusion)

$(\div 3)$ If $\alpha \notin K$ then $K \div \alpha = K$ (vacuity)

$(\div 4)$ If $\nvdash \alpha$ then $\alpha \notin K \div \alpha$ (success)

$(\div 5)$ If $\alpha \in K$ then $K \subseteq (K \div \alpha) + \alpha$ (recovery)

$(\div 6)$ If $\vdash \alpha \leftrightarrow \beta$ then $K \div \alpha = K \div \beta$ (extensionality)

$(\div 7)$ $K \div \alpha \cap K \div \beta \subseteq K \div \alpha \wedge \beta$ (conjunctive overlap)

$(\div 8)$ If $\alpha \notin K \div \alpha \wedge \beta$ then $K \div \alpha \wedge \beta \subseteq K \div \alpha$ (conjunctive inclusion)

For motivation and interpretation of these postulates see (GŁrdenfors 1988). Any operator $\div$ on K satisfying postulates $(\div 1)$–$(\div 6)$ is called a basic AGM contraction operator. The *supplementary postulates* $(\div 7)$ and $(\div 8)$ specify properties of composite belief contraction operators, which involve contraction by conjunction of sentences. Indeed, AGM also provides a third composite contraction postulate:

> Either $K \div \alpha \wedge \beta = K \div \alpha$, or
> $K \div \alpha \wedge \beta = K \div \beta$, or (conjunctive factoring)
> $K \div \alpha \wedge \beta = K \div \alpha \cap K \div \beta$.

A basic AGM contraction operator that satisfies conjunctive factoring, also satisfies both $(\div 7)$ and $(\div 8)$, and vice versa (Alchourrn, GŁrdenfors, and Makinson 1985).

Some of our beliefs are more *epistemically entrenched* than others, making them harder to give up. Based on this intuition, Grdenfors (1988) introduced epistemic entrenchment, and defined the properties of an order relation $\leq$ between sentences. Grdenfors and Makinson (1988) show that an AGM contraction operator $\div$ can be constructed using a $\leq$ relation, and that, conversely, an epistemic entrenchment relation $\leq$ can be constructed using an AGM contraction operator $\div$.

Turning now to belief base contraction, as with Hansson (1999), we assume that an operation needs to at least satisfy success and inclusion to be considered a belief contraction.

Definition 1. An operator $\div$ for a set B is an operator of contraction if and only if it satisfies success and inclusion.

Some other contraction axioms are listed below:

$B \cap \mathrm{Cn}(B \div \alpha) \subseteq B \div \alpha$ (relative closure)

If $\alpha \in \mathrm{Cn}(B')$ iff $\beta \in \mathrm{Cn}(B')$ for all $B' \subseteq B$ then $B \div \alpha = B \div \beta$ (uniformity)

If $\beta \in B$ and $\beta \notin B \div \alpha$ then (relevance)
$\alpha \notin \mathrm{Cn}(B')$ and $\alpha \in \mathrm{Cn}(B' \cup \{\beta\})$ for some $B \div \alpha \subseteq B' \subseteq B$

If $\beta \in B$ and $\beta \notin B \div \alpha$ then (core-retainment)
$\alpha \notin \mathrm{Cn}(B')$ and $\alpha \in \mathrm{Cn}(B' \cup \{\beta\})$ for some $B' \subseteq B$

Different combinations of the contraction axioms specify different contraction operations. In particular, we note the following:

Partial meet contraction: $(\div 1)$–$(\div 6)$ (Alchourrn, GŁrdenfors, and Makinson 1985); or success, inclusion, relevance and uniformity (Hansson 2003).

Kernel contraction: success, inclusion, core-retainment and uniformity (Hansson 1995).

Saturated (or smooth) kernel contraction: success, inclusion, core-retainment, uniformity and relative closure (Hansson 1995).

Belief Change and Dependence

Farias del Cerro and Herzig (1996) formalized the notion of dependence and its connection with belief change, in a similar approach to Gärdenfors and Makinson (1988) for epistemic entrenchment. To formalize dependence, they investigate a binary relation $\rightsquigarrow$ on formulas. $\alpha \rightsquigarrow \beta$ reads as "β depends on α" (or equivalently "α is relevant to β"). Independence, then, is denoted by $\not\rightsquigarrow$, which is the complement of $\rightsquigarrow$, so $\alpha \not\rightsquigarrow \beta$ reads as "β is independent of α" (or "α is irrelevant to β"). They provide the following axiomatization of dependence.

If $\alpha \leftrightarrow \beta$ and $\alpha \rightsquigarrow \delta$ then $\beta \rightsquigarrow \delta$ (LE^l)

If $\alpha \leftrightarrow \beta$ and $\delta \rightsquigarrow \alpha$ then $\delta \rightsquigarrow \beta$ (LE^r)

If $\alpha \wedge \beta \rightsquigarrow \delta$ then $\alpha \rightsquigarrow \delta$ or $\beta \rightsquigarrow \delta$ (CCI^l)

If $\delta \rightsquigarrow \alpha \wedge \beta$ then $\delta \rightsquigarrow \alpha$ or $\delta \rightsquigarrow \beta$ (CCI^r)

$\alpha \in K$ iff either $\vdash \alpha$ or $\alpha \rightsquigarrow \beta$ for some β (Def-K)

If $\alpha \rightsquigarrow \beta$ then $\alpha \rightsquigarrow \alpha$ (Cond-ID)

If $\vdash \alpha \vee \beta$ then $\alpha \not\rightsquigarrow \beta$ (Disj)

If $\alpha \rightsquigarrow \delta$ and $\alpha \wedge \beta \rightsquigarrow \alpha$ then $\alpha \wedge \beta \rightsquigarrow \delta$ (CCD_0^l)

If $\delta \rightsquigarrow \alpha$ and $\beta \rightsquigarrow \beta$ then $\delta \rightsquigarrow \alpha \wedge \beta$ (CCD_0^r)

The following are also derivable principles:

If $\alpha \rightsquigarrow \delta$ and $\beta \rightsquigarrow \delta$ then $\alpha \wedge \beta \rightsquigarrow \delta$. ($\mathsf{CCD}^l$)

If $\delta \rightsquigarrow \alpha$ and $\delta \rightsquigarrow \beta$ then $\delta \rightsquigarrow \alpha \wedge \beta$. ($\mathsf{CCD}^r$)

For motivation and interpretation of these postulates, please refer to their work. Here, it suffices to note that Keynes' CCD and Grdenfors' CCI are represented by CCD^l and CCI^l, respectively.

FH's dependence relation is defined as follows:

Definition 2. A relation $\rightsquigarrow$ is a *dependence* relation if and only if it satisfies the axioms LE^l, LE^r, CCI^l, CCI^r, Def-K, Cond-ID, Disj, CCD_0^l and CCD_0^r.

For studying the relationship between dependence and belief change, FH use the following *preservation criterion* as their guiding principle:

> "If a belief state is revised by a sentence A, then all sentences in K that are independent of the validity of A should be retained in the revised state of belief" (GŁrdenfors 1990).

For example, if $\beta \in K$ to begin with, but $\beta \notin K \div \alpha$, then we can say that β depends on α, or $\alpha \rightsquigarrow \beta$.

Similar to epistemic entrenchment, to provide the connection between dependence and contraction, FH introduce two conditions, namely, $\mathsf{Cond}\rightsquigarrow$ and $\mathsf{Cond}\div$.

$\alpha \rightsquigarrow \beta$ iff $\beta \in K$ and $\beta \notin K \div \alpha$. ($\mathsf{Cond}\rightsquigarrow$)

This equivalence condition allows one to define $\rightsquigarrow$ based on a given AGM contraction operation $\div$ for belief set K.

Theorem 3 (FH). *Given two relations $\rightsquigarrow$ and $\div$ such that $\mathsf{Cond}\rightsquigarrow$ holds, if $\div$ is an AGM contraction, then $\rightsquigarrow$ is a dependence relation.*

The next condition allows defining an AGM contraction operation $\div$, given a dependence relation $\rightsquigarrow$.

$\beta \in K \div \alpha$ iff either $\vdash \beta$ or $\beta \rightsquigarrow \beta$ and $\alpha \not\rightsquigarrow \beta$. ($\mathsf{Cond}\div$)

An AGM contraction operation $\div$ is defined with respect to some belief set K. Thus, $\div$ obtained via $\mathsf{Cond}\div$ also requires an associated K to be specified. For this purpose, FH provide the following definition for the belief set $K_\rightsquigarrow$:

$$K_\rightsquigarrow = \{\alpha \mid \vdash \alpha \text{ or } \alpha \rightsquigarrow \beta \text{ for some } \beta\}.$$

For the sake of brevity, FH simply use K to refer to $K_\rightsquigarrow$ afterwards. The next theorem defines a contraction operation, given a dependence relation using $\mathsf{Cond}\div$.

Theorem 4 (FH). *Given two relations $\rightsquigarrow$ and $\div$ such that $\mathsf{Cond}\div$ holds, if $\rightsquigarrow$ is a dependence relation then $\div$ is an AGM contraction.*

As the last step, FH need to complete the link between AGM contraction and dependence using a characterization theorem to state that for any two arbitrary relations $\rightsquigarrow$ and $\div$ that satisfy $\mathsf{Cond}\rightsquigarrow$, $\div$ is an AGM contraction iff $\rightsquigarrow$ is a dependence relation. To achieve this, however, it turns out that they first have to make the following assumption:

Remark 5. In order to establish an axiomatic characterization based on $\mathsf{Cond}\rightsquigarrow$, it is assumed that the relation $\div$ satisfies inclusion, $K \div \alpha \subseteq K$.

Theorem 6 (FH). *Let two relations $\rightsquigarrow$ and $\div$ be such that $\div$ satisfies* inclusion *and that $\mathsf{Cond}\rightsquigarrow$ holds. Then $\div$ is an AGM contraction if and only if $\rightsquigarrow$ is a dependence relation.*

This completes FH's work. Also another characterization theorem that they provide for a weaker dependence relation proves to be useful in our study.

Theorem 7 (FH). *Let two relations $\rightsquigarrow$ and $\div$ be such that $\div$ satisfies* inclusion *and that $\mathsf{Cond}\rightsquigarrow$ holds. Then $\div$ is a basic AGM contraction satisfying $(\div 1)$–$(\div 6)$ if and only if $\rightsquigarrow$ is a dependence relation satisfying LE^l, LE^r, CCI^r, Def-K, Cond-ID, Disj and CCD_0^r.*

Belief Change and Base Dependence

Overview and Problem Definition

Gärdenfors' preservation criterion, as with FH, lays the foundation of the present work. Our work is another attempt to connect notions of dependence and belief change, but using belief bases instead of belief sets.

As discussed, belief bases are a generalization of belief sets. Hence, it seems natural to anticipate that base dependence also be a generalization of FH's dependence relation. Furthermore, base dependence should ideally be a *reversible generalization* of dependence. That is, where a base dependence relation corresponds to a belief set, the base dependence relation should reduce to FH's dependence.

Finally, one significant feature of FH's formalism is that it adheres to Keynes' CCD and Gärdenfors' CCI. We would like to preserve this characteristic of FH's dependence while generalizing it to base dependence. It turns out that our base dependence formalism meets a third maxim, CCDF, that implies both CCD and CCI.

Characteristics of an Anticipated Solution

A formalization of Gärdenfors' preservation criterion that involves belief bases instead of belief sets should still retain the general scheme of FH's work. More specifically, we need an *axiomatization of base dependence*, as well as a suitable corresponding *belief base contraction*. We also need a *conditional, similar to FH's* Cond$\rightsquigarrow$, that allows construction of a base dependence given a base contraction, and another *conditional, similar to FH's* Cond$\div$, that allows construction of a base contraction using a base dependence.

As discussed, base dependence should be a reversible generalization of FH's dependence. Naturally, an appropriate base contraction to correspond to base dependence must also be a *reversible generalization of AGM contraction*.

Finally, our base dependence and its corresponding base contraction must be such that CCD and CCI (and ideally CCDF) are satisfied.

These characteristics are pictured in Figure 1, located toward the end of our paper. The remainder of this work is to establish the background concepts and theorems necessary to justify the diagram in Figure 1.

Base Dependence

The meaning of "dependence" in base dependence is the same as what Fariñas and Herzig (and Grdenfors) studied, which refers to the dependence or relevance of logical statements towards one another. Using their notation, we read $\alpha \rightsquigarrow \beta$ as "β depends on α" or "doubting in α leads to doubting in β."

In FH's study, dependence can only happen between (contingent) sentences from K:

$$\text{If } \alpha \rightsquigarrow \beta \text{ then } \alpha \in K \text{ and } \beta \in K.$$

If B is a base for K, $K = \mathrm{Cn}(B)$, then we have:

$$\text{If } \alpha \rightsquigarrow \beta \text{ then } \alpha \in \mathrm{Cn}(B) \text{ and } \beta \in \mathrm{Cn}(B). \quad (1)$$

One way to generalize the dependence relation $\rightsquigarrow$ is to make α or β be from B instead of $\mathrm{Cn}(B)$. Therefore, our sought-for *base dependence* should somehow involve formulas explicitly mentioned in a belief base, thus the name.

Using $\overset{\sim}{\rightsquigarrow}$ to denote base dependence, we read $\alpha \overset{\sim}{\rightsquigarrow} \beta$ as "β *base-depends* on α," which is the same as $\alpha \rightsquigarrow \beta$ except that $\alpha \overset{\sim}{\rightsquigarrow} \beta$ also implies that α or β or both are formulas in the base. Now, we need to decide which one of these three alternatives should be the case.

$$\text{If } \alpha \overset{\sim}{\rightsquigarrow} \beta \text{ then } \alpha \in B \text{ and } \beta \in \mathrm{Cn}(B) \quad (2a)$$
$$\text{If } \alpha \overset{\sim}{\rightsquigarrow} \beta \text{ then } \alpha \in \mathrm{Cn}(B) \text{ and } \beta \in B \quad (2b)$$
$$\text{If } \alpha \overset{\sim}{\rightsquigarrow} \beta \text{ then } \alpha \in B \text{ and } \beta \in B. \quad (2c)$$

We believe the third alternative (2c), requiring both α and β to be in B, appears to be too strong to try first. The second alternative (2b) offers a more interesting semantics, compared to the first alternative (2a). The second alternative means that "doubting in α leads to doubting in β from the base." It allows us to study how the statements in the *base* depend on, or are susceptible to, changes of other statements. Stated in terms of belief change, it means contracting B by any formula α from the *infinite* set $\mathrm{Cn}(B)$ can result in removal of β from the *finite* set $B \setminus B \div \alpha$. On the other hand, the first alternative (2a) means contracting B by any formula α from the usually *finite* set B can result in removal of β from the *infinite* set $\mathrm{Cn}(B) \setminus \mathrm{Cn}(B \div \alpha)$.

Therefore, although the alternatives (2a) and (2c) remain open and may be found useful in other studies, we proceed with (2b), and from now on we assume $\alpha \overset{\sim}{\rightsquigarrow} \beta$ requires that $\beta \in B$:

$$\text{If } \alpha \overset{\sim}{\rightsquigarrow} \beta \text{ then } \beta \in B. \quad (3)$$

It turns out that (3) does not need to be explicitly specified as an axiom. Rather, it will be implied by other axioms and conditions for base dependence which will be put forward in the upcoming sections (e.g., Def-B and Cond$\overset{\sim}{\rightsquigarrow}$).

Example 8. Assume Mary believes that p, q and $q \to r$; i.e., $B = \{p,\ q,\ q \to r\}$. By implication, she also believes that r, as it is entailed by q and $q \to r$. Now, say, for some reason, she starts to doubt that r is true. Consequently, this leads her to also doubt either q, or $q \to r$, or even both. Thus we know that at least one of $r \overset{\sim}{\rightsquigarrow} q$ or $r \overset{\sim}{\rightsquigarrow} (q \to r)$ hold, and that $r \not\rightsquigarrow p$ and $r \not\rightsquigarrow r$. □

Mutual Construction

From Contraction to Base Dependence As discussed earlier, FH use Cond$\rightsquigarrow$ to construct a dependence relation via a given AGM contraction. Cond$\rightsquigarrow$ can be straightforwardly transformed to an equivalent base-generated representation. That is, if $K = \mathrm{Cn}(B)$ and $\div$ is a base-generated contraction, which exists for any given AGM contraction (Hansson 1993), then Cond$\rightsquigarrow$ can be stated as follows:

$$\alpha \rightsquigarrow \beta \text{ iff } \beta \in \mathrm{Cn}(B) \text{ and } \beta \notin \mathrm{Cn}(B \div \alpha). \quad (\text{Cond}\rightsquigarrow)$$

Note that we have used the same name "Cond$\rightsquigarrow$" here since this is only an alternative representation. This new, base-generated representation makes it easier to compare and contrast Cond$\rightsquigarrow$ with the corresponding conditions for belief bases that will be introduced shortly.

If $\alpha \rightsquigarrow \beta$ then β is retracted as a result of α's contraction, so $\beta \in [\mathrm{Cn}(B) \setminus \mathrm{Cn}(B \div \alpha)]$. For base dependence, we assume that (3) holds: if $\alpha \overset{\sim}{\rightsquigarrow} \beta$ then $\beta \in B$. Thus, it is intuitively appealing to say that if $\alpha \overset{\sim}{\rightsquigarrow} \beta$, then β is retracted from B as a result of α's contraction, so $\beta \in [B \setminus B \div \alpha]$. With this intuition in mind, we propose the following to correspond to FH's Cond$\rightsquigarrow$:

$$\alpha \overset{\sim}{\rightsquigarrow} \beta \text{ iff } \beta \in B \text{ and } \beta \notin B \div \alpha. \quad (\text{Cond}\overset{\sim}{\rightsquigarrow})$$

Notice that in common with FH, if α is a tautology, no formula contributes to its truth, and $\alpha \overset{\sim}{\rightsquigarrow} \beta$ cannot hold for any β. Also, if β is not in B, then $\alpha \overset{\sim}{\rightsquigarrow} \beta$ cannot hold for any α by definition. Therefore, both $\beta \rightsquigarrow \beta$ and $\beta \overset{\sim}{\rightsquigarrow} \beta$ imply that β is contingent, and the latter additionally implies that β is in B. This will prove useful in the next section when constructing contraction operations using (base) dependence, via Cond$\div$ and Cond$\overset{\sim}{\div}$.

From Base Dependence to Contraction We first provide a simplifying notation $\vdash_B$ to help represent *tautologies present in the base*.

Definition 9. Given a base B and an entailment relation $\vdash$, the *base entailment* relation $\vdash_B$ is defined as follows: $A \vdash_B \beta$ if and only if $\beta \in B$ and $A \vdash \beta$.

A useful special case is when $A = \emptyset$. For example, $\vdash_B \beta$ means β is a tautology in the base: $\beta \in B$ and $\vdash \beta$. One important usage is to help handling tautologies in base dependence axioms. Such axioms are primarily concerned with contingencies, but they have to also deal with tautologies, usually as exceptional cases.

Next, we need to reconstruct belief bases, given base dependence relations. We saw that FH provide the following:

$$K_{\rightsquigarrow} = \{\alpha \mid \vdash \alpha \text{ or } \alpha \rightsquigarrow \beta \text{ for some } \beta\}.$$

Note that we could swap the role of α and β above and obtain the same results:

$$K_{\rightsquigarrow} = \{\beta \mid \vdash \beta \text{ or } \alpha \rightsquigarrow \beta \text{ for some } \alpha\}.$$

Similarly, a base dependence relation $\bar{\rightsquigarrow}$ is associated with a belief base B. Thus, it should be possible to recreate the associated belief base B via a given $\bar{\rightsquigarrow}$ relation:

$$B_{\bar{\rightsquigarrow}} = \{\beta \mid \alpha \bar{\rightsquigarrow} \beta \text{ for some } \alpha\}.$$

Note, however, that one caveat is that $B_{\bar{\rightsquigarrow}}$ will not contain any *tautologies* that may be in B. Still, we can say that B and $B_{\bar{\rightsquigarrow}}$ are equivalent for most practical purposes. Also, their closure is obviously equivalent:

$$\mathrm{Cn}(B_{\bar{\rightsquigarrow}}) = \mathrm{Cn}(B).$$

If in addition to the base dependence relation $\bar{\rightsquigarrow}$, we are also given $\vdash_B$ that identifies tautologies in the base, then we can have the following, which guarantees that $B_{\bar{\rightsquigarrow}} = B$:

$$B_{\bar{\rightsquigarrow}} = \{\beta \mid \vdash_B \beta \text{ or } \alpha \bar{\rightsquigarrow} \beta \text{ for some } \alpha\}$$

In the rest of this work, we assume $B_{\bar{\rightsquigarrow}} = B$. In the worst case scenario, there are tautologies in B and only $\bar{\rightsquigarrow}$ is given, so the tautologies in B are not present in $B_{\bar{\rightsquigarrow}}$.

Now for $\mathsf{Cond}\bar{\div}$, again we start with $\mathsf{Cond}\div$. As in the case of $\mathsf{Cond}\rightsquigarrow$, we present a straightforward transformation to the equivalent base-generated operation. Again, we reuse the equation's name, "$\mathsf{Cond}\div$":

$$\beta \in \mathrm{Cn}(B \div \alpha) \text{ iff either } \vdash \beta \text{ or } \beta \rightsquigarrow \beta \text{ and } \alpha \not\rightsquigarrow \beta. \qquad (\mathsf{Cond}\div)$$

$\mathsf{Cond}\div$ says $\beta \in \mathrm{Cn}(B \div \alpha)$ means either that β is a tautology, or that β is a contingent truth, $\beta \rightsquigarrow \beta$, but contraction by α does not lead to retraction of β, meaning $\alpha \not\rightsquigarrow \beta$.

To adapt this for belief bases, we need something along the line of the following: $\beta \in B \div \alpha$ means either that β is a tautology in B, $\vdash_B \beta$, or that β is a contingent truth in B, $\beta \bar{\rightsquigarrow} \beta$, but contraction by α does not lead to retraction of β from B, $\alpha \not\rightsquigarrow \beta$:

$$\beta \in B \div \alpha \text{ iff either } \vdash_B \beta \text{ or } \beta \bar{\rightsquigarrow} \beta \text{ and } \alpha \not\rightsquigarrow \beta. \qquad (\mathsf{Cond}\bar{\div})$$

Basic Postulates of Base Dependence

A goal of this work is to provide an axiomatization of base dependence as a generalization of FH's dependence. It turns out that some of base dependence axioms closely resemble dependence axioms (e.g. $\mathsf{Cond\text{-}ID}^B$), and some remain valid and derivable but are no longer needed as axioms (e.g. Disj^B). Yet, there are also some other axioms offered for base dependence (e.g. redundancy) that are not similar to any of the dependence axioms. The following are the basic postulates of base dependence.

$\beta \in B$ iff either $\vdash_B \beta$ or $\alpha \bar{\rightsquigarrow} \beta$ for some α. (Def-B)

If $\alpha \bar{\rightsquigarrow} \beta$ then $\beta \bar{\rightsquigarrow} \beta$. ($\mathsf{Cond\text{-}ID}^B$)

If $\alpha \in \mathrm{Cn}(B')$ iff $\beta \in \mathrm{Cn}(B')$ for all $B' \subseteq B$ then $\alpha \bar{\rightsquigarrow} \delta$ iff $\beta \bar{\rightsquigarrow} \delta$. (conjugation)

If $\alpha \bar{\rightsquigarrow} \beta$ then (contribution)
$\alpha \notin \mathrm{Cn}(B')$ and $\alpha \in \mathrm{Cn}(B' \cup \{\beta\})$ for some $B' \subseteq B$.

If $\alpha \in \mathrm{Cn}(B')$ and $B' \subseteq B$ then (modularity)
either $\vdash \alpha$ or $\alpha \bar{\rightsquigarrow} \beta$ for some $\beta \in B'$.

If $\beta \in \mathrm{Cn}(B')$ and $B' \subseteq B$ then (redundancy)
either $\alpha \not\rightsquigarrow \beta$ or $\alpha \bar{\rightsquigarrow} \delta$ for some $\delta \in B'$.

A brief description of these axioms is as follows:

(Def-B) To say that β is in the base, $\beta \in B$, is equivalent to saying either that β is a tautology in the base, $\vdash_B \beta$, or that it is a contingency in the base. The contingent truth of β then has to be inferentially relevant to some (contingent) formula α (where α could be β), so $\alpha \bar{\rightsquigarrow} \beta$.

($\mathsf{Cond\text{-}ID}^B$) The inferential relevance between α and β means that neither is a tautology. Also, β is in the base because $\alpha \bar{\rightsquigarrow} \beta$. Thus, β is a contingency in the base, or $\beta \bar{\rightsquigarrow} \beta$.

(conjugation) When α and β are logically equivalent, $\vdash \alpha \leftrightarrow \beta$, there is inferential relevance between α and δ from B if and only if there is inferential relevance between β and δ. This makes sense not only for α and β, but also for the formulas that are true *just because* α or β are true.

(contribution) This axiom says that if β from B is inferentially relevant to α then β must somehow contribute to the justification of α.

(modularity) Consider a subset $B' \subseteq B$ that implies α, $\alpha \in \mathrm{Cn}(B')$. This could be because α is a tautology. But when $\nvdash \alpha$, there is some β from the same subset B' that base-depends on α.

(redundancy) To consider the principal case of redundancy, assume that: $\beta \in \mathrm{Cn}(B')$ and $B' \subseteq B$ and $\alpha \bar{\rightsquigarrow} \beta$. When $\beta \in B'$, $\alpha \bar{\rightsquigarrow} \delta$ for some $\delta \in B'$ trivially holds because then δ could be β which means $\alpha \bar{\rightsquigarrow} \beta$, which is assumed. When $\beta \notin B'$, there is some redundancy in the base B because on the one hand $\beta \in B$ (as $\alpha \bar{\rightsquigarrow} \beta$), and on the other hand there is $B' \subseteq B$ such that $\beta \notin B'$ but $\beta \in \mathrm{Cn}(B')$. Thus, in order for $\alpha \bar{\rightsquigarrow} \beta$ to hold, $\alpha \bar{\rightsquigarrow} \delta$ should also hold at least for one formula $\delta \in B'$.

The following principles, which are derivable from the above axioms, also have counterpart in FH's framework:

$$\text{If } \vdash \alpha \vee \beta \text{ then } \alpha \not\sim \beta. \qquad (\mathsf{Disj}^B)$$

$$\text{If } \vdash \alpha \leftrightarrow \beta \text{ and } \alpha \mathrel{\tilde{\rightarrow}} \delta \text{ then } \beta \mathrel{\tilde{\rightarrow}} \delta. \qquad (\mathsf{LE}^B)$$

Example 10. Assume that $B = \{p \leftrightarrow q, p \vee q, p\}$, and that $\mathrel{\tilde{\rightarrow}}$ is a relation such that $(p \wedge q) \mathrel{\tilde{\rightarrow}} (p \vee q)$ and $(p \wedge q) \not\mathrel{\tilde{\rightarrow}} p$ hold. We show that $\mathrel{\tilde{\rightarrow}}$ violates redundancy. Let $B' = \{p\}$. Clearly $B' \subseteq B$ and $p \vee q \in \mathrm{Cn}(B')$, and, by assumption, $(p \wedge q) \mathrel{\tilde{\rightarrow}} (p \vee q)$. Thus, by redundancy, $(p \wedge q) \mathrel{\tilde{\rightarrow}} \delta$ for some $\delta \in B'$. Since $B' = \{p\}$, δ has to be p, so $(p \wedge q) \mathrel{\tilde{\rightarrow}} p$. This contradicts the initial assumption that $(p \wedge q) \not\mathrel{\tilde{\rightarrow}} p$. □

Definition 11. A relation $\mathrel{\tilde{\rightarrow}}$ is a *base dependence* if and only if it satisfies the axioms Def-B, Cond-ID^B, conjugation, contribution, modularity and redundancy.

Notice that so far we have not specified any criteria on how to handle conjunctions, which we will do shortly.

Saturated Kernel Contraction and Base Dependence

As discussed, we need a base contraction to correspond to base dependence. We also saw that a suitable candidate base contraction must be a reversible generalization of AGM contraction. Indeed, saturated kernel contraction is a subclass of kernel contraction that is a reversible generalization of basic AGM contraction. That is, saturated kernel contraction is a base contraction, and when it corresponds to a belief set, it is equivalent to AGM partial meet contraction (Hansson 1995).

In this section, we show that indeed saturated kernel contraction and base dependence have a mutual correspondence.

From Base Dependence to Contraction To construct a contraction operator $\div$, assume all the following are present: a base dependence relation $\mathrel{\tilde{\rightarrow}}$ (Definition 11), a list of tautologies present in the base $T \subseteq B$ where $T = \{\beta \mid \vdash_{_B} \beta\}$, and the Cond$\mathrel{\tilde{\div}}$.

We do *not* need to assume that B is provided because it can be obtained using $\mathrel{\tilde{\rightarrow}}$ and $\vdash_{_B}$.

Theorem 12 states that the contraction operator $\div$ obtained from $\mathrel{\tilde{\rightarrow}}$ is indeed a saturated kernel contraction.

Theorem 12 (Base Dependence to Contraction). *Given relations $\mathrel{\tilde{\rightarrow}}$ and $\div$ for base B such that* Cond$\mathrel{\tilde{\div}}$ *holds, if $\mathrel{\tilde{\rightarrow}}$ is a base dependence, then $\div$ is a saturated kernel contraction.*

To prove this theorem, we assume the Cond$\mathrel{\tilde{\div}}$ and postulates of base dependence hold, and we show one by one that the postulates of saturated kernel contraction also hold.

From Contraction to Base Dependence This subsection shows how to obtain a base dependence $\mathrel{\tilde{\rightarrow}}$ relation given a saturated kernel contraction operator $\div$. We assume the following are present: a saturated kernel contraction operator $\div$, and the Cond$\mathrel{\tilde{\rightarrow}}$. Theorem 13 states that, given the above assumptions, all axioms of base dependence $\mathrel{\tilde{\rightarrow}}$ relation are satisfied.

Theorem 13 (Contraction to Base Dependence). *Given relations $\mathrel{\tilde{\rightarrow}}$ and $\div$ for base B such that* Cond$\mathrel{\tilde{\rightarrow}}$ *holds, if $\div$ is a saturated kernel contraction, then $\mathrel{\tilde{\rightarrow}}$ is a base dependence.*

For this theorem, assuming the Cond$\mathrel{\tilde{\rightarrow}}$ and axioms of saturated kernel contraction, we show one by one that the properties of base dependence hold.

Axiomatic Characterization We now need an axiomatic characterization theorem. We also adopt the FH assumption in Remark 5, which means that inclusion needs to be assumed in the characterization theorem. The rationale for this assumption is as follows. When constructing the $\mathrel{\tilde{\rightarrow}}$ relation using a contraction operation via Cond$\mathrel{\tilde{\rightarrow}}$, the set of all β such that $\alpha \mathrel{\tilde{\rightarrow}} \beta$ is equal to those $\beta \in B$ and $\beta \notin B \div \alpha$, or using set difference notation $\beta \in B \setminus (B \div \alpha)$. We know as a matter of fact that $B \div \alpha \subseteq B$ holds because, by Definition 1, any contraction operator satisfies inclusion. However, even if, for the sake of argument, $\div$ did not satisfy inclusion and there were some statements in $B \div \alpha$ that were not in B, such statements would have been lost in the set difference $\beta \in B \setminus (B \div \alpha)$. That, in turn, means that to use $\mathrel{\tilde{\rightarrow}}$ to construct a contraction $\div$ via Cond$\mathrel{\tilde{\rightarrow}}$, we do not have enough information to prove or disprove inclusion. Instead, we have to assume that $\div$ already satisfies inclusion. Since all contraction operations satisfy inclusion, this assumption is not a serious loss of generality.

Theorem 14 (Characterization). *Let the relations $\mathrel{\tilde{\rightarrow}}$ and $\div$ for base B be such that $\div$ satisfies* inclusion *and that* Cond$\mathrel{\tilde{\rightarrow}}$ *holds. Then, $\div$* is a saturated kernel contraction if and only if $\mathrel{\tilde{\rightarrow}}$ is a base dependence.

To prove this characterization theorem, we show that in presence of inclusion, Cond$\mathrel{\tilde{\rightarrow}}$ entails Cond$\mathrel{\tilde{\div}}$. Thus, assuming inclusion and Cond$\mathrel{\tilde{\rightarrow}}$, based on Theorems 12 and 13, saturated kernel contraction and base dependence are logically equivalent.

Conjunction Criterion of Dependence Factoring

We have seen Keynes' CCD and Grdenfors' CCI, and the respective dependence axioms CCD^I and CCI^I. Likewise, we have:

$$\text{If } \alpha \mathrel{\tilde{\rightarrow}} \delta \text{ and } \beta \mathrel{\tilde{\rightarrow}} \delta \text{ then } \alpha \wedge \beta \mathrel{\tilde{\rightarrow}} \delta. \qquad (\mathsf{CCD}^B)$$

$$\text{If } \alpha \wedge \beta \mathrel{\tilde{\rightarrow}} \delta \text{ then } \alpha \mathrel{\tilde{\rightarrow}} \delta \text{ or } \beta \mathrel{\tilde{\rightarrow}} \delta. \qquad (\mathsf{CCI}^B)$$

CCD and CCI state intuitions regarding dependence on conjunctions in the form of *conditional* statements. One wonders whether it is possible to capture such intuitions regarding dependence on conjunctions using *equivalences*. Such a statement would have to capture different cases. That is, for any reasonable dependence relation, at least one of the following statements hold:

Case 1: The set of formulas that depend on $\alpha \wedge \beta$ is *the same as* the set of those that depend on α

Case 2: The set of formulas that depend on $\alpha \wedge \beta$ is *the same as* the set of those that depend on β

Case 3: The set of formulas that depend on $\alpha \wedge \beta$ is *the same as* the set of those that depend on α *or* depend on β

Using set notation, these cases can be stated as follows:

$$\begin{aligned} \text{Either } \{\delta \mid \alpha \wedge \beta \mathrel{\tilde{\rightarrow}} \delta\} &= \{\delta \mid \alpha \mathrel{\tilde{\rightarrow}} \delta\}, \text{ or} \\ \{\delta \mid \alpha \wedge \beta \mathrel{\tilde{\rightarrow}} \delta\} &= \{\delta \mid \beta \mathrel{\tilde{\rightarrow}} \delta\}, \text{ or} \\ \{\delta \mid \alpha \wedge \beta \mathrel{\tilde{\rightarrow}} \delta\} &= \{\delta \mid \alpha \mathrel{\tilde{\rightarrow}} \delta\} \cup \{\delta \mid \beta \mathrel{\tilde{\rightarrow}} \delta\} \end{aligned} \qquad (4)$$

or equivalently,

$$\begin{array}{rl} \text{Either } [\alpha \wedge \beta \mathrel{\tilde{\hookrightarrow}} \delta_1 & \text{iff } \alpha \mathrel{\tilde{\hookrightarrow}} \delta_1], \text{ or} \\ [\alpha \wedge \beta \mathrel{\tilde{\hookrightarrow}} \delta_2 & \text{iff } \beta \mathrel{\tilde{\hookrightarrow}} \delta_2], \text{ or} \\ [\alpha \wedge \beta \mathrel{\tilde{\hookrightarrow}} \delta_3 & \text{iff } \alpha \mathrel{\tilde{\hookrightarrow}} \delta_3 \text{ or } \beta \mathrel{\tilde{\hookrightarrow}} \delta_3]. \end{array} \quad (\mathsf{CCDF}^B)$$

Each line of CCDF^B needs to use a unique variable name δ_1, δ_2 and δ_3 because, in each line of (4), $\{\delta \mid \alpha \wedge \beta \mathrel{\tilde{\hookrightarrow}} \delta\}$ refers to a different set.

CCDF^B is a formalization of the intuition expressed in the three cases above, which we restate more concisely as follows, calling it the *Conjunction Criterion of Dependence Factoring*, CCDF:

> The set of all formulas that depend on $\alpha \wedge \beta$ is the same as the set of all formulas that depend on α, or on β, or on either of them. (CCDF)

Indeed, CCDF may be considered as a third maxim for dependence of conjunctions in addition to Keynes' CCD and Grdenfors' CCI.

As a side note, although it seems that the third clause of CCDF^B should be redundant, in light of the first two, in fact it isn't.

Example 15. Assume α, β, θ_1, θ_2 and θ_3 are formulas and $\tilde{\hookrightarrow}$ is a relation such that

$$\begin{array}{lll} \alpha \wedge \beta \mathrel{\tilde{\hookrightarrow}} \theta_1 & \alpha \mathrel{\tilde{\hookrightarrow}} \theta_1 & \beta \not\mathrel{\tilde{\hookrightarrow}} \theta_1 \\ \alpha \wedge \beta \mathrel{\tilde{\hookrightarrow}} \theta_2 & \alpha \not\mathrel{\tilde{\hookrightarrow}} \theta_2 & \beta \mathrel{\tilde{\hookrightarrow}} \theta_2 \\ \alpha \wedge \beta \mathrel{\tilde{\hookrightarrow}} \theta_3 & \alpha \mathrel{\tilde{\hookrightarrow}} \theta_3 & \beta \mathrel{\tilde{\hookrightarrow}} \theta_3. \end{array}$$

Clearly, $\tilde{\hookrightarrow}$ violates the first two clauses of CCDF^B, but not the third one. This may be easier to see using (4). Note that $\{\delta \mid \alpha \wedge \beta \mathrel{\tilde{\hookrightarrow}} \delta\} = \{\theta_1, \theta_2, \theta_3\}$, $\{\delta \mid \alpha \mathrel{\tilde{\hookrightarrow}} \delta\} = \{\theta_1, \theta_3\}$ and $\{\delta \mid \beta \mathrel{\tilde{\hookrightarrow}} \delta\} = \{\theta_2, \theta_3\}$, which satisfy the third clause of (4) but not the first two. □

As a second note, CCDF^B is only one way of formalizing CCDF, using base dependence relation; of course, it can also be formalized using FH's dependence relation as shown below, which we call CCDF^l:

$$\begin{array}{rl} \text{Either } [\alpha \wedge \beta \mathrel{\sim} \delta_1 & \text{iff } \alpha \mathrel{\sim} \delta_1], \text{ or} \\ [\alpha \wedge \beta \mathrel{\sim} \delta_2 & \text{iff } \beta \mathrel{\sim} \delta_2], \text{ or} \\ [\alpha \wedge \beta \mathrel{\sim} \delta_3 & \text{iff } \alpha \mathrel{\sim} \delta_3 \text{ or } \beta \mathrel{\sim} \delta_3]. \end{array} \quad (\mathsf{CCDF}^l)$$

Finally, an important observation here is that CCDF^B is a more specific criterion than CCD^B and CCI^B, and it implies both of them.

Theorem 16. *If a relation $\tilde{\hookrightarrow}$ satisfies CCDF^B, then it also satisfies both CCD^B and CCI^B.*

Notice that although Theorem 16 is stated in terms of base dependence $\tilde{\hookrightarrow}$, it does not have to be. Indeed, the theorem (and its proof) may straightforwardly be restated in terms of CCDF that implies both CCD and CCI. As such, the dependence version of CCDF, i.e. CCDF^l, also implies both FH's CCD^l and CCI^l.

The following are all the conjunction criteria and related axioms we have discussed:

Criterion	Dependence	Base Dependence
CCD (Keynes)	CCD^l (FH)	CCD^B
CCI (Grdenfors)	CCI^l (FH)	CCI^B
CCDF	CCDF^l	CCDF^B

We may now state axiomatic characterization and its associated theorems, with the addition of corresponding conjunction criteria as follows.

Theorem 17 (Base Dependence to Contraction). *Given relations $\tilde{\hookrightarrow}$ and $\div$ for base B such that* Cond$\tilde{\div}$ *holds, if $\tilde{\hookrightarrow}$ is a base dependence that satisfies* CCDF^B*, then $\div$ is a saturated kernel contraction that satisfies* conjunctive factoring.

Theorem 18 (Contraction to Base Dependence). *Given relations $\tilde{\hookrightarrow}$ and $\div$ for base B such that* Cond$\tilde{\hookrightarrow}$ *holds, if $\div$ is a saturated kernel contraction that satisfies* conjunctive factoring*, then $\tilde{\hookrightarrow}$ is a base dependence that satisfies* CCDF^B.

Theorem 19 (Main Characterization). *Let the relations $\tilde{\hookrightarrow}$ and $\div$ for base B be such that $\div$ satisfies* inclusion*, $B \div \alpha \subseteq B$, and that* Cond$\tilde{\hookrightarrow}$ *holds: $\alpha \mathrel{\tilde{\hookrightarrow}} \beta$ iff $\beta \in B$ and $\beta \notin B \div \alpha$. Then, $\div$ is a saturated kernel contraction that satisfies* conjunctive factoring *if and only if $\tilde{\hookrightarrow}$ is a base dependence that satisfies* CCDF^B.

Base Dependence as a Reversible Generalization of Dependence

Last, we show that base dependence is a reversible generalization of FH's dependence.

Theorem 20 (Dependence Generalization). *Let relations $\tilde{\hookrightarrow}$, $\sim$ and $\div$ for base B be such that* Cond$\tilde{\hookrightarrow}$ *and* Cond$\sim$ *hold and* inclusion *is satisfied. In the case where B is logically closed,*

(1) *the following are logically equivalent:*

a) *$\tilde{\hookrightarrow}$ is a base dependence, which satisfies* Def-B, Cond-ID^B, conjugation, contribution, modularity *and* redundancy

b) *$\sim$ is a dependence that satisfies* Def-K, Cond-ID, Disj, LE^l, LE^r, CCI^r *and* CCD$^r_0$

c) *$\div$ is a saturated kernel contraction, which satisfies* success, inclusion, core-retainment, uniformity *and* relative closure

d) *$\div$ is a basic AGM contraction, which satisfies* $(\div 1)$–$(\div 6)$

(2) *if any one of* 1.a–1.d *above hold, then $\tilde{\hookrightarrow}$ reduces to $\sim$:* $\alpha \mathrel{\tilde{\hookrightarrow}} \beta$ iff $\alpha \mathrel{\sim} \beta$.

Now everything is in place to extend the formalism for a base dependence relation $\tilde{\hookrightarrow}$ that also satisfies CCDF^B. Satisfying CCDF^B allows $\tilde{\hookrightarrow}$ to meet both CCD and CCI.

Theorem 21 (Dependence Generalization with Conjunction). *Let relations $\tilde{\hookrightarrow}$, $\sim$ and $\div$ for base B be such that* Cond$\tilde{\hookrightarrow}$ *and* Cond$\sim$ *hold and* inclusion *is satisfied. In the case where B is logically closed,*

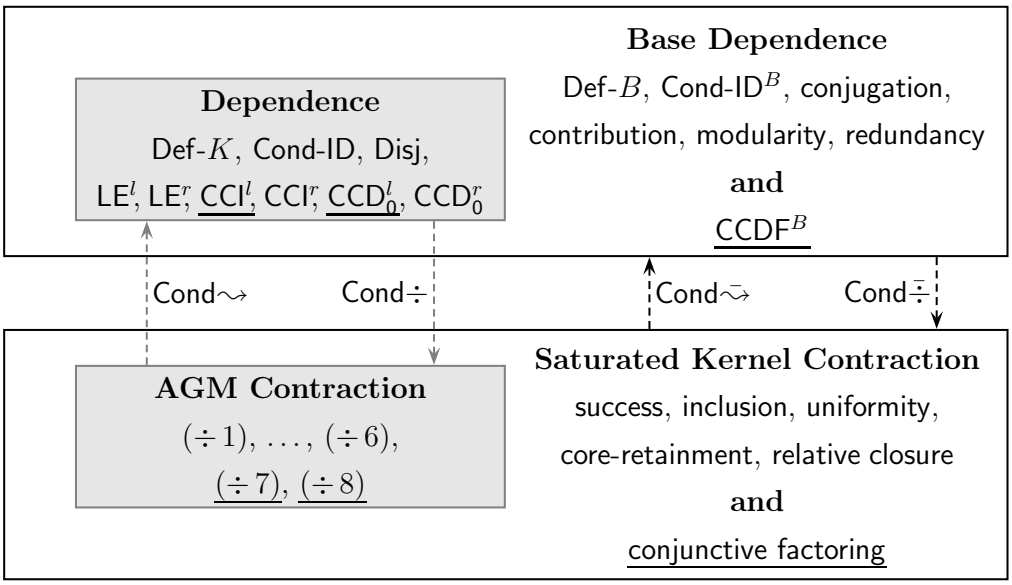

Figure 1: Belief Change and Base Dependence (omitting the underlined axioms results in a weaker characterization)

(1) *the following are logically equivalent:*
   a) $\bar{\rightsquigarrow}$ *is a base dependence that satisfies* Def-B, Cond-ID^B, conjugation, contribution, modularity, redundancy *and* CCDF^B
   b) $\rightsquigarrow$ *is a dependence, which satisfies* Def-K, Cond-ID, Disj, LE^l, LE^r, CCI^l, CCI^r, CCD$^l_0$ *and* CCD$^r_0$
   c) $\div$ *is a saturated kernel contraction that satisfies* success, inclusion, core-retainment, uniformity, relative closure *and* conjunctive factoring
   d) $\div$ *is an AGM contraction, which satisfies* $(\div 1)$–$(\div 6)$, $(\div 7)$ *and* $(\div 8)$

(2) *if any one of* 1.a–1.d *above hold, then* $\bar{\rightsquigarrow}$ *reduces to* $\rightsquigarrow$*:* $\alpha \bar{\rightsquigarrow} \beta$ iff $\alpha \rightsquigarrow \beta$.

This concludes our work. The diagram in Figure 1 captures the key results from Theorems 12-21.

Discussion and Related Work

There are several works that define the concepts of relevance and dependence of formulas. Hansson and Wassermann (2002) propose that these can be classified into two groups. Some authors capture relevance/dependence of formulas through syntactical means such as variable sharing and language splitting, including (Parikh 1999; Chopra and Parikh 2000; Makinson and Kourousias 2006; Kourousias and Makinson 2007; Makinson 2007; Ji, Qi, and Haase 2008; Suntisrivaraporn et al. 2008; Ismail and Kasrin 2010; Wu, Zhang, and Zhang 2011; Perrussel, Marchi, and Zhang 2011; Falappa et al. 2011). Other authors have focused on inferential dependency of formulas, or, in other words, how some formulas deductively contribute to inference of other formulas. Examples of this approach include (Farias del Cerro and Herzig 1996; Hansson and Wassermann 2002; Cuenca Grau, Halaschek-Wiener, and Kazakov 2007), as well as the work reported in the present paper. Typically, syntactical approaches are simpler and computationally more efficient compared to inferential approaches. However, the latter usually provide a more accurate and tighter definition of relevance and dependence than syntactical approaches.

What sets FH's work and our work apart from all other works, is the integration with the theory of belief change. This has an important implication: it provides the most theoretically accurate definition of dependence in the context of belief change. For example, because FH construct their dependence relation using AGM contraction, any other definition of dependence that is put forward to be used in relation to AGM contraction is either as good as their dependence relation or less accurate in capturing dependence of formulas in this context. Of course, being a generalization of FH's work, our framework inherits this property for belief sets, and preserves it for belief bases as well.

Conclusion

With these results, we have provided a formalism of Gärdenfors' preservation criterion such that it generalizes the dependence formalism studied by FH so that it works for belief bases (and belief sets). In the case when a belief base is closed the generalized dependence, base dependence, is equivalent to the original FH dependence relation. While generalizing FH's work, it preserves some of the important characteristics of their study such as Keynes' conjunction criterion for dependence (CCD) and Grdenfors' conjunction criterion for independence (CCI). Additionally, we provide a more specific intuition called *conjunction criterion of dependence factoring*, CCDF, that encompasses both Keynes' CCD and Grdenfors' CCI intuitions.

Belief Change and Semiorders

Abstract

A central result in the AGM framework for belief revision is the construction of revision functions in terms of *total preorders* on possible worlds. These preorders encode comparative plausibility: $r \prec r'$ states that the world r is at least as *plausible* as r'. *Indifference* in the plausibility of two worlds, r, r', denoted $r \sim r'$, is defined as $r \not\prec r'$ and $r' \not\prec r$. Herein we take a closer look at plausibility indifference. We contend that the transitivity of indifference assumed in the AGM framework is not always a desirable property for comparative plausibility. Our argument originates from similar concerns in *preference modelling*, where a structure weaker than a total preorder, called a *semiorder*, is widely consider to be a more adequate model of preference. In this paper we essentially re-construct revision functions using semiorders instead of total preorders. We formulate postulates to characterise this new, wider, class of revision functions, and prove that the postulates are sound and complete with respect to the semiorder-based construction. The corresponding class of contraction functions (via the Levi and Harper Identities) is also characterised axiomatically.

Introduction

Plausibility rankings lie at the heart of modelling *belief change*. They take different forms depending on the approach employed and the type of belief change encoded – see (Peppas and Williams 1995) – ranging from *preorders* on possible worlds (Katsuno and Mendelzon 1991), to *epistemic entrenchments* (Gardenfors and Makinson 1988), to *ordering on remainders* (Alchourron, Gardenfors, and Makinson 1985). The essence however in all such forms is the same: plausibility ranking are used to determine the most plausible objects (worlds, sentences, or remainders respectively), among the alternatives in view of the epistemic input and the given type of belief change. That is, whenever during belief change, one is forced to choose between α or β, the most plausible of the two will be selected (as determined by the corresponding plausibility ranking).

An underlying assumption employed in the prevalent *AGM framework*[1] for belief change, is that *indifference of comparative plausibility is transitive*. To better illustrate our point, let us focus on plausibility rankings $\leqslant$ on possible worlds, called *faithful preorders* in (Katsuno and Mendelzon 1991).

Suppose that two distinct possible worlds w_1, w_2 are equally plausible (or implausible) relative to the agents' current belief state K. We shall denote this by $w_1 \sim w_2$; formally, $w_1 \sim w_2$ iff $w_1 \not\prec w_2$ and $w_2 \not\prec w_1$, where $\prec$ denotes the strict part of $\leqslant$. Suppose now that w_2 is equally plausible to a third world w_3; i.e. $w_2 \sim w_3$. In the AGM framework we automatically conclude that $w_1 \sim w_3$.

Economists on the other hand are more cautious. It has long been acknowledged in the area of *preference modelling* that transitivity is not always a natural property for indifference of preference. The following quote from (Luce 1956) illustrates the problem:

> *"Find a subject who prefers a cup of coffee with one cube of sugar to one with five cubes (this should not be difficult). Now prepare 401 cups of coffee with* $(1 + i/100) \cdot x$ *grams of sugar,* $i = 0, 1, \cdots, 400$*, where x is the weight of one cube of sugar. It is evident that he will be indifferent between cup i and cup* $i + 1$*, for any i, but by choice he is not indifferent between* $i = 0$ *and* $i = 400$*."*

The above example, along with further arguments made in (Luce 1956), support the view that rational agents tend to discriminate between two alternatives α, β only when their difference[2] exceeds a certain *threshold*. As noted by Armstrong in (Armstrong 1950),

> *"The nontransitiveness of indifference must be recognized and explained on [sic] any theory of choice, and the only explanation that seems to work is based on the imperfect powers of discrimination of the human mind whereby inequalities become recognizable only when of sufficient magnitude."*

One can imagine similar scenarios in the context of belief change. To use (an adequately adjusted variation of) a

[1] The AGM framework is the formal framework introduced by *Alchourron, Gardenfors, and Makinson* in (Alchourron, Gardenfors, and Makinson 1985), and further developed by many others (see (Peppas 2008)) for the study of belief change. We shall review its main constituents later in the paper.

[2] Or more accurately, the difference of their respective utilities.

well known example, called *the bald man paradox* – see (Ludwig and Ray 2002) – suppose that our agent, Myrto, believes that her grandfather Speros, whom she never met, had a full head of hair. It is therefore reasonable to assume that the possible world w_{5000} in which her grandfather has 5000 hairs is more plausible to Myrto than the world w_{50} in which Speros has only 50 hairs. On the other hand, it is also reasonable to assume that Myrto is indifferent between worlds, like w_{4657} and w_{4656}, which differ only in that Speros has a single hair less in the latter. If indifference was transitive (as it is the case in the AGM framework), with 4050 applications of transitivity we would derive that Myrto is indifferent between w_{5000} and w_{50}, which of course it is not true.

Indifference between alternatives with fine variations may also be conscious, and not due to 'imperfect powers of discrimination". Ackerman illustrates this point with the following example, (Ackerman 1994):

> *"It is entirely plausible to suppose that an instructor would be indifferent to having the number of students in his seminar be 6 vs. 7, 7 vs. 8, etc., without being indifferent to having it be 6 vs. 15; he might consider 15 students too many for a seminar. But he can certainly discriminate between 6 and 7 students or 7 and 8, etc."*

Another reason for the intransitivity of preference indifference (and likewise, for the intransitivity of plausibility indifference) is the *multi-dimensionality of alternatives*. To take a two-dimensional example from (Fishburn 1970a):[3]

> *"You are going to buy a car. You have no definite preference between (Ford, at $2600) and (Chevrolet, at $2700), and also have no definite preference between (Ford, at $2600) and (Chevrolet, at $2705). However, (Chevrolet, at $2705) < (Chevrolet, at $2700)."*

Considerations like these led Luce to develop in (Luce 1956) a new structure, called a *semiorder*, which has since become widely accepted in the community of mathematical psychology as an adequate model for human preference (see for example, (Fishburn 1970b), (Jamison and Lau 1973), (Pirlot and Vincke 1997), (Rabinovitch 1977), (Rubinstein 2012)).

Herein, and for similar reasons, semiorders are imported in Belief Change; i.e. we re-construct the basic models and results of the AGM framework using semiorders (instead of total preorder) to model comparative plausibility. In particular, we formulate postulates that characterize the (wider) class of revision functions induced from semiorders, and we prove their correctness (i.e. we show that the postulates are *sound* and *complete* with respect to the semiorders-based construction). Moreover, we characterize axiomatically the class of *contraction functions* corresponding, via the Levi and Harper Identities, to semiorder-based revision functions.

The paper is structured as follows. In the next three sections we introduce some notation, we briefly review the AGM framework, and we recall the main definitions and results on semiorders. Following that there are two sections containing the main results of the paper. Finally, in the last two sections we discuss related works and make some concluding remarks.

[3]Notice that in this example "better" items appear higher in the $<$-ordering. This is essentially the reverse of the case with faithful preorders where the more plausible a world is, the lower it appears in the preorder.

Formal Preliminaries

Throughout this paper we work with a finite set of propositional variables P. We define L to be the propositional language generated from P (using the standard boolean connectives $\wedge, \vee, \rightarrow, \leftrightarrow, \neg$ and the special symbols $\top, \bot$) and governed by classical propositional logic.

For a set of sentences Γ of L, we denote by $Cn(\Gamma)$ the set of all logical consequences of Γ, i.e., $Cn(\Gamma) = \{x \in L: \Gamma \models x\}$. We shall often write $Cn(x_1, \ldots, x_n)$, for sentences $x_1, \ldots, x_n$, as an abbreviation of $Cn(\{x_1, \ldots, x_n\})$. For any two sentences x, y we shall write $x \equiv y$ iff $Cn(x) = Cn(y)$.

A theory K of L is any set of sentences of L closed under $\models$, i.e., $K = Cn(K)$. We shall denote the set of all theories of L by $\mathcal{T}$. We define a *possible world* r (or simply a *world*), to be a consistent set of literals such that for any propositional variables $x \in P$, either $x \in r$ or $\neg x \in r$. We will often identify a world r with the conjunction of its literals, leaving it to the context to resolve any ambiguity (for example in "$\neg r$", r is a sentence, whereas in "$r \cap \{x\}$", r is a set of literals). We denote the set of all possible worlds by $\mathcal{M}$.

For a set of sentences Γ of L, $[\Gamma]$ denotes the set of all possible worlds that entail Γ; i.e. $[\Gamma] = \{r \in \mathcal{M} : r \models \Gamma\}$. Often we use the notation $[x]$ for a sentence $x \in L$, as an abbreviation of $[\{x\}]$. For a theory K and a set of sentences Γ of L, we denote by $K + \Gamma$ the closure under $\models$ of $K \cup \Gamma$, i.e., $K + \Gamma = Cn(K \cup \Gamma)$. For a sentence $x \in L$ we often write $K + x$ as an abbreviation of $K + \{x\}$.

Finally, some definitions on binary relations. Let V be a nonempty set and R a binary relation in V. For any subset S of V, by $min(S, R)$ we denote the set $min(S, R) = \{w \in S$: for all $w' \in S$, $w'Rw$ entails $wRw'\}$. The elements in $min(S, R)$ are called *minimal in* S with respect to R (or simply *minimal in* S, when R is understood from the context). Observe that if R is irreflexive and anti-symmetric, the above definition of *min* is equivalent to: $min(S, R) = \{w \in S$: there is no $w' \in S$, such that $w'Rw\}$.

We shall say that a binary R relation in V is a preorder iff R is *reflexive* and *transitive*. Moreover, R is said to be *total* iff for all $w, w' \in V$, wRw' or $w'Rw$.

The AGM Framework

Much research in belief change is based on the work of Alchourron, Gardenfors and Makinson (Alchourron, Gardenfors, and Makinson 1985), who have developed a research framework for this process, known as the *AGM framework*. In this section we shall briefly review the *rationality postulates* for the two most important types of belief change, namely *belief revision* and *belief contraction*, as well a constructive model for belief revision based on total preorders on possible worlds.

The AGM Postulates

In the AGM framework, belief revision is modeled as a function $*$ mapping a theory K and a sentence x to the theory $K*x$. Alchourron, Gardenfors, and Makinson have proposed the following set of postulates for belief revision:

(K*1) $K * x$ is a theory.

(K*2) $x \in K * x$.

(K*3) $K * x \subseteq K + x$.

(K*4) If $\neg x \notin K$ then $K + x \subseteq K * x$.

(K*5) If $x \not\models \bot$ then $K * x \not\models \bot$.

(K*6) If $x \equiv y$ then $K * x = K * y$.

(K*7) $K * (x \wedge y) \subseteq (K * x) + y$.

(K*8) If $\neg y \notin K * x$ then $(K * x) + y \subseteq K * (x \wedge y)$.

A revision function $*$ models the process by which a rational agents modifies her belief set K to incorporate some new information x. A *contraction function* $\div$ on the other hand models the process by which a rational agent uproots a belief x from K.

Formally, a contraction function is defined as a function $\div$ mapping a theory K and a sentence x to the theory $K \div x$, that satisfies the following postulates:

(K$\div$1) $K \div x$ is a theory.

(K$\div$2) $K \div x \subseteq K$.

(K$\div$3) If $x \notin K$ then $K \div x = K$.

(K$\div$4) If $\not\models x$ then $x \notin K \div x$.

(K$\div$5) If $x \in K$, then $K \subseteq (K \div x) + x$.

(K$\div$6) If $x \equiv y$ then $K \div x = K \div y$.

(K$\div$7) $(K \div x) \cap (K \div y) \subseteq K \div (x \wedge y)$.

(K$\div$8) If $x \notin K \div (x \wedge y)$ then $K \div (x \wedge y) \subseteq K \div x$.

Revision and contraction functions are connected through the following well known identities:

$$K \div x = (K * \neg x) \cap K \quad \text{(Harper Identity)}$$

$$K * x = (K \div \neg x) + x \quad \text{(Levi Identity)}$$

It has been shown that for every revision function $*$ satisfying (K*1) - (K*8), the function $\div$induced from $*$ via the Harper Identity, satisfies (K$\div$1) - (K$\div$8). And conversely, for every contraction function $\div$ satisfying (K$\div$1) - (K$\div$8), the function $*$ induced from $\div$ via the Levi Identity, satisfies (K*1) - (K*8) – see (Gardenfors 1988), (Peppas 2008), (Alchourron and Makinson 1982) for details.

Faithful Preorders

Apart from axiomatic approaches to belief change, a number of explicit constructions have also been proposed. One popular such construction is the one proposed by Grove, (Grove 1988), based on a structure called a *system of spheres*. Later Katsuno and Mendelzon, (Katsuno and Mendelzon 1991), re-casted Grove's model for the special case of finitary propositional logic, introducing the notion of *faithful preorders* on possible worlds.

Figure 1: Semiorder with Intransitive Indifference

For a theory K, a preorder on possible worlds $\preccurlyeq$ is said to be *faithful* to K iff it is total and such that the minimal worlds (wrt $\preccurlyeq$) are those satisfying K; i.e. $min(\mathcal{M}, \preccurlyeq) = [K]$.[4] Given a preorder $\preccurlyeq$ that is faithful to K, the revision of K by any sentence x can be defined as follows:

(RP) $[K * x] = min([x], \preccurlyeq)$.

Intuitively $\preccurlyeq$ represents a plausibility ranking on possible worlds: the more plausible a world r is, the lower it appears in the ranking. Hence (RP) essentially defines $K * x$ are the theory induced by the most plausible worlds satisfying the new information x.

Katsuno and Mendelzon proved that the family of functions induced from faithful preorders via (RP), are precisely those satisfying the AGM postulates for revision.

Semiorders

As mentioned in the introduction, semiorders were proposed in (Luce 1956) as a more natural alternative to total preorders for modelling preference.

Given a finite set of choices V, a semiorder $\prec$ in V is defined as a binary relation in V that satisfies the following axioms, for any $r_1, r_2, r_3, w \in V$:

(SO1) $r_1 \not\prec r_1$.

(SO2) If $r_1 \prec r_2 \prec r_3$ then $r_1 \prec w$ or $w \prec r_3$.

(SO3) If $r_1 \prec r_2$ and $r_3 \prec r_4$ then $r_1 \prec r_4$ or $r_3 \prec r_2$.

For any two choices $r_1, r_2 \in V$, we shall say that we are *indifferent* between r_1 and r_2, denoted $r_1 \sim r_2$, iff $r_1 \not\prec r_2$ and $r_2 \not\prec r_1$. It is not hard to verify that with semiorders, indifference is not in general transitive. Consider for example the semiorder $\prec$ depicted in Figure 1, where the arrows between alternatives indicate preference. It is easy to verify that $\prec$ satisfies (SO1) - (SO3). Moreover observe that $r_2 \sim r_3$, $r_3 \sim r_4$, and yet $r_2 \prec r_4$.

A central result on semiorders that sheds light to their inner workings, relates to their numerical representation. It was been shown, (Scott and Suppes 1958), (Rabinovitch 1977), that every semiorder $\prec$ in V can be mapped to a *utility function* $u : V \mapsto \mathbb{R}$ such that for all $r_1, r_2 \in V$, $r_1 \prec r_2$ iff $u(r_2) - u(r_1) \geqslant 1$, and $r_1 \sim r_2$ iff $|u(r_2) - u(r_1)| < 1$. Intuitively this result says that the agent differentiates between two alternatives r_1 and r_2 iff the difference in their

[4] To be precise, in (Katsuno and Mendelzon 1991) a belief state is represented as a sentence rather than as a theory, and accordingly, faithful preorders are associated to sentences rather than theories. However, given that we are working with a language built over finitely many propositional variables, the two approaches are equivalent.

corresponding utilities exceeds a certain threshold (set to 1 in this case). For example, the semiorder $\prec$ of Figure 1 can be represented by the following utility function u:

$$u(r_1) = 0$$
$$u(r_2) = 1$$
$$u(r_3) = 1.5$$
$$u(r_4) = 2$$

Semiorders in Belief Revision

As mentioned in the introduction, the main aim of this article is to re-build (the main elements of) the AGM framework using semiorders rather than total preorders as models of comparative plausibility. In this section we start with revision functions.

Let $\prec$ be a semiorder in the set $\mathcal{M}$ of possible worlds. The function $* : \mathcal{T} \times L \mapsto \mathcal{T}$ induced from $\prec$ is defined by condition (AS) below:[5]

(AS) $\quad [K * x] = min([x], \prec)$.

We are interested in the class of functions induced from semiorders via (AS). Consider in particular the following set of postulates:

(A1) $\quad K * x$ is a theory.

(A2) $\quad x \in K * x$.

(A3) $\quad K * x \subseteq K + x$.

(A4) $\quad$ If $\neg x \notin K$ then $K + x \subseteq K * x$.

(A5) $\quad$ If $x \not\models \bot$ then $K * x \not\models \bot$.

(A6) $\quad$ If $x \equiv y$ then $K * x = K * y$.

(A7) $\quad K * (x \wedge y) \subseteq (K * x) + y$.

(A8) $\quad K * (x \vee y) \subseteq (K * x) + (K * y)$.

(A9) $\quad$ If $K * y \nsubseteq (K * x) + y$ then $K * x \subseteq (K * y) + x$.

(A10) $\quad$ If $\neg y \in K * x$ and $\neg z \notin K * x$ then $K * (x \wedge y) \subseteq (K * z) + (x \wedge y)$.

Postulates (A1) - (A7) are identical to the AGM postulates (K*1) - (K*7) for revision. Postulate (K*8) however cannot simply be copied across.

To see this, assume that the semiorder $\prec$ in Figure 1 represents the comparative plausibility of the worlds r_1, r_2, r_3, r_4. Moreover assume that the agent's current belief set is $K = Cn(r_1)$. In (Gardenfors 1988) it was shown in that (K*8) is equivalent to the following condition:

(3.15) $\quad$ If $\neg y \notin K * (x \vee y)$ then $K * (x \vee y) \subseteq K * y$

Set $x = r_2 \vee r_3 \vee r_4$ and $y = r_3 \vee r_4$. From Figure 1 and (AS) it follows that $[K * x] = \{r_2, r_3\}$, $[K * y] = \{r_3, r_4\}$, and $[K * (x \vee y)] = \{r_2, r_3\}$. Hence $\neg y \notin K * (x \vee y)$ and therefore by (3.15), $[K * y] \subseteq [K * (x \vee y)]$. This of course leads us to a contradiction since $r_4 \in [K * y]$ and $r_4 \notin [K * (x \vee y)]$.

Postulate (K*8) is therefore too strong for semiorder-based revision functions. It turns out, as shown by Theorems 1, 2 below, that (A8) - (A10) are precisely the weakening of (K*8) required to characterise the functions induced from semiorders via (AS).

[5]Condition (AS) is derived from (RP) with semiorders $\prec$ replacing preorders $\preccurlyeq$.

We note that postulate (A8) is not new. It has been used, in a slightly different format, by Benferhat et. al. in their axiomatization of revision functions induced from *partial preorders* (see postulate (P7) in (Benferhat, Lagrue, and Papini 2005)).

Before we present our representation results we need to adjust the definition of faithfulness to semiorders.

Let $\prec$ be a semiorder in $\mathcal{M}$ and K a theory of L. We shall say that $\prec$ is *faithful to* K iff the following conditions are satisfied:

(i) $\quad$ If $r \in [K]$ then there is no $r' \in \mathcal{M}$ such that $r' \prec r$.

(ii) $\quad$ If $r \in [K]$ and $r' \in (\mathcal{M} - [K])$ then $r \prec r'$.

Theorem 1 *Let K be a theory and $*$ a revision function satisfying (A1) - (A10). Then there exists a semiorder $\prec$ faithful to K, that satisfies (AS).*

Proof. Define $\prec$ to be the following binary relation in $\mathcal{M}$: $r \prec r'$ iff $r' \notin [K * (r \vee r')]$. Firstly we show that $\prec$ satisfies (SO1). Consider any possible world $r \in \mathcal{M}$. By (A6), $[K * (r \vee r)] = [K * r]$. Moreover, by (A2), (A5), it follows that $[K * r] = \{r\}$, and therefore $[K * (r \vee r)] = \{r\}$. Hence $r \nprec r$ as desired.

Next we show that (AS) is satisfied by showing $[K * x] \subseteq min([x], \prec)$ and $min([x], \prec) \subseteq [K * x]$.

Starting with the former, let r be any world in $[K * x]$. By (A2), $r \in [x]$. Consider now any world $r' \in [x]$. By (A7), $[K * x] \cap [r \vee r'] \subseteq [K * (x \wedge (r \vee r'))]$. Moreover notice that from $r, r' \in [x]$, it follows that $x \wedge (r \vee r') \equiv r \vee r'$. Hence by (A6), $[K * x] \cap [r \vee r'] \subseteq [K * (r \vee r')]$ and therefore $r \in [K * (r \vee r')]$. Hence $r' \nprec r$. Since r' was chosen as an arbitrary element of $[x]$ it then follows that $r \in min([x], \prec)$. Hence $[K * x] \subseteq min([x], \prec)$.

We prove the converse by induction on the size of $[x]$. If $|[x]| = 1$, then $[x] = \{r\}$. In this case, from (A2) and (A5), and (SO1) (established above) we derive that $[K * x] = \{r\} = min([x], \prec)$.

Assume that $\min([x], \prec) \subseteq [K * x]$, for any $x \in L$ such that $|[x]| \leqslant k$ (Induction Hypothesis).

For the inductive step, assume $|[x]| = k + 1$, and let r be any world in $min([x], \prec)$. We will show that $r \in [K * x]$. To this end, consider any world $r' \in [x]$ that is different from r, and define y to be the sentence $y = x \wedge (\neg r')$. Clearly $[y] = [x] - \{r'\}$ and therefore $r \in min([y], \prec)$. Moreover, $|[y]| = k$, and therefore by the induction hypothesis, $r \in [K * y]$. Also notice that since $r \in min([x], \prec)$ and $r' \in [x]$, it follows that $r' \nprec r$ and therefore, by the construction of $\prec$, $r \in [K * (r \vee r')]$. Hence by (A8), $r \in [K * (y \vee r \vee r')]$, and consequently by (A6), $r \in [K * x]$ as desired. Therefore (AS) holds.

Faithfulness of $\prec$ to K is straightforward. In particular, assume $r \in [K]$ and let r' be an arbitrary possible world. By (A3) - (A4), $[K * (r \vee r')] = [K] \cap [r \vee r']$ and therefore, $r \in [K * (r \vee r')]$. Hence $r' \nprec r$. Notice moreover that if $r' \notin [K]$, then $[K * (r \vee r')] = [K] \cap [r \vee r'] = \{r\}$, and consequently $r \prec r'$. Hence $\prec$ is faithful to K.

To conclude the proof of Theorem 1 we need to show that $\prec$ also satisfies (SO2) and (SO3). To this end, we will first show that $\prec$ is transitive.

Consider any three worlds $r_1, r_2, r_3 \in \mathcal{M}$ such that $r_1 \prec r_2 \prec r_3$. By (AS) it follows that $[K * (r_1 \vee r_2 \vee r_3)] = \{r_1\}$.

Clearly then, $[K * (r_1 \vee r_2 \vee r_3)] \cap [r_2 \vee r_3] = \emptyset$ and $[K * (r_1 \vee r_2 \vee r_3)] \cap [r_1 \vee r_3] \neq \emptyset$, which by (A6) and (A10) entails that $[K * (r_1 \vee r_3)] \cap [r_2 \vee r_3] \subseteq [K * (r_2 \vee r_3)]$. Hence, since $r_2 \prec r_3$ we derive that $r_3 \notin [K * (r_1 \vee r_3)]$, and therefore $r_1 \prec r_3$. Consequently $\prec$ is transitive.

Next for (SO2), let $r_1, r_2, r_3 \in \mathcal{M}$ be any three worlds such that $r_1 \prec r_2 \prec r_3$. Assume towards contradiction that there is a $w \in \mathcal{M}$ such that $r_1 \not\prec w$ and $w \not\prec r_3$. Notice that if $r_2 \prec w$ or $r_3 \prec w$, then transitivity gives us $r_1 \prec w$ which of course contradicts our assumption. Hence $r_2 \not\prec w$ and $r_3 \not\prec w$ (on top of $r_1 \not\prec w$), which combined with (SO1) and (AS) gives us, $w \in [K * (r_1 \vee r_2 \vee r_3 \vee w)]$ and $r_2, r_3 \notin [K * (r_1 \vee r_2 \vee r_3 \vee w)]$. Hence, $[K * (r_1 \vee r_2 \vee r_3 \vee w)] \cap [r_2 \vee r_3] = \emptyset$ and $[K * (r_1 \vee r_2 \vee r_3 \vee w)] \cap [r_3 \vee w] \neq \emptyset$, which by (A6) and (A10) entails $[K * (r_3 \vee w)] \cap [r_2 \vee r_3] \subseteq [K * (r_2 \vee r_3)]$. Consequently, since $r_3 \notin [K * (r_2 \vee r_3)]$ it follows that $r_3 \notin [K * (r_3 \vee w)]$, and therefore $w \prec r_3$, which of course contradicts our initial assumption.

Finally for (SO3), assume towards contradiction that for some $r_1, r_2, r_3, r_4 \in \mathcal{M}$, $r_1 \prec r_2$, $r_3 \prec r_4$, $r_1 \not\prec r_4$, and $r_3 \not\prec r_2$. From transitivity we then derive that $r_2 \not\prec r_4$, and $r_4 \not\prec r_2$. Consequently, by (SO1) and (AS), $r_4 \in [K * (r_1 \vee r_2 \vee r_4)]$ and $r_4 \notin [K * (r_2 \vee r_3 \vee r_4)]$. (A9) then entails that $[K * (r_2 \vee r_3 \vee r_4)] \cap [r_1 \vee r_2 \vee r_4] \subseteq [K * (r_1 \vee r_2 \vee r_4)]$. On the other hand, from (SO1) and (AS) we derive that $r_2 \in [K * (r_2 \vee r_3 \vee r_4)]$, and therefore $r_2 \in [K * (r_1 \vee r_2 \vee r_4)]$. This of course contradicts $r_1 \prec r_2$. ■

In proving the converse of Theorem 1, the following result will be useful:

Lemma 1 *Let $\prec$ be a semiorder in $\mathcal{M}$ and $S \subseteq \mathcal{M}$ a nonempty set of worlds. Then,*

- *(a)* *$\prec$ is transitive.*
- *(b)* *$min(S, \prec) \neq \emptyset$.*
- *(c)* *if $min(S, \prec) \neq \emptyset$, $r \in S$, and $r \notin min(S, \prec)$, then there exists a $r' \in min(S, \prec)$ such that $r' \prec r$.*

Proof. The transitivity of a semiorder follows directly from (Luce 1956). Nevertheless we include the proof herein for completeness. Consider any three worlds $r_1, r_2, r_3 \in \mathcal{M}$ such that $r_1 \prec r_2$ and $r_2 \prec r_3$. From (SO3) it follows that $r_1 \prec r_3$ or $r_2 \prec r_2$. The latter is excluded by (SO1), and consequently $r_1 \prec r_3$ as desired.

Next we prove the third statement of Lemma 1 by induction on the size of S. If $|S| = 1$, then $S = \{r\}$ for some world r. Consequently by (SO1), $min(S, \prec) = \{r\}$ and hence (c) trivially holds.

Assume that (c) is true for all nonempty sets with cardinality no greater than k (Induction Hypothesis).

For the inductive step, consider a set $S \subseteq \mathcal{M}$ such that $|S| = k + 1$, and assume that $min(S, \prec) \neq \emptyset$, and for some $r \in S$, $r \notin min(S, \prec)$. Then there is a $r' \in S$ such that $r' \prec r$. From transitivity and (SO1) we then derive that $r' \neq r$ and $r \not\prec r'$. Consider now the set $S - \{r\}$. Clearly, $r' \in (S - \{r\})$ and $|S - \{r\}| = k$. If $r' \in min(S - \{r\}, \prec)$, then from $r \not\prec r'$ it follows that $r' \in min(S, \prec)$, and therefore $r' \prec r$ gives us (c). Assume therefore that $r' \notin min(S - \{r\}, \prec)$. Then by the induction hypothesis, there exists a $r'' \in min(S - \{r\}, \prec)$ such that $r'' \prec r'$. Then transitivity entails $r'' \prec r$. Moreover (SO1) together with transitivity entail $r \not\prec r''$. Hence $r'' \in min(S, \prec)$. Combined with $r'' \prec r$ we derive (c).

Finally we prove (b), once again using induction on the size of S. If $|S| = 1$, then $S = \{r\}$ for some world r. Then by (SO1), $min(S, \prec) = \{r\}$ and hence $min(S, \prec) \neq \emptyset$.

Assume that (b) is true for all nonempty sets $S \subseteq \mathcal{M}$ of size up to k (Induction Hypothesis).

Suppose now that $S \subseteq \mathcal{M}$ is a set with cardinality $|S| = k + 1$. Pick an arbitrary world $r \in S$. If $r \in min(S, \prec)$ then (b) is satisfied. Assume therefore that $r \notin min(S, \prec)$. Then there is a $r' \in S$ such that $r' \prec r$. From (SO1) and transitivity it follows that $r' \neq r$ and $r \not\prec r'$. Hence $r' \in (S - \{r\})$. If $r' \in min(S - \{r\}, \prec)$, from $r \not\prec r'$ we derive that $r' \in min(S - \{r\}, \prec)$ and therefore $min(S, \prec) \neq \emptyset$ as desired. Assume therefore that $r' \notin min(S - \{r\}, \prec)$. By the induction hypothesis we derive that $min(S - \{r\}, \prec) \neq \emptyset$. Hence from (c) it follows that there is a $r'' \in min(S - \{r\}, \prec)$ such that $r'' \prec r'$. Transitivity then entails that $r'' \prec r$, and consequently from (SO1) and transitivity it follows that $r \not\prec r''$. This again entails that $r'' \in min(S, \prec)$, and therefore, $min(S, \prec) \neq \emptyset$. ■

With the aid of Lemma 1 we can now prove the soundness of our postulates wrt the semiorder-based construction:

Theorem 2 *Let K be a theory and $\prec$ a semiorder faithful to K. The revision function $*$ induced from $\prec$ via (AS), satisfies (A1) - (A10).*

Proof. The validity of (A1), (A2), and (A6) is straightforward. For (A3), notice that if $\neg x \in K$ then $K + x = L$, and therefore $K * x \subseteq K + x$. Assume now that $\neg x \notin K$, or equivalently, $[K] \cap [x] \neq \emptyset$. Then by the faithfulness of $\prec$ to K it follows that $min([x], \prec) = [K] \cap [x]$. Hence by (AS), $K * x = K + x$. This proves (A3). Moreover, the second part of the argument also proves (A4).

For (A5), assume that $x \not\models \bot$ or equivalently that $[x] \neq \emptyset$. Then from Lemma 1.(b) it follows that $min([x], \prec) \neq \emptyset$. Hence $K * x$ is consistent as desired.

For (A7), let r be any world in $[(K * x) + y]$ and assume towards contradiction that $r \notin [K * (x \wedge y)]$. From $r \in [(K * x) + y]$ it follows that $[x \wedge y] \neq \emptyset$, and hence from $r \notin [K * (x \wedge y)]$ we derive that for some $r' \in [x] \cap [y]$, $r' \prec r$. Consequently, $r \notin min([x], \prec)$, which of course contradicts $r \in [(K * x) + y]$.

For (A8), assume that $r \in [K * x] \cap [K * y]$. Clearly then $[x] \neq \emptyset$ and $[y] \neq \emptyset$. Suppose contrary to (A8), that $r \notin [K * (x \vee y)]$. Then, since $r \in [x \vee y]$ we derive that there is a $r' \in [x \vee y]$ such that $r' \prec r$. Since $[x \vee y] = [x] \cup [y]$ it follows that $r \in [x]$ or $r \in [y]$. In the first case, from $r' \prec r$ we derive that $r \in min([x], \prec)$. In the second case we derive that $r \in min([y], \prec)$. Hence in both cases we have that $r \notin [K * x] \cap [K * y]$, contradicting our initial assumption.

For (A9), assume that for some $x, y \in L$, $[K * x] \cap [y] \not\subseteq [K * y]$. Then there is a $r \in [K * x] \cap [y]$ such that $r \notin [K * y]$. From $r \in [K * x] \cap [y]$ it follows that $[x] \neq \emptyset$ and $[y] \neq \emptyset$. Hence from $r \notin [K * y]$ we derive that there is a $r' \in [y]$ such that $r' \prec r$. Now assume toward contradiction that $[K * y] \cap [x] \not\subseteq [K * x]$, and let $w \in \mathcal{M}$ be such that $w \in [K * y] \cap [x]$ and $w \notin [K * x]$. From the latter we derive that there is a $w' \in [x]$ such that $w' \prec w$. Then (SO3) entails

that $r' \prec w$ or $w' \prec r$. In the first case, since $r' \in [y]$, it follows that $w \notin min([y], \prec)$, which of course contradicts $w \in [K * y]$. In the second case, from $w' \in [x]$ we derive that $r \notin min([x], \prec)$, which contradicts $r \in [K * x]$. Hence, in both case we derive a contradiction, and therefore (A9) is true.

Finally for (A10), let $x, y, z \in L$ be such that $[K*x] \cap [y] = \emptyset$, and $[K * x] \cap [z] \neq \emptyset$. Assume towards contradiction that there exists a $r \in [K*z] \cap [x] \cap [y]$ such that $r \notin [K*(x \wedge y)]$. Then, by Lemma 1.(c), there exists a $r' \in min([x \wedge y], \prec)$ such that $r' \prec r$. From $[K * x] \cap [y] = \emptyset$ we then derive that $r' \notin min([x], \prec)$. Hence from Lemma 1.(c) it follows that there is a $r'' \in min([x], \prec)$ such that $r'' \prec r'$. Moreover from $[K * x] \cap [z] \neq \emptyset$ we derive that there is a $w \in [z]$ such that $w \in [K * x]$. From $r'' \prec r' \prec r$ and (SO2) we derive that $r'' \prec w$ or $w \prec r$. In the first case, since $r'' \in [x]$, it follows that $w \notin min([x], \prec)$, contradicting $w \in [K * x]$. In the latter case, since $w \in [z]$, we derive that $r \notin min([z], \prec)$, contradicting $r \in [K * z]$. Hence in both cases we derive a contradiction. Thus (A10) hold. ■

Semiorders in Belief Contraction

In this section we identify the class of contraction functions that correspond, via the Harper and Levi Identities, to semiorder-induced revision functions.

In particular, consider the following postulates:

(B1) $K \div x$ is a theory.

(B2) $K \div x \subseteq K$.

(B3) If $x \notin K$ then $K \div x = K$.

(B4) If $\not\models x$ then $x \notin K \div x$.

(B5) If $x \in K$ then $K \subseteq (K \div x) + x$.

(B6) If $x \equiv y$ then $K \div x = K \div y$.

(B7) $(K \div x) \cap (K \div y) \subseteq K \div (x \wedge y)$.

(B8) $K \div (x \wedge y) \subseteq (K \div x) + (K \div y)$.

(B9) If $K \div y \notin (K \div x) + \neg y$ then $K \div x \subseteq (K \div y) + \neg x$.

(B10) If $x \vee y \in K \div x$, and $x \vee z \notin K \div x$ then $K \div (x \vee y) \subseteq K \div (x \vee z) + \neg(x \vee y)$.

Postulates (B1) - (B7) are identical to (K÷1) - (K÷7). On the other hand (B8) - (B10) are weaker variants of (K÷8) (assuming the presence of (B1) - (B7)).

The following results show that the class of contraction functions satisfying (B1) - (B10) corresponds precisely, via the Levi and Harper Identities, to the class of revision functions satisfying (A1) - (A10).

Theorem 3 *Let K be a theory, $*$ a revision function satisfying (A1) - (A10), and $\div$ the function induced from $*$ via the Harper Identity. Then $\div$ satisfies (B1) - (B10).*

Proof. From Theorems 3.4, 3.5 in (Gardenfors 1988), it follows that $\div$ satisfies (B1) - (B7).

For (B8), consider any $x, y \in L$. By the Harper Identity, $[K \div x] \cap [K \div y] = ([K * \neg x] \cup [K]) \cap ([K * \neg y] \cup [K]) = ([K*\neg x] \cap [K*\neg y]) \cup ([K*\neg x] \cap [K]) \cup ([K*\neg y] \cap [K]) \cup [K]$. Moreover by (B2), $[K] \subseteq [K * \neg x]$, $[K] \subseteq [K * \neg y]$, and by (A6) and (A8), $[K*\neg x] \cap [K*\neg y] \subseteq [K*\neg(x \wedge y)]$. Consequently, $[K \div x] \cap [K \div y] \subseteq [K * \neg(x \wedge y)] \cup [K]$. Hence, by the Harper Identity, $K \div (x \wedge y) \subseteq (K \div x) + (K \div y)$ as desired.

For (B9), consider any $x, y \in L$ such that $[K \div x] \cap [\neg y] \notin [K \div y]$. Then by the Harper Identity, $([K * \neg x] \cup [K]) \cap [\neg y] \notin [K*\neg y] \cup [K]$ and consequently, $([K*\neg x] \cap [\neg y]) \cup ([K] \cap [\neg y]) \notin [K * \neg y] \cup [K]$. Since by (A3) $[K] \cap [\neg y] \subseteq [K * \neg y]$, we then derive that $[K * \neg x] \cap [\neg y] \notin [K * \neg y]$. Then by (A9) it follows that $[K * \neg y] \cap [\neg x] \subseteq [K * \neg x]$. Hence $([K*\neg y] \cap [\neg x]) \cup [K] \subseteq [K*\neg x] \cup [K]$ and therefore $([K * \neg y] \cup [K]) \cap ([\neg x] \cup [K]) \subseteq [K * \neg x] \cup [K]$. By the Harper Identity we then derive $([K \div y] \cap ([\neg x] \cup [K]) \subseteq [K \div x]$, and therefore, $([K \div y] \cap [\neg x]) \cup ([K \div y] \cap [K]) \subseteq [K \div x]$. Hence $[K \div y] \cap [\neg x] \subseteq [K \div x]$ or equivalently, $K \div x \subseteq (K \div y) + \neg x$.

Finally for (B10), assume that for some $x, y, z \in L$, $[K \div x] \cap [\neg x] \subseteq [y]$, and $[K \div x] \cap [\neg x] \notin [z]$. Firstly assume that $x \notin K$. Then by (B3), $K \div x = K$. Hence from $[K \div x] \cap [\neg x] \notin [z]$ we derive that $(x \vee z) \notin K$, and consequently by (B3), $K \div (x \vee z) = K$. Then by (B2), $K \div (x \vee y) \subseteq K \div (x \vee z)$, and therefore, $K \div (x \vee y) \subseteq K \div (x \vee z) + \neg(x \vee y)$ as desired.

Assume therefore that $x \in K$. From $[K \div x] \cap [\neg x] \subseteq [y]$, and $[K \div x] \cap [\neg x] \notin [z]$ and the Harper Identity it follows that $([K * \neg x] \cup [K]) \cap [\neg x] \subseteq [y]$, and $([K * \neg x] \cup [K]) \cap [\neg x] \notin [z]$. Consequently, $([K * \neg x] \cap [\neg x]) \cup ([K] \cap [\neg x]) \subseteq [y]$, and $([K * \neg x] \cap [\neg x]) \cup ([K] \cap [\neg x]) \notin [z]$. Since $x \in K$ we then derive, $[K*\neg x] \cap [\neg x] \cap [\neg y] = \emptyset$, and $[K*\neg x] \cap [\neg x] \cap [\neg z] \neq \emptyset$, or equivalently, $[K*\neg x] \cap [\neg x \wedge \neg y] = \emptyset$, and $[K*\neg x] \cap [\neg x \wedge \neg z] \neq \emptyset$. Axiom (A10) then entails that $[K*(\neg x \wedge \neg z)] \cap [\neg x \wedge \neg y] \subseteq [K*(\neg x \wedge \neg y)]$. Hence $([K*(\neg x \wedge \neg z)] \cap [\neg x \wedge \neg y]) \cup [K] \subseteq [K*(\neg x \wedge \neg y)] \cup [K]$, and consequently, by (A6), $([K * \neg(x \vee z)] \cup [K]) \cap ([\neg x \wedge \neg y] \cup [K]) \subseteq [K*\neg(x \vee y)] \cup [K]$. Therefore by the Harper Identity, $[K \div (x \vee z)] \cap ([\neg(x \vee y)] \cup [K]) \subseteq [K \div (x \vee y)]$. Hence $([K \div (x \vee z)] \cap [\neg(x \vee y)]) \cup ([K \div (x \vee z)] \cap [K]) \subseteq [K \div (x \vee y)]$, and consequently, $K \div (x \vee y) \subseteq K \div (x \vee z) + \neg(x \vee y)$ as desired. ■

Theorem 4 *Let K be a theory, $*$ a contraction function satisfying (B1) - (B10), and $*$ the function induced from $*$ via the Levi Identity. Then $*$ satisfies (A1) - (A10).*

Proof. From Theorems 3.2, 3.3 in (Gardenfors 1988), it follows that $*$ satisfies (A1) - (A7).

For (A8), let x, y be any sentences in L. By the Levi Identity, $[K * x] \cap [K * y] = [K \div \neg x] \cap [x] \cap [K \div \neg y] \cap [y]$ and therefore by (B8) and (B6), $[K * x] \cap [K * y] \subseteq [K \div \neg(x \vee y)] \cap [x \wedge y]$. Moreover notice that $[x \wedge y] \subseteq [x \vee y]$ and consequently we derive $[K * x] \cap [K * y] \subseteq [K \div \neg(x \vee y)] \cap [x \vee y]$. Hence from the Levi Identity it follows that $K * (x \vee y) \subseteq (K * x) + (K * y)$ as desired.

For (A9), assume that for some $x, y \in L$, $[K * x] \cap [y] \notin [K * y]$. Then by the Levi Identity we have that $[K \div \neg x] \cap [x] \cap [y] \notin [K \div \neg y] \cap [y]$ and consequently $[K \div \neg x] \cap [y] \notin [K \div \neg y]$. Then by (B9), $[K \div \neg y] \cap [x] \subseteq [K \div \neg x]$, and therefore $[K \div \neg y] \cap [x] \subseteq [K \div \neg x] \cap [x]$. This again entails $[K \div \neg y] \cap [x] \cap [y] \subseteq [K \div \neg x] \cap [x]$ which by the Levi Identity entails $[K * y] \cap [x] \subseteq [K * x]$, or equivalently, $K * x \subseteq (K * y) + x$ as desired.

Finally for (A10), assume that for some $x, y, z \in L$, $[K * x] \cap [y] = \emptyset$ and $[K * x] \cap [z] \neq \emptyset$. Then by the Levi Identity we get, $[K \div \neg x] \cap [x] \cap [y] = \emptyset$ and $[K \div \neg x] \cap [x] \cap [z] \neq \emptyset$, or equivalently, $\neg y \in (K \div \neg x) + x$ and $\neg z \notin (K \div \neg x) + x$. Hence by (B10) and (B6), $[K \div \neg(x \wedge z)] \cap [x \wedge y] \subseteq [K \div \neg(x \wedge y)]$, and consequently, $[K \div \neg(x \wedge z)] \cap [x \wedge y] \subseteq [K \div \neg(x \wedge y)] \cap [x \wedge y]$. This again entails, $[K \div \neg(x \wedge z)] \cap [x \wedge z] \cap [x \wedge y] \subseteq [K \div \neg(x \wedge y)] \cap [x \wedge y]$, and therefore by the Levi Identity we derive, $K * (x \wedge y) \subseteq K * (x \wedge z) + (x \wedge y)$. Moreover by (A6) - (A7), $K * (x \wedge z) \subseteq (K * z) + x$ and therefore $K * (x \wedge y) \subseteq (K * z) + (x \wedge y)$ as desired. ■

Related Work

To our knowledge, this is the first time that semiorders are used in Belief Change. Yet a number of researchers have considered other weaker alternatives of total preorders as models of comparative plausibility. We have already mentioned (Benferhat, Lagrue, and Papini 2005), in which the authors study revision functions based on *partial preorders*.

Another instance is (Rott to appear). In this paper Rott, focuses on contraction functions, and uses the metaphor of a multilayer edifice to classify them. In particular, on the ground floor of the edifice one encounters the contraction functions satisfying the basic postulates $(K \div 1)$ - $(K \div 6)$. On the top floor dwell the fully fledged AGM contraction functions satisfying all eight postulates $(K \div 1)$ - $(K \div 8)$. In the space between the ground and the top floors, Rott identifies three more floors, each of which is of interest in its own right. The 3rd floor of the edifice is the one most relevant to the present work: on this floor live the relational partial meet contraction functions induced from *interval orders* (on remainders).[6] We recall that an interval order is a binary relation $<$ satisfying (SO1) and (SO3); hence every semiorder is an interval order, but not vice versa.

Rott proves that the functions residing on the 3rd floor can be characterised axiomatically by $(K \div 1)$ - $(K \div 7)$, together with the postulates $(K \div 8\text{c})$ and $(K \div 8\text{d})$ below; notice the close resemblance between $(K \div 8\text{d})$ and our postulate (B8):

$(K \div 8\text{c})$ If $y \in K \div (x \wedge y)$, then $K \div (x \wedge y) \subseteq K \div x$.

$(K \div 8\text{d})$ $K \div (x \wedge y) \subseteq (K \div x) \cup (K \div y)$.

In view of the prominence of semiorders in modeling intransitivity of preference indifference (and of plausibility indifference), we believe that an extra floor could be added to Rott's edifice between the 3rd and the top floor, to accommodate the contraction functions of the previous section.

Interval orders have also been used in (Booth and Meyer 2011). However, whereas herein we use semiorders to model comparative plausibility, in (Booth and Meyer 2011) interval orders are used at a meta-level to guide the *iterated revision* process (with comparative plausibility still been modelled with total preorders like in the classical AGM framework).

Conclusion

Researchers in the *preference modelling* community have long argued in favour of *semiorders* over *total preorders* as a more natural model for preference. The main advantage of semiorders is the intransitivity of indifference.

Herein we have argued that in the context of Belief Change indifference in plausibility could also be non-transitive. We therefore re-built the AGM framework with semiorders replacing total preorders. In particular we characterize axiomatically the class of revision functions induced by semiorders, along with the corresponding class or contraction functions (via the Levi and Harper Identities). Future work will include similar results for the epistemic entrenchment and the partial meet models.

Of course Belief Change is not the only area in Knowledge Representation that uses plausibility rankings. *Nonmonotonic Reasoning* for example also relies heavily on such rankings. Moreover, like in Belief Change, plausibility indifference in Nonmonotonic Reasoning is also typically assumed to be transitive. Hence we believe that the study of semiorders in the context of Nonmonotonic Reasoning is an important avenue for future work that could lead to significant contributions.

[6] See (Gardenfors 1988), (Peppas 2008) for details on the partial meet model for contraction.

Acknowledgements

We are grateful to Abhaya Nayak and Maurice Pagnucco for many valuable discussion on this work. Moreover we would like to thank the anonymous reviewers for their detailed comments and insightful input, as well as Hans Rott for bringing (Rott to appear) to our attention.

David Poole's Specificity Revised*

FB AI, Harz University of Applied Sciences, 38855 Wernigerode, Germany
wirth@logic.at, fstolzenburg@hs-harz.de

Abstract

In the middle of the 1980s, David Poole introduced a semantical, model-theoretic notion of specificity to the artificial-intelligence community. Since then it has found further applications in non-monotonic reasoning, in particular in defeasible reasoning. Poole's notion, however, turns out to be intricate and problematic, which — as we show — can be overcome to some extent by a closer approximation of the intuitive human concept of specificity. Besides the intuitive advantages of our novel specificity ordering over Poole's specificity relation in the classical examples of the literature, we also report some hard mathematical facts: Contrary to what was claimed before, we show that Poole's relation is not transitive. Our new notion of specificity is transitive and also monotonic w.r.t. conjunction.

Keywords: specificity, defeasible reasoning, argumentation.

1 Introduction

A possible explanation of how humans manage to interact with reality — in spite of the fact that their information on the world is partial and inconsistent — mainly consists of the following two points: Humans use a certain amount of rules for default reasoning and are aware that some arguments relying on these rules may be defeasible. In case of the frequent conflicting or even contradictory results of their reasoning, they prefer more specific arguments to less specific ones. An intuitive concept of specificity plays an essential rôle in this explanation, which seems to be highly successful in practice. On the long way approaching this proven intuitive human concept of specificity, the first milestone marks the development of a semantical, model-theoretic notion of specificity having passed first tests of its usefulness and empirical validity. Indeed, at least as the first step, a semantical, model-theoretic notion will probably offer a broader and better basis for applications in systems for common sense reasoning than notions of specificity that depend on peculiarities of special calculi or even on extra-logical procedures. This holds in particular if the results of these systems are to be accepted by humans.

David Poole (1985) has sketched such a notion as a binary relation on arguments and evaluated its intuitive validity with some examples. Poole's notion of specificity was given a more appropriate formalization in (Simari and Loui 1992). The properties of this formalization were examined in detail in (Stolzenburg et al. 2003).

In this paper, before we give a specification of the formal requirements on any reasonably conceivable relation of specificity in Sect. 4, we present a detailed analysis of the intentional motivation of our *intuition that Poole's specificity is a first step on the right way* (Sect. 3). Moreover, in Sect. 5, we clearly disambiguate Poole's specificity from slightly improved versions such as the one in (Simari and Loui 1992), and introduce a novel specificity relation ($\lesssim_{\mathrm{CP1}}$), which presents a major correction of Poole's specificity because it removes a crucial shortcoming of Poole's original relation ($\lesssim_{\mathrm{P1}}$) and its slight improvements ($\lesssim_{\mathrm{P2}}$, $\lesssim_{\mathrm{P3}}$), namely their lack of transitivity. Finally, in Sect. 6, we present several examples that will convince every carefully contemplating reader of the superiority of our novel specificity relation $\lesssim_{\mathrm{CP1}}$ w.r.t. human intuition, including monotonicity w.r.t. conjunction. We briefly discuss related works in Sect. 7, and conclude with Sect. 8.

2 Basic Notions and Notation

Let us narrow the general logical setting of specificity down to the concrete framework of *defeasible logic with the restrictions of logic programming*, as found e.g. in (Stolzenburg et al. 2003; Chesñevar et al. 2003).

A *literal* is an atom, possibly prefixed with the symbol "$\neg$" for negation. A *rule* is a literal, but possibly suffixed with a reverse implication symbol "$\Leftarrow$" that is followed by a conjunction of literals, consisting of one literal at least. Let Π be a set of rules. The *theory of* Π is the set $\mathfrak{T}_\Pi$ inductively defined to contain all instances of literals from Π and all literals L for which there is a conjunction C of literals from $\mathfrak{T}_\Pi$ such that $L \Leftarrow C$ is an instance of a rule in Π. For $\mathfrak{L} \subseteq \mathfrak{T}_\Pi$, we also say that Π *derives* $\mathfrak{L}$, and write $\Pi \vdash \mathfrak{L}$. Π is *contradictory* if there is an atom A such that $\Pi \vdash \{A, \neg A\}$; otherwise Π is *non-contradictory*.

Throughout this paper, we will assume a set of literals and two sets of rules to be given: A set Π^{F} of literals meant to describe the *Facts* of the concrete situation under consideration, a set Π^{G} of *General rules* meant to hold in all possible worlds, and a set Δ of *defeasible* (or default) rules meant to hold in most situations. The set $\Pi := \Pi^{\mathrm{F}} \cup \Pi^{\mathrm{G}}$ is the set of *strict* rules that — contrary to the defeasible rules — are considered to be safe and are not doubted in any concrete situation. There is no difference in derivations between the strict rules from Π and the defeasible rules from Δ. If a contradiction occurs, however, we will narrow the defeasible rules from Δ down to a subset $\mathcal{A}$ of its *ground* instances, i.e. instances without free variables, such that no further instantiation can occur. Such a subset, together with the literal whose derivation is in focus, is called an *argument*. With implicit reference to the fixed sets of rules Π and Δ, we formally define:

Definition 2.1 (Argument)
$(\mathcal{A}, L)$ is an *argument* if $\mathcal{A}$ is a set of ground instances of rules from Δ and $\mathcal{A} \cup \Pi \vdash \{L\}$.

For ease of distinction, we will use the special symbol "$\leftarrow$" as a syntactical sugar in concrete examples of defeasible rules from Δ, instead of the symbol "$\Leftarrow$", which — in our concrete examples — will be used only in strict rules.

Example 2.2 (Poole 1985, Example 1)
$\Pi^{\mathrm{F}}_{2.2} := \{\ \mathsf{bird(tweety)},\ \mathsf{emu(edna)}\ \},$
$\Pi^{\mathrm{G}}_{2.2} := \left\{ \begin{array}{l} \mathsf{bird}(x) \Leftarrow \mathsf{emu}(x), \\ \neg\mathsf{flies}(x) \Leftarrow \mathsf{emu}(x) \end{array} \right\},$
$\Delta_{2.2} := \{\ \mathsf{flies}(x) \leftarrow \mathsf{bird}(x)\ \},$
$\mathcal{A}_2 := \{\ \mathsf{flies(edna)} \leftarrow \mathsf{bird(edna)}\ \}.$
We have $\mathfrak{T}_{\Pi_{2.2}}$=$\{\mathsf{bird(tweety)}, \mathsf{emu(edna)}, \mathsf{bird(edna)}, \neg\mathsf{flies(edna)}\}$, $\mathfrak{T}_{\Pi_{2.2}\cup\Delta_{2.2}}$=$\{\mathsf{flies(edna)}, \mathsf{flies(tweety)}\} \cup \mathfrak{T}_{\Pi_{2.2}}$. It is intuitively clear here that we prefer the argument $(\emptyset, \neg\mathsf{flies(edna)})$ to the argument $(\mathcal{A}_2, \mathsf{flies(edna)})$, simply because the former is more specific. We will further discuss this in Example 5.17.

We will use several binary relations comparing arguments according to their specificity. For any relation written as $\lesssim_N$ ("being more or equivalently specific w.r.t. N"), we set
$\gtrsim_N := \{\ (X,Y) \mid Y \lesssim_N X\ \}$ ("less or equivalently specific"),
$\approx_N := \lesssim_N \cap \gtrsim_N$ ("equivalently specific"),
$<_N := \lesssim_N \setminus \gtrsim_N$ ("properly more specific"),
$\leq_N := <_N \cup \{\ (X,X) \mid X \text{ is an argument}\ \}$ ("more specific or equal"),
$\triangle_N := \left\{ (X,Y) \;\middle|\; \begin{array}{l} X, Y \text{ are arguments with} \\ X \not\lesssim_N Y \text{ and } X \not\gtrsim_N Y \end{array} \right\}$ ("incomparable w.r.t. specificity").
A *quasi-ordering* is a reflexive transitive relation. An *(irreflexive) ordering* is an irreflexive transitive relation. A *reflexive ordering* (also called: "partial ordering") is an antisymmetric quasi-ordering. An *equivalence* is a symmetric quasi-ordering.

Corollary 2.3
If $\lesssim_N$ is a quasi-ordering, then $\approx_N$ is an equivalence, $<_N$ is an ordering, and $\leq_N$ is a reflexive ordering.

3 An Intuitive Notion of Specificity

It is part of general knowledge that a criterion is [properly] more specific than another one if the *class of candidates that satisfy it* is a [proper] subclass of that of the other one. Analogously — taking logical formulas as the criteria — a formula A is [properly] more specific than a formula B, if the model class of A is a [proper] subclass of the model class of B, i.e. if $A \models B$ [and $B \not\models A$].

To enable a closer investigation of the critical parts of a defeasible derivation, we have to isolate its defeasible parts. Abstracting from the concrete derivation of a literal L, let us take the set $\mathcal{A}$ of the ground instances of the defeasible rules that are actually applied in the derivation, and form the pair $(\mathcal{A}, L)$, which we already called an *argument* in Definition 2.1.

If we want to classify a derivation with defeasible rules according to its specificity, then we have to isolate the defeasible part of the derivation and look at its input. In our setting, the input consists of the set of those literals on which the defeasible part of the derivation is based, called the *activation set* for the defeasible part of the derivation. In our framework of defeasible logic programming, the only relevant property of an activation set can be the conjunction of its literals which is immediately represented by the set itself.

Because all literals of an activation set have been derived from the given specification, it does not make sense to compare activation sets w.r.t. the models of the entire specification. Indeed, only a comparison w.r.t. the models of a sub-specification can show any differences between them.

It is clear that we want to have the *entire* set Π^{G} for our comparison of activation sets, simply because we want to base our specificity classification on our specification, namely on its general and strict part. We have to exclude Π^{F} from this comparison, however. This exclusion makes sense because the defeasible rules are typically default rules not written in particular for the given concrete situation that is formalized by Π^{F}, and because the inclusion of Π^{F} would trivially admit every activation set. Moreover, as we want to compare the defeasible parts of derivations, we should exclude the defeasible rules from Δ from this comparison. We conclude that Π^{G} is that part of our specification according to which activation sets are to be compared.

Very roughly speaking, if we have fewer activation sets, then we have fewer models, which again means to have a higher specificity. Accordingly, a first sketch of a notion of specificity can now be given as follows:

> An argument $(\mathcal{A}_1, L_1)$ is [properly] *more specific than* an argument $(\mathcal{A}_2, L_2)$ if, for each activation set H_1 for $(\mathcal{A}_1, L_1)$, there is an activation set $H_2 \subseteq \mathfrak{T}_{H_1 \cup \Pi^{\mathrm{G}}}$ for $(\mathcal{A}_2, L_2)$ [but not vice versa].

Note that this notion of specificity is preliminary, and that the notion of an activation set for argument has not been properly defined yet.

On the one hand, the argument $(\mathcal{A}, L)$ is a nice abstraction from the derivation of L, because it perfectly suits our model-theoretic intentions described in Sect. 1. By this abstraction, on the other hand, we lose the possibility to isolate the defeasible parts of the derivation more precisely.

Let us compare this set $\mathcal{A}$ with an *and-tree of the derivation*. Every node in such a tree is labeled with the conclusion of an instance of a rule, such that its children are labeled exactly with the elements of the conjunction in the condition of this instance.

An isolation of the defeasible parts of an and-tree of the derivation may proceed as follows:

- Starting from the root of the tree, we iteratively erase all applications of strict rules. This results in a set of trees, each of which has the application of a defeasible rule at the root.
- Starting now from the leaves of these trees, we again erase all applications of strict rules. This results in a set of trees where all nodes *all* of whose children are leaves result from an application of a defeasible rule.

In a first approximation, we may now take all leaves of all resulting trees as the activation set for the original derivation.

Note that in the set of trees resulting from the described procedure, there may well have remained instances of rules from Π^{G} connecting a defeasible root application with the defeasible applications right at the leaves. Thus — to cover the whole defeasible part of the derivation in our abstraction — we have to consider the set $\mathcal{A} \cup \Pi^{\mathrm{G}}$ instead of just the set $\mathcal{A}$.

More precisely, we have to include all proper rules (i.e. those with non-empty conditions) from Π^{G}, and may also include the literals in Π^{G} because they cannot do any harm. As a consequence, in the modeling via our abstraction $\mathcal{A}$, we cannot prevent the precisely isolated defeasible sub-trees resulting from the described procedure from using the rules from Π^{G} to grow toward the root and toward the leaves again. It is clear, however, that only the growth toward the leaves can affect our activation sets and our notion of specificity.

Let us have a closer look at the effects of such a growth toward the leaves in the most simple case. In addition to a given activation set $\{\mathsf{Q}(\mathsf{a})\}$, in the presence of a general rule

$$\mathsf{Q}(x) \Leftarrow \mathsf{P}_0(x) \wedge \cdots \wedge \mathsf{P}_{n-1}(x)$$

from Π^{G}, we will also have to consider the activation set $\{\, \mathsf{P}_i(\mathsf{a}) \mid i \in \{0, \ldots, n-1\} \,\}$. This has two effects.

The first effect is that we immediately realize that every model of Π^{G} that is represented by the activation set $\{\, \mathsf{P}_i(\mathsf{a}) \mid i \in \{0, \ldots, n-1\} \,\}$ is also represented by the activation set $\{\mathsf{Q}(\mathsf{a})\}$; simply because $\{\, \mathsf{P}_i(\mathsf{a}) \mid i \in \{0, \ldots, n-1\} \,\}$ is added to the activation sets by the growth toward the leaves, such that an argument based on $\{\mathsf{Q}(\mathsf{a})\}$ becomes obviously less (or equivalently) specific than any argument that gets along with $\{\, \mathsf{P}_i(\mathsf{a}) \mid i \in \{0, \ldots, n-1\} \,\}$.

3.1 Preference of the "More Concise"

The second effect is that an argument that gets along with $\{\mathsf{Q}(\mathsf{a})\}$ becomes even *properly* less specific than one that actually requires $\{\, \mathsf{P}_i(\mathsf{a}) \mid i \in \{0, \ldots, n-1\} \,\}$ and does not get along with $\{\mathsf{Q}(\mathsf{a})\}$, simply because the former argument has the additional activation set $\{\mathsf{Q}(\mathsf{a})\}$. This effect is called *preference of the "more concise",* cf. e.g. (Stolzenburg et al. 2003, p. 94), (García and Simari 2004, p. 108). The standard example for the preference of the "more concise" is the following minor variation of Example 2.2.

Example 3.1 (Poole 1985, Example 2)
$\Pi^{\mathrm{F}}_{3.1} := \Pi^{\mathrm{F}}_{2.2} \qquad \Pi^{\mathrm{G}}_{3.1} := \{\ \mathsf{bird}(x) \Leftarrow \mathsf{emu}(x)\ \},$
$\Delta_{3.1} := \left\{ \begin{array}{l} \neg\mathsf{flies}(x) \leftarrow \mathsf{emu}(x), \\ \mathsf{flies}(x) \leftarrow \mathsf{bird}(x) \end{array} \right\},$
$\mathcal{A}_1 := \{\ \neg\mathsf{flies}(\mathsf{edna}) \leftarrow \mathsf{emu}(\mathsf{edna})\ \},$
$\mathcal{A}_2 := \{\ \mathsf{flies}(\mathsf{edna}) \leftarrow \mathsf{bird}(\mathsf{edna})\ \}.$
The argument $(\mathcal{A}_2, \mathsf{flies}(\mathsf{edna}))$ gets along with the activation set $\{\mathsf{bird}(\mathsf{edna})\}$, and thus it is properly less specific than the argument $(\mathcal{A}_1, \neg\mathsf{flies}(\mathsf{edna}))$, which actually requires the stronger $\{\mathsf{emu}(\mathsf{edna})\}$.

The problem now is that the statement

$$\mathsf{Q}(\mathsf{a}) \not\models \mathsf{P}_0(\mathsf{a}) \wedge \cdots \wedge \mathsf{P}_{n-1}(\mathsf{a}),$$

which is required to justify the the appropriateness of this effect, is not explicitly given by the specification via $(\Pi^{\mathrm{F}}, \Pi^{\mathrm{G}}, \Delta)$.

Nevertheless — if we do not just want to see it as a matter-of-fact property of notions of specificity in the style of Poole — the preference of the "more concise" can be justified by the habits of human specifiers as follows: If human specifiers write an implication in form of a rule $\mathsf{Q}(x) \Leftarrow \mathsf{P}_0(x) \wedge \cdots \wedge \mathsf{P}_{n-1}(x)$ into a specification Π of strict (i.e. non-defeasible) knowledge, then they typically intend that the implication is proper in the sense that its converse does not hold in general; otherwise they would have used an equivalence or equality symbol instead of the implication symbol, or replaced each occurrence of each $\mathsf{Q}(t)$ with $\mathsf{P}_0(t) \wedge \cdots \wedge \mathsf{P}_{n-1}(t)$, respectively. In particular, in our setting of logic programming — where disjunctive properties of the definition of a predicate are spread over several rules — the implications definitely tend to be proper. Therefore, if seasoned specifiers write down such a rule, then they do not want to exclude models where Q holds for some object a, but not all of the P_i do. This means that if we find such a rule in the strict and general part Π^{G} of a specification, then it is reasonable to assume that the implication is proper w.r.t. the intuition captured in the defeasible rules in Δ.

Thus, it makes sense to consider a defeasible argument based on $\{\, \mathsf{P}_i(\mathsf{a}) \mid i \in \{0, \ldots, n-1\} \,\}$ to be properly more specific than an argument that can get along with $\mathsf{Q}(\mathsf{a})$.

Finally, let us remark that our justification for the preference of the "more concise" does not apply if

$$\mathsf{Q}(x) \Leftarrow \mathsf{P}_0(x) \wedge \cdots \wedge \mathsf{P}_{n-1}(x)$$

is a *defeasible* rule instead of a strict one, because we then have the following three problems:

- the inclusion given by the rule is not generally intended (otherwise the rule should be a strict one),
- we cannot easily describe the actual instances to which the default rule is meant to apply (otherwise this more concrete description of the defeasible rule should be stated as a strict rule), and
- the direct treatment of a defeasible equivalence neither has to be appropriate as a default rule in the given situation, nor do we have any means to express a defeasible equivalence in the current setting.

Example 3.2 (Poole 1985, Example 3, renamed)
$\Pi^{\mathrm{F}}_{3.2} := \{\ \mathsf{emu(edna)}\ \}, \qquad \Pi^{\mathrm{G}}_{3.2} := \emptyset,$
$\Delta_{3.2} := \left\{ \begin{array}{l} \neg\mathsf{flies}(x) \leftarrow \mathsf{emu}(x), \\ \mathsf{flies}(x) \leftarrow \mathsf{bird}(x), \\ \mathsf{bird}(x) \leftarrow \mathsf{emu}(x) \end{array} \right\},$
$\mathcal{A}_1 := \{\ \neg\mathsf{flies(edna)} \leftarrow \mathsf{emu(edna)}\ \},$
$\mathcal{A}_2 := \left\{ \begin{array}{l} \mathsf{flies(edna)} \leftarrow \mathsf{bird(edna)}, \\ \mathsf{bird(edna)} \leftarrow \mathsf{emu(edna)} \end{array} \right\}.$
According to the above discussion, there is no clear reason why we should consider the argument $(\mathcal{A}_2, \mathsf{flies(edna)})$ to be *properly* less specific than the argument $(\mathcal{A}_1, \neg\mathsf{flies(edna)})$.

3.2 Preference of the "More Precise"

By an analogous argumentation, we can say that an argument that essentially requires an activation set $\{\ \mathsf{P}_i(\mathsf{a}) \mid i \in \{0,\ldots,n\}\ \}$ is *properly* more specific than an argument that gets along with a proper subset $\{\ \mathsf{P}_i(\mathsf{a}) \mid i \in I\ \}$ for some index set $I \subsetneq \{0,\ldots,n\}$. The effect of the assumption of this intention is called *preference of the "more precise"*.

There is, however, an exception to be observed where this analogy does not apply, namely the case that we actually can derive the set from its subset with the help of Π^{G}. In this case, the before-mentioned growth toward the leaves with rules from Π^{G} again implements the approximation of the subclass relation among model classes via the one among activation sets. This is demonstrated in the following example, which also nicely shows that a notion of specificity based only on single defeasible rules (without considering the context of the strict rules as a whole) cannot be intuitively adequate.

Example 3.3 (Stolzenburg et al. 2003, p. 95)
$\Pi^{\mathrm{F}}_{3.3} := \{\ \mathsf{q(a)}\ \}, \quad \Pi^{\mathrm{G}}_{3.3} := \{\ \mathsf{s}(x) \Leftarrow \mathsf{q}(x)\ \},$
$\Delta_{3.3} := \left\{ \begin{array}{l} \mathsf{p}(x) \leftarrow \mathsf{q}(x), \\ \neg\mathsf{p}(x) \leftarrow \mathsf{q}(x) \wedge \mathsf{s}(x) \end{array} \right\},$
$\mathcal{A}_1 := \{\ \neg\mathsf{p(a)} \leftarrow \mathsf{q(a)} \wedge \mathsf{s(a)}\ \},$
$\mathcal{A}_2 := \{\ \mathsf{p(a)} \leftarrow \mathsf{q(a)}\ \}$
The arguments $(\mathcal{A}_1, \neg\mathsf{p(a)})$ and $(\mathcal{A}_2, \mathsf{p(a)})$ are equivalently specific because the minimal activation set of each of them is $\{\mathsf{q(a)}\}$.

Apart from this exception, however, there is again a problem, namely that it is not the case that
$$\bigwedge_{i\in I} \mathsf{P}_i(\mathsf{a}) \not\models \bigwedge_{i\in\{0,\ldots,n\}} \mathsf{P}_i(\mathsf{a})$$
would be explicitly given by the specification via $(\Pi^{\mathrm{F}}, \Pi^{\mathrm{G}}, \Delta)$.

Nevertheless — if we do not just want to see preference of the "more precise" as a matter-of-fact property of notions of specificity in the style of Poole — we can again justify that it is unlikely that a seasoned specifier would not have intended this non-consequence statement, namely by an argumentation analogous to the one we gave for the preference of the "more concise". Indeed, a seasoned specifier who wants to exclude the above non-consequence would just specify a rule like $\mathsf{P}_j(x) \Leftarrow \bigwedge_{i\in I} \mathsf{P}_i(x)$, for each $j \in \{0,\ldots,n\}\backslash I$.

Example 3.4 *(continuing Example 3.3)*
For an example of preference of the "more precise" let us modify Example 3.3 by setting $\Pi^{\mathrm{F}}_{3.3} := \{\mathsf{q(a)}, \mathsf{s(a)}\}$ and $\Pi^{\mathrm{G}}_{3.3} := \emptyset$. Then $(\mathcal{A}_1, \neg\mathsf{p(a)})$ becomes properly more specific than $(\mathcal{A}_2, \mathsf{p(a)})$, because the latter argument has the additional activation set $\{\mathsf{q(a)}\}$.

4 Requirements Specification

With implicit reference to specification via $(\Pi^{\mathrm{F}}, \Pi^{\mathrm{G}}, \Delta)$, let us designate Poole's relation of being more (or equivalently) specific by "$\lesssim_{\mathrm{P1}}$". Here, "P1" stands for "Poole's original version".

The standard usage of the symbol "$\lesssim$" is to denote a *quasi-ordering* (cf. Sect. 2). Instead of the symbol "$\lesssim$", however, Poole (1985) uses the symbol "$\leq$". The standard usage of the symbol "$\leq$" is to denote a *reflexive ordering* (cf. Sect. 2). We cannot conclude from this, however, that Poole intended the additional property of anti-symmetry; indeed, we find a concrete example specification in (Poole 1985) where the lack of anti-symmetry of $\lesssim_{\mathrm{P1}}$ is made explicit (see last three sentences of Sect. 3.2 in (Poole 1985, p.145)).

The possible lack of anti-symmetry of quasi-orderings — i.e. that different arguments may have an equivalent specificity — cannot be a problem because any quasi-ordering $\lesssim_N$ immediately provides us with its equivalence $\approx_N$, its ordering $<_N$, and its reflexive ordering $\leq_N$ (cf. Corollary 2.3).

By contrast to the non-intended anti-symmetry, *transitivity* is obviously a *conditio sine qua non* for any useful notion of specificity. Indeed, if we already have an argument $(\mathcal{A}_2, \mathsf{wine})$ that is more specific than another argument $(\mathcal{A}_3, \mathsf{vodka})$, and if we come up with yet another argument $(\mathcal{A}_1, \mathsf{beer})$ that is even more specific than $(\mathcal{A}_2, \mathsf{wine})$, then, by all means, $(\mathcal{A}_1, \mathsf{beer})$ should be more specific than the argument $(\mathcal{A}_3, \mathsf{vodka})$ as well. It is obvious that a notion of specificity without transitivity could hardly be helpful in practice.

A further *conditio sine qua non* for any useful notion of specificity is that the conjunctive combination of respectively more specific arguments results in a more specific argument. Indeed, if a square is more specific than a rectangle and a circle is more specific than an ellipse, then a square inscribed into a circle should be more specific than a rectangle inscribed into an ellipse. This property is called monotonicity of conjunction, which we discuss in Sect. 6.2.

5 Formalizations of Specificity

A generative, bottom-up (i.e. from the leaves to the root) derivation with defeasible rules can now be split into three phases of derivation of literals from literals. This splitting follows the discussion in Sect. 3 on how to isolate the defeasible parts of a derivation (phase 2) from strict parts that may occur toward the root (phase 3) and toward the leaves (phase 1):

(phase 1) First we derive the literals that provide the basis for specificity considerations.

In our approach we derive the set $\mathfrak{T}_\Pi$ here. Poole takes the set $\mathfrak{T}_{\Pi\cup\Delta}$ instead.

(phase 2) On the basis of

- a subset H of the literals derived in phase 1,
- the first item $\mathcal{A}$ of a given argument $(\mathcal{A}, L)$, and
- the general rules Π^{G},

we derive a further set of literals $\mathfrak{L}$: $H\cup\mathcal{A}\cup\Pi^{\mathrm{G}}\vdash\mathfrak{L}$.

(phase 3) Finally, on the basis of $\mathfrak{L}$, the literal of the argument is derived: $\mathfrak{L}\cup\Pi\ \vdash\ \{L\}$.

In Poole's approach, phase 3 is empty and we simply have $\mathfrak{L}=\{L\}$. In our approach, however, it is admitted to use the facts from Π^{F} in phase 3, in addition to the general rules from Π^{G}, which were already admitted in phase 2.

With implicit reference to our sets $\Pi = \Pi^{\mathrm{F}} \cup \Pi^{\mathrm{G}}$ and Δ, the phases 2 and 3 can be more easily expressed with the help of the following notions.

Definition 5.1 (Activation Set)
Let $\mathcal{A}$ be a set of ground instances of rules from Δ, and let L be a literal. H is a *simplified activation set for* $(\mathcal{A}, L)$ if $L \in \mathfrak{T}_{H\cup\mathcal{A}\cup\Pi^{\mathrm{G}}}$. H is an *activation set for* $(\mathcal{A}, L)$ if $L \in \mathfrak{T}_{\mathfrak{L}\cup\Pi}$ for some $\mathfrak{L} \subseteq \mathfrak{T}_{H\cup\mathcal{A}\cup\Pi^{\mathrm{G}}}$. H is a *minimal* [*simplified*] *activation set for* $(\mathcal{A}, L)$ if H is an [simplified] activation set for $(\mathcal{A}, L)$, but no proper subset of H is an [simplified] activation set for $(\mathcal{A}, L)$.

Roughly speaking, an argument is now more (or equivalently) specific than another one if, for each of its activation sets H_1, the same set H_1 is also an activation set for the other argument. Note that we have replaced here the option of some $H_2 \subseteq \mathfrak{T}_{H_1\cup\Pi^{\mathrm{G}}}$ of the first straightforward sketch for a notion of specificity displayed in Sect. 3 with the more restrictive $H_2 = H_1$. Indeed, this simplification applies here because all we consider from any activation set H in Definition 5.1 (such as H_2 in this case) is just the closure $\mathfrak{T}_{H\cup\mathcal{A}\cup\Pi^{\mathrm{G}}} = \mathfrak{T}_{\mathfrak{T}_{H\cup\Pi^{\mathrm{G}}}\cup\mathcal{A}\cup\Pi^{\mathrm{G}}}$.

Activation sets that are not simplified differ from simplified ones by the admission of facts from Π^{F} (in addition to the general rules Π^{G}) after the defeasible part of the derivation is completed (cf. Example 6.6 for an occurrence of this difference).

Our introduction of activation sets that are not simplified is a conceptually important correction of Poole's approach: It must be admitted to use the facts besides the general rules in a purely strict derivation that is based on literals resulting from completed defeasible arguments, simply because the defeasible parts of a derivation (cf. Sect. 3) should not get more specific by the later use of additional facts that do not provide input to the defeasible parts.

5.1 Poole's Specificity Relations P1, P2, P3

In this section we will define the binary relations $\lesssim_{\mathrm{P1}}$, $\lesssim_{\mathrm{P2}}$, $\lesssim_{\mathrm{P3}}$ of "being more or equivalently specific according to David Poole" with implicit reference to our sets of facts and of general and defeasible rules (i.e. to Π^{F}, Π^{G}, and Δ, respectively).

The relation $\lesssim_{\mathrm{P1}}$ of the following definition is precisely Poole's original relation $\geq$ as defined at the bottom of the left column on page 145 of (Poole 1985). See Sect. 4 for our reasons to write "$\gtrsim$" instead of "$\geq$" as a first change. Moreover, as a second change required by mathematical standards, we have replaced the symbol "$\gtrsim$" with the symbol "$\lesssim$" (such that the smaller argument becomes the more specific one), so that the relevant well-foundedness becomes the one of its ordering $<$ instead of the reverse $>$.

Definition 5.2 $(\mathcal{A}_1, L_1) \lesssim_{\mathrm{P1}} (\mathcal{A}_2, L_2)$ if $(\mathcal{A}_1, L_1)$ and $(\mathcal{A}_2, L_2)$ are arguments, and if, for every $H \subseteq \mathfrak{T}_{\Pi\cup\Delta}$ that is a simplified activation set for $(\mathcal{A}_1, L_1)$ but not a simplified activation set for $(\mathcal{A}_2, L_1)$, H is also a simplified activation set for $(\mathcal{A}_2, L_2)$.

The relation $\lesssim_{\mathrm{P2}}$ of the following definition is the relation $\succeq$ of Definition 10 on page 94 of (Stolzenburg et al. 2003) (attributed to Poole 1985). Moreover, the relation $>_{\mathrm{spec}}$ of Definition 2.12 on page 132 of (Simari and Loui 1992) (attributed to (Poole 1985) as well) is the relation $<_{\mathrm{P2}} := \lesssim_{\mathrm{P2}} \setminus \gtrsim_{\mathrm{P2}}$.

Definition 5.3 $(\mathcal{A}_1, L_1) \lesssim_{\mathrm{P2}} (\mathcal{A}_2, L_2)$ if $(\mathcal{A}_1, L_1)$ and $(\mathcal{A}_2, L_2)$ are arguments, and if, for every $H \subseteq \mathfrak{T}_{\Pi\cup\Delta}$ that is a simplified activation set for $(\mathcal{A}_1, L_1)$ but not a simplified activation set for $(\emptyset, L_1)$, H is also a simplified activation set for $(\mathcal{A}_2, L_2)$.

The only change in Definition 5.3 as compared to Definition 5.2 is that "$(\mathcal{A}_2, L_1)$" is replaced with "$(\emptyset, L_1)$". We did not encounter any example yet where this most appropriate correction of the counter-intuitive variant "$(\mathcal{A}_2, L_1)$" of Definition 5.2 makes any difference to today's standard "$(\emptyset, L_1)$" in Definition 5.3.

The relations $\lesssim_{\mathrm{P1}}$ and $\lesssim_{\mathrm{P2}}$ were not meant to compare arguments for literals that do not need any defeasible rules — or at least they do not show an intuitive behavior on such arguments, as shown in Example 5.6 (right after the next definition and its corollary).

To overcome this minor flaw, we finally add an implication as an additional requirement in Definition 5.4. This implication guarantees that no argument that requires defeasible rules can be more specific than an argument not requiring any defeasible rules at all.

Definition 5.4 $(\mathcal{A}_1, L_1) \lesssim_{\mathrm{P3}} (\mathcal{A}_2, L_2)$ if $(\mathcal{A}_1, L_1)$ and $(\mathcal{A}_2, L_2)$ are arguments, $L_2 \in \mathfrak{T}_\Pi$ implies $L_1 \in \mathfrak{T}_\Pi$, and if, for every $H \subseteq \mathfrak{T}_{\Pi\cup\Delta}$ that is a [minimal] simplified activation set for $(\mathcal{A}_1, L_1)$ but not a simplified activation set for $(\emptyset, L_1)$, H is also a simplified activation set for $(\mathcal{A}_2, L_2)$.

Trivially, $\lesssim_{\mathrm{P3}} \subseteq \lesssim_{\mathrm{P2}}$. As every simplified activation set that passes the condition of Definition 5.2 passes the one of Definition 5.3, we have:

Corollary 5.5 $\lesssim_{\mathrm{P3}} \subseteq \lesssim_{\mathrm{P2}} \subseteq \lesssim_{\mathrm{P1}}$.

Example 5.6 (Minor Flaw of $\lesssim_{\mathrm{P1}}$ and $\lesssim_{\mathrm{P2}}$)
$\Pi^{\mathrm{F}}_{5.6} := \{\ \mathsf{thirst}\ \}$, $\Pi^{\mathrm{G}}_{5.6} := \{\ \mathsf{drink} \Leftarrow \mathsf{thirst}\ \}$,
$\Delta_{5.6} := \{\ \mathsf{beer} \leftarrow \mathsf{thirst}\ \}$, $\mathcal{A}_1 := \Delta_{5.6}$.
Let us compare the specificity of the arguments $(\mathcal{A}_1, \mathsf{beer})$ and $(\emptyset, \mathsf{drink})$. $\mathfrak{T}_{\Pi_{5.6}} = \{\mathsf{thirst}, \mathsf{drink}\}$, $\mathfrak{T}_{\Pi_{5.6}\cup\Delta_{5.6}} = \{\mathsf{beer}\} \cup \mathfrak{T}_{\Pi_{5.6}}$.
We have $(\mathcal{A}_1, \mathsf{beer}) \lesssim_{\mathrm{P2}} (\emptyset, \mathsf{drink})$ because for every $H \subseteq \mathfrak{T}_{\Pi_{5.6}\cup\Delta_{5.6}}$ that is a simplified activation set for $(\mathcal{A}_1, \mathsf{beer})$, but not a simplified activation set for $(\emptyset, \mathsf{beer})$, we have $H = \{\mathsf{thirst}\}$, which is a simplified activation set also for $(\emptyset, \mathsf{drink})$.
We have $(\emptyset, \mathsf{drink}) \lesssim_{\mathrm{P2}} (\mathcal{A}_1, \mathsf{beer})$ because there cannot be a simplified activation set for $(\emptyset, \mathsf{drink})$ that is not a simplified activation set for $(\emptyset, \mathsf{drink})$.
All in all, we get $(\mathcal{A}_1, \mathsf{beer}) \approx_{\mathrm{P2}} (\emptyset, \mathsf{drink})$, although $(\emptyset, \mathsf{drink}) <_{\mathrm{P3}} (\mathcal{A}_1, \mathsf{beer})$ should be given according to intuition, because, if beer produces a conflict with our drinking habits, there is no reason to prefer it to another drink. Finally note that by Corollary 5.5, we get $(\mathcal{A}_1, \mathsf{beer}) \approx_{\mathrm{P1}} (\emptyset, \mathsf{drink})$ as well.

Corollary 5.7 *If $(\mathcal{A}_1, L_1)$, $(\mathcal{A}_2, L_2)$ are arguments and we have $\mathcal{A}_1 \subseteq \mathcal{A}_2$ and $L_1 = L_2$, then we have $(\mathcal{A}_1, L_1) \lesssim_{\mathrm{P3}} (\mathcal{A}_2, L_2)$.*

By Corollaries 5.5 and 5.7, $\lesssim_{\mathrm{P1}}, \lesssim_{\mathrm{P2}}, \lesssim_{\mathrm{P3}}$ are reflexive relations, but — as we will show in Example 5.8 and state in Theorem 5.10 — not quasi-orderings in general.

Example 5.8 (Counterexample to Transitivities)
$\Pi^{\mathrm{F}}_{5.8} := \{\ \mathsf{alcohol},\ \mathsf{blessing},\ \mathsf{thirst}\ \}$,
$\Pi^{\mathrm{G}}_{5.8} := \{\ \mathsf{wine} \Leftarrow \mathsf{e}\ \}$, $\Delta_{5.8} := \mathcal{A}_1 \cup \mathcal{A}_2 \cup \mathcal{A}_3$,
$\mathcal{A}_1 := \left\{ \begin{array}{l} \mathsf{e} \leftarrow \mathsf{alcohol} \wedge \mathsf{blessing} \wedge \mathsf{thirst}, \\ \mathsf{beer} \leftarrow \mathsf{e} \end{array} \right\}$,
$\mathcal{A}_2 := \{\ \mathsf{wine} \leftarrow \mathsf{alcohol} \wedge \mathsf{blessing}\ \}$,
$\mathcal{A}_3 := \{\ \mathsf{vodka} \leftarrow \mathsf{alcohol}\ \}$.
Compare the arguments $(\mathcal{A}_1, \mathsf{beer})$, $(\mathcal{A}_2, \mathsf{wine})$, and $(\mathcal{A}_3, \mathsf{vodka})$!

Lemma 5.9 *There are a specification $(\Pi^{\mathrm{F}}, \Pi^{\mathrm{G}}, \Delta)$ without any negative literals (i.e. $\Pi^{\mathrm{F}} \cup \Pi^{\mathrm{G}} \cup \Delta$ is non-contradictory), and arguments $(\mathcal{A}_1, L_1)$, $(\mathcal{A}_2, L_2)$, $(\mathcal{A}_3, L_3)$ with respective minimal sets $\mathcal{A}_1$, $\mathcal{A}_2$, $\mathcal{A}_3$ (i.e. $(\mathcal{A}'_i, L_i)$ is not an argument for any proper subset $\mathcal{A}'_i \subsetneq \mathcal{A}_i$), such that*
$(\mathcal{A}_1, L_1) \lesssim_{\mathrm{P3}} (\mathcal{A}_2, L_2) \lesssim_{\mathrm{P3}} (\mathcal{A}_3, L_3) \not\gtrsim_{\mathrm{P1}} (\mathcal{A}_1, L_1)$ *and*
$(\mathcal{A}_1, L_1) \not\gtrsim_{\mathrm{P1}} (\mathcal{A}_2, L_2) \not\gtrsim_{\mathrm{P1}} (\mathcal{A}_3, L_3)$.

Proof of Lemma 5.9 Looking at Example 5.8, we see that only the quasi-ordering properties in the last two lines of Lemma 5.9 are non-trivial.
$\mathfrak{T}_{\Pi_{5.8}} = \{\mathsf{alcohol}, \mathsf{blessing}, \mathsf{thirst}\}$, $\mathfrak{T}_{\Pi_{5.8}\cup\Delta_{5.8}} = \{\mathsf{e}, \mathsf{beer}, \mathsf{wine}, \mathsf{vodka}\} \cup \mathfrak{T}_{\Pi_{5.8}}$. Thus, regarding the arguments $(\mathcal{A}_1, \mathsf{beer})$, $(\mathcal{A}_2, \mathsf{wine})$, $(\mathcal{A}_3, \mathsf{vodka})$, the additional implication condition of Definition 5.4 as compared to Definitions 5.2 and 5.3 is always satisfied, simply because its condition is always false.
$(\mathcal{A}_3, \mathsf{vodka}) \not\gtrsim_{\mathrm{P1}} (\mathcal{A}_1, \mathsf{beer}) \lesssim_{\mathrm{P3}} (\mathcal{A}_2, \mathsf{wine})$: The minimal simplified activation sets for $(\mathcal{A}_1, \mathsf{beer})$ that are subsets of $\mathfrak{T}_{\Pi_{5.8}\cup\Delta_{5.8}}$ and no simplified activation sets for $(\emptyset, \mathsf{beer})$ (or, without any difference, for $(\mathcal{A}_3, \mathsf{beer})$) are $\{\mathsf{alcohol}, \mathsf{blessing}, \mathsf{thirst}\}$ and $\{\mathsf{e}\}$, which are simplified activation sets for $(\mathcal{A}_2, \mathsf{wine})$ — but $\{\mathsf{e}\}$ is no simplified activation set for $(\mathcal{A}_3, \mathsf{vodka})$.
$(\mathcal{A}_1, \mathsf{beer}) \not\gtrsim_{\mathrm{P1}} (\mathcal{A}_2, \mathsf{wine}) \lesssim_{\mathrm{P3}} (\mathcal{A}_3, \mathsf{vodka})$: The only minimal simplified activation set for $(\mathcal{A}_2, \mathsf{wine})$ that is a subset of $\mathfrak{T}_{\Pi_{5.8}\cup\Delta_{5.8}}$ and no simplified activation set for $(\emptyset, \mathsf{wine})$ (such as $\{\mathsf{e}\}$) (or, without any difference, for $(\mathcal{A}_1, \mathsf{wine})$) is $\{\mathsf{alcohol}, \mathsf{blessing}\}$, which is a simplified activation set for $(\mathcal{A}_3, \mathsf{vodka})$, but not for $(\mathcal{A}_2, \mathsf{beer})$.
$(\mathcal{A}_2, \mathsf{wine}) \not\gtrsim_{\mathrm{P1}} (\mathcal{A}_3, \mathsf{vodka})$: The only minimal simplified activation set for $(\mathcal{A}_3, \mathsf{vodka})$ that is a subset of $\mathfrak{T}_{\Pi_{5.8}\cup\Delta_{5.8}}$ and no simplified activation set for $(\mathcal{A}_2, \mathsf{vodka})$ is $\{\mathsf{alcohol}\}$, which is not a simplified activation set for $(\mathcal{A}_2, \mathsf{wine})$. **Q.e.d. (Lemma 5.9)**

The relations stated in Lemma 5.9 hold not only for the given indices, but — by Corollary 5.5 — actually for all of P1, P2, P3; and so we immediately get:

Theorem 5.10 *There is a specification $(\Pi^{\mathrm{F}}, \Pi^{\mathrm{G}}, \Delta)$, such that $\Pi^{\mathrm{F}} \cup \Pi^{\mathrm{G}} \cup \Delta$ is non-contradictory, but none of $\lesssim_{\mathrm{P1}}$, $\lesssim_{\mathrm{P2}}$, $\lesssim_{\mathrm{P3}}$, $<_{\mathrm{P1}}$, $<_{\mathrm{P2}}$, $<_{\mathrm{P3}}$ is transitive.*

Note that in the given counterexample to transitivity (Example 5.8) all arguments have minimal sets of ground instances of defeasible rules.

As a consequence of Theorem 5.10, the respective relations in (Simari and Loui 1992) and (Stolzenburg et al. 2003) are not transitive. This means that these relations are not quasi-orderings, let alone reflexive orderings. See (Wirth and Stolzenburg 2013, Sect. 5.2) for details.

5.2 Our Novel Specificity Ordering CP1

In the previous section, we have seen that *minor corrections* of Poole's original specificity relation P1 (such as P2, P3) do not cure the (up to our finding of Example 5.8) hidden and even denied formal deficiency of these relations, namely their lack of transitivity. Therefore, in this section, we now define our major correction of Poole's specificity — the binary relation $\lesssim_{\mathrm{CP1}}$ — with implicit reference to our sets of facts and of general and defeasible rules (i.e. to Π^{F}, Π^{G}, and Δ, respectively) as follows.

Definition 5.11 (Our Version of Specificity $\lesssim_{\mathrm{CP1}}$)
$(\mathcal{A}_1, L_1) \lesssim_{\mathrm{CP1}} (\mathcal{A}_2, L_2)$ if $(\mathcal{A}_1, L_1)$ and $(\mathcal{A}_2, L_2)$ are arguments, and we have
1. $L_1 \in \mathfrak{T}_\Pi$ or
2. $L_2 \notin \mathfrak{T}_\Pi$ and every $H \subseteq \mathfrak{T}_\Pi$ that is an [minimal] activation set for $(\mathcal{A}_1, L_1)$ is also an activation set for $(\mathcal{A}_2, L_2)$.

The crucial change in Definition 5.11 as compared to Definition 5.4 is not the merely technical emphasis it puts on the case "$L_1 \in \mathfrak{T}_\Pi$", which has no effect on the extension of the relation as compared to $\lesssim_{\mathrm{P3}}$. The crucial changes actually are

- the replacement of "$H \subseteq \mathfrak{T}_{\Pi\cup\Delta}$" with "$H \subseteq \mathfrak{T}_\Pi$", and the thereby enabled
- omission of the previously technically required, but unintuitive negative condition on derivability ("but not a simplified activation set for $(\emptyset, L_1)$").

An additional minor change, which we have already discussed in Sect. 5, is the one from simplified to (non-simplified) activation sets.

Corollary 5.12 *If $(\mathcal{A}_1, L_1)$, $(\mathcal{A}_2, L_2)$ are arguments and we have $\mathcal{A}_1 \subseteq \mathcal{A}_2$ and $L_1 = L_2$, then we have $(\mathcal{A}_1, L_1) \lesssim_{\mathrm{CP1}} (\mathcal{A}_2, L_2)$.*

Theorem 5.13
$\lesssim_{\mathrm{CP1}}$ is a quasi-ordering on arguments.

The proof of Theorem 5.13 is straightforward and can be found in (Wirth and Stolzenburg 2013, Sect. 5.3, Proof of Theorem 5.13).

Example 5.14 (continuing Example 5.8)
The following holds for our specification of Example 5.8 by Lemma 5.9 and Corollary 5.5:
$(\mathcal{A}_1, \mathsf{beer}) <_{\mathrm{P3}} (\mathcal{A}_2, \mathsf{wine}) <_{\mathrm{P3}} (\mathcal{A}_3, \mathsf{vodka}) \not\gtrsim_{\mathrm{P3}}$
$(\mathcal{A}_1, \mathsf{beer})$. We have now:
$(\mathcal{A}_1, \mathsf{beer}) <_{\mathrm{CP1}} (\mathcal{A}_2, \mathsf{wine}) <_{\mathrm{CP1}} (\mathcal{A}_3, \mathsf{vodka}) >_{\mathrm{CP1}}$
$(\mathcal{A}_1, \mathsf{beer})$, simply because the trouble-making set $\{\mathsf{e}\}$ is not to be considered: it is not a subset of $\mathfrak{T}_{\Pi_{5.8}}$!

Obviously, an argument is ranked by $\lesssim_{\mathrm{CP1}}$ firstly on whether its literal is in $\mathfrak{T}_\Pi$, and, if not, secondly on the set of its activation sets, which is an element of the power set of the power set of $\mathfrak{T}_\Pi$. So we get:

Corollary 5.15
If $\mathfrak{T}_\Pi$ is finite, then $<_{\mathrm{CP1}}$ is well-founded.

Theorem 5.16 *$\lesssim_{\mathrm{P3}} \subseteq \lesssim_{\mathrm{CP1}}$ holds if, for each instance $L \Leftarrow L'_0 \wedge \ldots \wedge L'_n$ with $n \geq 1$ of each rule in Π^{G}, we have $L'_j \notin \mathfrak{T}_\Pi$ for all $j \in \{0, \ldots, n\}$.*

Please find the lengthy proof of Theorem 5.16 in (Wirth and Stolzenburg 2013, Sect. 5.4, Theorem 5.15). Here, however, is a typical application of it:

Example 5.17 (continuing Example 2.2)
We have $(\mathcal{A}_2, \mathsf{flies(edna)}) \not\lesssim_{\mathrm{CP1}} (\emptyset, \neg\mathsf{flies(edna)})$ because $\mathsf{flies(edna)} \notin \mathfrak{T}_{\Pi_{2.2}}$ and $\neg\mathsf{flies(edna)} \in \mathfrak{T}_{\Pi_{2.2}}$.
We have $(\emptyset, \neg\mathsf{flies(edna)}) \lesssim_{\mathrm{P3}} (\mathcal{A}_2, \mathsf{flies(edna)})$, because $\neg\mathsf{flies(edna)} \in \mathfrak{T}_{\Pi_{2.2}}$ and because the premise of the last condition in Definition 5.4 is contradictory for $\mathcal{A}_1 := \emptyset$, and cannot be satisfied by any set $H \subseteq \mathfrak{T}_{\Pi_{2.2}\cup\Delta_{2.2}}$. All in all, by Theorem 5.16
we get $(\emptyset, \neg\mathsf{flies(edna)}) <_{\mathrm{CP1}} (\mathcal{A}_2, \mathsf{flies(edna)})$
and $(\emptyset, \neg\mathsf{flies(edna)}) <_{\mathrm{P3}} (\mathcal{A}_2, \mathsf{flies(edna)})$.

6 Specificity and Human Intuition

Let us now put the two notions of specificity — as formalized in the two binary relations $\lesssim_{\mathrm{P3}}$ and $\lesssim_{\mathrm{CP1}}$ — to test w.r.t. our changed phase 1 of Sect. 5 in a series of classical examples.

6.1 Preference of the "More Concise"

Example 6.1 *(continuing Example 3.1)*
Let us compare the arguments $(\mathcal{A}_1, \neg\mathsf{flies(edna)})$ and $(\mathcal{A}_2, \mathsf{flies(edna)})$. $\mathfrak{T}_{\Pi_{3.1}} = \{\mathsf{bird(tweety)}, \mathsf{emu(edna)}, \mathsf{bird(edna)}\}$, $\mathfrak{T}_{\Pi_{3.1}\cup\Delta_{3.1}} = \{\neg\mathsf{flies(edna)}, \mathsf{flies(edna)}, \mathsf{flies(tweety)}\} \cup \mathfrak{T}_{\Pi_{3.1}}$. We have
$(\mathcal{A}_2, \mathsf{flies(edna)}) \not\lesssim_{\mathrm{CP1}} (\mathcal{A}_1, \neg\mathsf{flies(edna)})$
because $\mathsf{flies(edna)} \notin \mathfrak{T}_{\Pi_{3.1}}$ and because $\{\mathsf{bird(edna)}\} \subseteq \mathfrak{T}_{\Pi_{3.1}}$ is an activation set for $(\mathcal{A}_2, \mathsf{flies(edna)})$, but not for $(\mathcal{A}_1, \neg\mathsf{flies(edna)})$. We have
$(\mathcal{A}_1, \neg\mathsf{flies(edna)}) \lesssim_{\mathrm{P3}} (\mathcal{A}_2, \mathsf{flies(edna)})$,
because $\mathsf{flies(edna)} \notin \mathfrak{T}_{\Pi_{3.1}}$ and, if $H \subseteq \mathfrak{T}_{\Pi_{3.1}\cup\Delta_{3.1}}$ is a simplified activation set for $(\mathcal{A}_1, \neg\mathsf{flies(edna)})$, but not for $(\emptyset, \neg\mathsf{flies(edna)})$, then we have $\mathsf{emu(edna)} \in H$, and thus H is a simplified activation set also for $(\mathcal{A}_2, \mathsf{flies(edna)})$. By Theorem 5.16, we get $(\mathcal{A}_1, \neg\mathsf{flies(edna)}) <_{\mathrm{CP1}} (\mathcal{A}_2, \mathsf{flies(edna)})$
and $(\mathcal{A}_1, \neg\mathsf{flies(edna)}) <_{\mathrm{P3}} (\mathcal{A}_2, \mathsf{flies(edna)})$.

Example 6.2 *(continuing Example 3.2)*
Let us compare the arguments $(\mathcal{A}_1, \neg\mathsf{flies(edna)})$ and $(\mathcal{A}_2, \mathsf{flies(edna)})$. $\mathfrak{T}_{\Pi_{3.2}} = \{\mathsf{emu(edna)}\}$, $\mathfrak{T}_{\Pi_{3.2}\cup\Delta_{3.2}} = \{\mathsf{bird(edna)}, \mathsf{flies(edna)}, \neg\mathsf{flies(edna)}\} \cup \mathfrak{T}_{\Pi_{3.2}}$.
We have $(\mathcal{A}_2, \mathsf{flies(edna)}) \lesssim_{\mathrm{CP1}} (\mathcal{A}_1, \neg\mathsf{flies(edna)})$ because $\neg\mathsf{flies(edna)} \notin \mathfrak{T}_{\Pi_{3.2}}$ and, for every activation set $H \subseteq \mathfrak{T}_{\Pi_{3.2}}$ for $(\mathcal{A}_2, \mathsf{flies(edna)})$, we get $\mathsf{emu(edna)} \in H$, so H is an activation set also for $(\mathcal{A}_1, \neg\mathsf{flies(edna)})$.
$(\mathcal{A}_2, \mathsf{flies(edna)}) \not\lesssim_{\mathrm{P3}} (\mathcal{A}_1, \neg\mathsf{flies(edna)})$ is still the case because $\{\mathsf{bird(edna)}\} \subseteq \mathfrak{T}_{\Pi_{3.2}\cup\Delta_{3.2}}$ is a simplified activation set for $(\mathcal{A}_2, \mathsf{flies(edna)})$, but neither for $(\emptyset, \mathsf{flies(edna)})$, nor for $(\mathcal{A}_1, \neg\mathsf{flies(edna)})$.
We have $(\mathcal{A}_1, \neg\mathsf{flies(edna)}) \lesssim_{\mathrm{P3}} (\mathcal{A}_2, \mathsf{flies(edna)})$, because of $\mathsf{flies(edna)} \notin \mathfrak{T}_{\Pi_{3.2}}$ and because, if $H \subseteq \mathfrak{T}_{\Pi_{3.2}\cup\Delta_{3.2}}$ is a simplified activation set for $(\mathcal{A}_1, \neg\mathsf{flies(edna)})$, but not for $(\emptyset, \neg\mathsf{flies(edna)})$, then we have $\mathsf{emu(edna)} \in H$ and thus H is a simplified activation set also for $(\mathcal{A}_2, \mathsf{flies(edna)})$.
All in all, by Theorem 5.16, this time
we get $(\mathcal{A}_1, \neg\mathsf{flies(edna)}) \approx_{\mathrm{CP1}} (\mathcal{A}_2, \mathsf{flies(edna)})$
and $(\mathcal{A}_1, \neg\mathsf{flies(edna)}) <_{\mathrm{P3}} (\mathcal{A}_2, \mathsf{flies(edna)})$.
From a conceptual point of view, we have to ask ourselves, whether we would like a *defeasible* rule instance such as $\mathsf{bird(edna)} \leftarrow \mathsf{emu(edna)}$ to reduce the specificity of $\mathcal{A}_2$ as compared to a system that seems equivalent for the given argument for $\mathsf{flies(edna)}$, namely the argument
$(\{\mathsf{flies(edna)} \leftarrow \mathsf{emu(edna)}\}, \mathsf{flies(edna)})$?
Does the specificity of a defeasible reasoning step really reduce if we introduce intermediate literals?

According to human intuition, this question has a negative answer, as we have already explained at the end of Sect. 3.1. Moreover, Example 6.3 will exhibit a strong reason to deny it.

Finally, see Example 6.5 for another example that makes even clearer why defeasible rules should be considered for their global semantical effect instead of their syntactical fine structure.

6.2 Monotonicity w.r.t. Conjunction

Monotonicity w.r.t. conjunction means for a quasi-ordering $\lesssim_N$ that, in case of $(\mathcal{A}_1^i, L_1^i) \lesssim_N (\mathcal{A}_2^i, L_2^i)$ for $i \in \{1,2\}$, we always have $(\mathcal{A}_1^1 \cup \mathcal{A}_1^2, L_1') \lesssim_N (\mathcal{A}_2^i \cup \mathcal{A}_2^i, L_2')$ for fresh constant literals L_j' with additional general rules $L_j' \Leftarrow L_j^1 \wedge L_j^2 \in \Pi^{\mathrm{G}}$ $(j \in \{1,2\})$. For $\lesssim_{\mathrm{CP1}}$, this property is trivially given in case of $L_1^1, L_1^2 \in \mathfrak{T}_\Pi$, but cannot be expected in case of $L_1^i \notin \mathfrak{T}_\Pi \ni L_1^{3-i}$(for some $i \in \{1,2\}$), simply because then we get $L_1' \notin \mathfrak{T}_\Pi$. Also for the only remaining and most interesting case of $L_1^1, L_1^2 \notin \mathfrak{T}_\Pi$, this property is obviously given. For $\lesssim_{\mathrm{P1}}$, however, monotonicity is not even given in this most interesting case, as already noted in (Poole 1985):

Example 6.3 (Poole 1985, Example 6)
$\Pi_{6.3}^{\mathrm{F}} := \left\{ \begin{array}{l} \mathsf{a}, \\ \mathsf{d} \end{array} \right\}$, $\Pi_{6.3}^{\mathrm{G}} := \left\{ \begin{array}{l} \mathsf{g}_1 \Leftarrow \neg\mathsf{c} \wedge \neg\mathsf{f}, \\ \mathsf{g}_2 \Leftarrow \mathsf{c} \wedge \mathsf{f} \end{array} \right\}$,
$\Delta_{6.3} := \mathcal{A}_1 \cup \mathcal{A}_2$, $\mathcal{A}_1 := \{\ \neg\mathsf{c} \leftarrow \mathsf{a},\ \neg\mathsf{f} \leftarrow \mathsf{d}\ \}$,
$\mathcal{A}_2 := \{\ \mathsf{b} \leftarrow \mathsf{a},\ \mathsf{c} \leftarrow \mathsf{b},\ \mathsf{e} \leftarrow \mathsf{d},\ \mathsf{f} \leftarrow \mathsf{e}\ \}$
Let us compare the specificity of the arguments $(\mathcal{A}_1, \mathsf{g}_1)$ and $(\mathcal{A}_2, \mathsf{g}_2)$. $\mathfrak{T}_{\Pi_{6.3}} = \{\mathsf{a}, \mathsf{d}\}$. $\mathfrak{T}_{\Pi_{6.3} \cup \Delta_{6.3}} =$ $\{\mathsf{b},\mathsf{c},\mathsf{e},\mathsf{f}, \mathsf{g}_1, \mathsf{g}_2, \neg\mathsf{c}, \neg\mathsf{f}\} \cup \mathfrak{T}_{\Pi_{6.3}}$. $(\mathcal{A}_1, \mathsf{g}_1) \approx_{\mathrm{CP1}} (\mathcal{A}_2, \mathsf{g}_2)$ because $H \subseteq \mathfrak{T}_{\Pi_{6.3}}$ is an activation set for $(\mathcal{A}_i, \mathsf{g}_i)$ if and only if $H = \{\mathsf{a}, \mathsf{d}\}$. We have $(\mathcal{A}_1, \mathsf{g}_1) \triangle_{\mathrm{P3}} (\mathcal{A}_2, \mathsf{g}_2)$: $\{\mathsf{a}, \neg\mathsf{f}\} \subseteq \mathfrak{T}_{\Pi_{6.3} \cup \Delta_{6.3}}$ is a simplified activation set for $(\mathcal{A}_1, \mathsf{g}_1)$, but neither for $(\emptyset, \mathsf{g}_1)$, nor for $(\mathcal{A}_2, \mathsf{g}_2)$. $\{\mathsf{a}, \mathsf{f}\} \subseteq \mathfrak{T}_{\Pi_{6.3} \cup \Delta_{6.3}}$ is a simplified activation set for $(\mathcal{A}_2, \mathsf{g}_2)$, but neither for $(\emptyset, \mathsf{g}_2)$, nor for $(\mathcal{A}_1, \mathsf{g}_1)$.

In (Poole 1985), the same result for $\lesssim_{\mathrm{P1}}$ is described as "seemingly unintuitive", because, as we have seen in the isomorphic sub-specification of Example 3.2, we have both $(\mathcal{A}_1, \neg\mathsf{c}) <_{\mathrm{P3}} (\mathcal{A}_2, \mathsf{c})$ and $(\mathcal{A}_1, \neg\mathsf{f}) <_{\mathrm{P3}} (\mathcal{A}_2, \mathsf{f})$. Indeed, as already listed as an essential requirement in Sect. 4, the conjunction of two respectively more specific derivations should be more specific. On the other hand, considering $\lesssim_{\mathrm{CP1}}$ instead of $\lesssim_{\mathrm{P3}}$, the conjunction of two equivalently specific derivations results in an equivalently specific derivation — exactly as one intuitively expects.

Example 6.4 (1st Variation of Example 6.3)
$\Pi_{6.4}^{\mathrm{F}} := \Pi_{6.3}^{\mathrm{F}}$, $\mathcal{A}_1 := \{\ \neg\mathsf{c} \leftarrow \mathsf{a},\ \neg\mathsf{f} \leftarrow \mathsf{d}\ \}$,
$\Pi_{6.4}^{\mathrm{G}} := \{\ \mathsf{g}_1 \Leftarrow \neg\mathsf{c} \wedge \neg\mathsf{f},\ \mathsf{g}_2 \Leftarrow \mathsf{c} \wedge \mathsf{f},\ \mathsf{b} \Leftarrow \mathsf{a}\ \}$,
$\Delta_{6.4} := \mathcal{A}_1 \cup \mathcal{A}_2$, $\mathcal{A}_2 := \{\mathsf{c} \leftarrow \mathsf{b},\ \mathsf{e} \leftarrow \mathsf{d},\ \mathsf{f} \leftarrow \mathsf{e}\}$.
Let us compare the specificity of the arguments $(\mathcal{A}_1, \mathsf{g}_1)$ and $(\mathcal{A}_2, \mathsf{g}_2)$. $\mathfrak{T}_{\Pi_{6.4}} = \{\mathsf{a}, \mathsf{b}, \mathsf{d}\}$. $\mathfrak{T}_{\Pi_{6.4} \cup \Delta_{6.4}} =$ $\{\mathsf{c}, \mathsf{e}, \mathsf{f}, \mathsf{g}_1, \mathsf{g}_2, \neg\mathsf{c}, \neg\mathsf{f}\} \cup \mathfrak{T}_{\Pi_{6.4}}$. $(\mathcal{A}_2, \mathsf{g}_2) \not\lesssim_{\mathrm{CP1}} (\mathcal{A}_1, \mathsf{g}_1)$ because $\{\mathsf{b}, \mathsf{d}\} \subseteq \mathfrak{T}_{\Pi_{6.4}}$ is an activation set for $(\mathcal{A}_2, \mathsf{g}_2)$, but not for $(\mathcal{A}_1, \mathsf{g}_1)$. $(\mathcal{A}_1, \mathsf{g}_1) \lesssim_{\mathrm{CP1}} (\mathcal{A}_2, \mathsf{g}_2)$ because, for any activation set $H \subseteq \mathfrak{T}_{\Pi_{6.4}}$ for $(\mathcal{A}_1, \mathsf{g}_1)$, we have $\{\mathsf{a}, \mathsf{b}\} \subseteq H$; so H is also an activation set for $(\mathcal{A}_2, \mathsf{g}_2)$.

Again $(\mathcal{A}_1, \mathsf{g}_1) \triangle_{\mathrm{P3}} (\mathcal{A}_2, \mathsf{g}_2)$, for the same reason as in Example 6.3. Thus, the situation for $\lesssim_{\mathrm{P3}}$ is just as in Example 6.3, and just as "seemingly unintuitive" for exactly the same reason.

We have $(\mathcal{A}_1, \mathsf{g}_1) <_{\mathrm{CP1}} (\mathcal{A}_2, \mathsf{g}_2)$, which is intuitive because the conjunction of a more specific and an equivalently specific element, respectively, should be more specific. Indeed, from the isomorphic sub-specifications in Examples 3.1 and 3.2, we know that $(\mathcal{A}_1, \neg\mathsf{c}) <_{\mathrm{CP1}} (\mathcal{A}_2, \mathsf{c})$ and $(\mathcal{A}_1, \neg\mathsf{f}) \approx_{\mathrm{CP1}} (\mathcal{A}_2, \mathsf{f})$, resp.

All in all, $\lesssim_{\mathrm{P3}}$ fails in this example again, whereas $\lesssim_{\mathrm{CP1}}$ satisfies the monotonicity w.r.t. conjunction required in Sect. 4.

6.3 Preference of the "More Precise"

As primary sources of differences in specificity, the previous examples illustrated the effect of a chain of implications. We now consider examples where the primary source is an essentially required condition that is a super-conjunction of the condition of another rule.

Example 6.5 (2nd Variation of Example 6.3)
$\Pi_{6.5}^{\mathrm{F}} := \Pi_{6.3}^{\mathrm{F}}$, $\Pi_{6.5}^{\mathrm{G}} := \{\ \mathsf{g}_1 \Leftarrow \neg\mathsf{c},\ \mathsf{g}_2 \Leftarrow \mathsf{c} \wedge \mathsf{f}\ \}$,
$\Delta_{6.5} := \mathcal{A}_1 \cup \mathcal{A}_2$, $\mathcal{A}_1 := \{\ \neg\mathsf{c} \leftarrow \mathsf{a}\ \}$,
$\mathcal{A}_2 := \{\ \mathsf{b} \leftarrow \mathsf{a},\ \mathsf{c} \leftarrow \mathsf{b},\ \mathsf{e} \leftarrow \mathsf{d},\ \mathsf{f} \leftarrow \mathsf{e}\ \}$
Let us compare the specificity of the arguments $(\mathcal{A}_1, \mathsf{g}_1)$ and $(\mathcal{A}_2, \mathsf{g}_2)$. $\mathfrak{T}_{\Pi_{6.5}} = \{\mathsf{a}, \mathsf{d}\}$. $\mathfrak{T}_{\Pi_{6.5} \cup \Delta_{6.5}} = \{\mathsf{b}, \mathsf{c}, \mathsf{e}, \mathsf{f}, \mathsf{g}_1, \mathsf{g}_2, \neg\mathsf{c}\} \cup \mathfrak{T}_{\Pi_{6.5}}$. We have $(\mathcal{A}_1, \mathsf{g}_1) \not\lesssim_{\mathrm{CP1}} (\mathcal{A}_2, \mathsf{g}_2)$ because $\{\mathsf{a}\} \subseteq \mathfrak{T}_{\Pi_{6.5}}$ is an activation set for $(\mathcal{A}_1, \mathsf{g}_1)$, but not for $(\mathcal{A}_2, \mathsf{g}_2)$. We have $(\mathcal{A}_2, \mathsf{g}_2) \lesssim_{\mathrm{CP1}} (\mathcal{A}_1, \mathsf{g}_1)$ because any activation set for $(\mathcal{A}_2, \mathsf{g}_2)$ that is a subset of $\mathfrak{T}_{\Pi_{6.5}}$ includes a, and so is also an activation set for $(\mathcal{A}_1, \mathsf{g}_1)$. Considering Theorem 5.16 and the the activation set $\{\mathsf{b}, \mathsf{d}\}$ for $(\mathcal{A}_2, \mathsf{g}_2)$, we see $(\mathcal{A}_1, \mathsf{g}_1) \triangle_{\mathrm{P3}} (\mathcal{A}_2, \mathsf{g}_2)$.

All in all, $\lesssim_{\mathrm{CP1}}$ realizes the intuition that the super-conjunction $\mathsf{a} \wedge \mathsf{d}$ — which is essential to derive $\mathsf{c} \wedge \mathsf{f}$ according to $\mathcal{A}_2$ — is more specific than the "less precise" a.

Just like Example 3.2, this example shows again that $\lesssim_{\mathrm{P3}}$ does not really implement the intuition that defeasible rules should be considered for their global semantical effect instead of their syntactical fine structure.

Example 6.6 (Stolzenburg et al. 2003, p. 96)
$\Pi_{6.6}^{\mathrm{F}} := \{\ \mathsf{c}, \mathsf{d}, \mathsf{e}\ \}$, $\Pi_{6.6}^{\mathrm{G}} := \{\ \mathsf{x} \Leftarrow \mathsf{a} \wedge \mathsf{f}\ \}$,
$\Delta_{6.6} := \mathcal{A}^1 \cup \mathcal{A}^2 \cup \mathcal{A}^3 \cup \mathcal{A}^4 \cup \mathcal{A}^5$,
$\mathcal{A}^1 := \{\ \mathsf{x} \leftarrow \mathsf{a} \wedge \mathsf{b} \wedge \mathsf{c}\ \}$, $\mathcal{A}^2 := \{\ \neg\mathsf{x} \leftarrow \mathsf{a} \wedge \mathsf{b}\ \}$,
$\mathcal{A}^3 := \{\mathsf{f} \leftarrow \mathsf{e}\}$, $\mathcal{A}^4 := \{\mathsf{a} \leftarrow \mathsf{d}\}$, $\mathcal{A}^5 := \{\mathsf{b} \leftarrow \mathsf{e}\}$.
Let us compare the specificity of the arguments $(\mathcal{A}^1 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \mathsf{x})$, $(\mathcal{A}^2 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \neg\mathsf{x})$, $(\mathcal{A}^3 \cup \mathcal{A}^4, \mathsf{x})$. $\mathfrak{T}_{\Pi_{6.6}} = \{\mathsf{c}, \mathsf{d}, \mathsf{e}\}$. $\mathfrak{T}_{\Pi_{6.6} \cup \Delta_{6.6}} = \{\mathsf{a}, \mathsf{b}, \mathsf{f}, \mathsf{x}, \neg\mathsf{x}\} \cup \mathfrak{T}_{\Pi_{6.6}}$.
We have $(\mathcal{A}^1 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \mathsf{x}) <_{\mathrm{CP1}} (\mathcal{A}^2 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \neg\mathsf{x}) \approx_{\mathrm{CP1}} (\mathcal{A}^3 \cup \mathcal{A}^4, \mathsf{x})$, because of $\mathsf{x}, \neg\mathsf{x} \notin \mathfrak{T}_{\Pi_{6.6}}$, and because any activation set $H \subseteq \mathfrak{T}_{\Pi_{6.6}}$ for any of $(\mathcal{A}^1 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \mathsf{x})$, $(\mathcal{A}^2 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \neg\mathsf{x})$, $(\mathcal{A}^3 \cup \mathcal{A}^4, \mathsf{x})$ contains $\{\mathsf{d}, \mathsf{e}\}$, which is an activation set only for the latter two. This matches our intuition well, because the first of these arguments essentially requires the "more precise" $\mathsf{c} \wedge \mathsf{d} \wedge \mathsf{e}$ instead of the less specific $\mathsf{d} \wedge \mathsf{e}$.

We have $(\mathcal{A}^1 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \mathsf{x}) \triangle_{\mathrm{P3}} (\mathcal{A}^2 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \neg\mathsf{x}) \triangle_{\mathrm{P3}} (\mathcal{A}^3 \cup \mathcal{A}^4, \mathsf{x}) \triangle_{\mathrm{P3}} (\mathcal{A}^1 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \mathsf{x})$, however. This means that $\lesssim_{\mathrm{P3}}$ cannot compare these counterarguments and cannot help us to pick the more specific argument. What is most interesting under the computational aspect is that, for realizing

$$(\mathcal{A}^1 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \mathsf{x}) \not\lesssim_{\mathrm{P3}} (\mathcal{A}^2 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \neg\mathsf{x}),$$

we have to consider the defeasible rule of $\mathcal{A}^3$ (implicitly via $\{\mathsf{d}, \mathsf{f}\} \subseteq \mathfrak{T}_{\Pi_{6.6} \cup \Delta_{6.6}}$), which is not part of any of the two arguments under comparison. Note that such considerations are not required, however, for realizing the properties of $\lesssim_{\mathrm{CP1}}$, because defeasible rules not in the given argument can be completely ignored when calculating the minimal activation sets as subsets of $\mathfrak{T}_\Pi$ instead of $\mathfrak{T}_{\Pi \cup \Delta}$. This means in particular that the complication of *pruning* — as discussed in detail by Stolzenburg et al. (2003, Sect. 3.3) — does not have to be considered for the operationalization of $\lesssim_{\mathrm{CP1}}$.

Example 6.7 (Variation of Example 6.6)
$\Pi^{\mathrm{F}}_{6.7} := \{\ \mathsf{c}, \mathsf{d}, \mathsf{e}\ \}$, $\Pi^{\mathrm{G}}_{6.7} := \{\ \mathsf{x} \Leftarrow \mathsf{a} \wedge \mathsf{f},\ \mathsf{f} \Leftarrow \mathsf{e}\ \}$,
$\Delta_{6.7} := \mathcal{A}^1 \cup \mathcal{A}^2 \cup \mathcal{A}^4 \cup \mathcal{A}^5$,
$\mathcal{A}^1 := \{\ \mathsf{x} \leftarrow \mathsf{a} \wedge \mathsf{b} \wedge \mathsf{c}\ \}$, $\mathcal{A}^2 := \{\ \neg\mathsf{x} \leftarrow \mathsf{a} \wedge \mathsf{b}\ \}$,
$\mathcal{A}^4 := \{\ \mathsf{a} \leftarrow \mathsf{d}\ \}$, $\mathcal{A}^5 := \{\ \mathsf{b} \leftarrow \mathsf{e}\ \}$.
Let us compare the specificity of the arguments $(\mathcal{A}^1 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \mathsf{x})$, $(\mathcal{A}^2 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \neg\mathsf{x})$, $(\mathcal{A}^4, \mathsf{x})$. $\mathfrak{T}_{\Pi_{6.7}} = \{\mathsf{c}, \mathsf{d}, \mathsf{e}, \mathsf{f}\}$. $\mathfrak{T}_{\Pi_{6.7} \cup \Delta_{6.7}} = \{\mathsf{a}, \mathsf{b}, \mathsf{x}, \neg\mathsf{x}\} \cup \mathfrak{T}_{\Pi_{6.7}}$.
Obviously, $\mathsf{x}, \neg\mathsf{x} \notin \mathfrak{T}_{\Pi_{6.7}}$. Moreover, $\{\mathsf{d}\} \subseteq \mathfrak{T}_{\Pi_{6.7}}$ is an activation set for $(\mathcal{A}^4, \mathsf{x})$ (but not a simplified one) and, *a fortiori* (by Corollary 5.12), for $(\mathcal{A}^1 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \mathsf{x})$, but not for $(\mathcal{A}^2 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \neg\mathsf{x})$. Furthermore, every activation set $H \subseteq \mathfrak{T}_{\Pi_{6.7}}$ for $(\mathcal{A}^2 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \neg\mathsf{x})$ satisfies $\{\mathsf{d}, \mathsf{e}\} \subseteq H$, which is an activation set for $(\mathcal{A}^4, \mathsf{x})$ and $(\mathcal{A}^1 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \mathsf{x})$. Furthermore, every activation set $H \subseteq \mathfrak{T}_{\Pi_{6.7}}$ for $(\mathcal{A}^1 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \mathsf{x})$ satisfies $\{\mathsf{d}\} \subseteq H$ which is an activation set for $(\mathcal{A}^4, \mathsf{x})$. All in all, we have
$(\mathcal{A}^4, \mathsf{x}) \approx_{\mathrm{CP1}} (\mathcal{A}^1 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \mathsf{x}) >_{\mathrm{CP1}} (\mathcal{A}^2 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \neg\mathsf{x})$.
This is intuitively sound because $(\mathcal{A}^2 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \neg\mathsf{x})$ is activated only by the more specific $\mathsf{d} \wedge \mathsf{e}$, whereas $(\mathcal{A}^4, \mathsf{x})$ is activated also by the "less precise" d. Moreover, $\mathsf{c} \wedge \mathsf{d} \wedge \mathsf{e}$ is not essentially required for $(\mathcal{A}^1 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \mathsf{x})$, which thus is equivalent to $(\mathcal{A}^4, \mathsf{x})$.
We have $(\mathcal{A}^4, \mathsf{x}) <_{\mathrm{P3}} (\mathcal{A}^1 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \mathsf{x}) \triangle_{\mathrm{P3}} (\mathcal{A}^2 \cup \mathcal{A}^4 \cup \mathcal{A}^5, \neg\mathsf{x}) \triangle_{\mathrm{P3}} (\mathcal{A}^4, \mathsf{x})$, however. This means that $\lesssim_{\mathrm{P3}}$ fails here completely w.r.t. Poole's intuition.

Example 6.8 *(continuing Example 3.3)*
Let us compare the specificity of the arguments $(\mathcal{A}_1, \neg\mathsf{p}(\mathsf{a}))$ and $(\mathcal{A}_2, \mathsf{p}(\mathsf{a}))$. $\mathfrak{T}_{\Pi_{3.3}} = \{\mathsf{q}(\mathsf{a}), \mathsf{s}(\mathsf{a})\}$, $\mathfrak{T}_{\Pi_{3.3} \cup \Delta_{3.3}} = \{\mathsf{p}(\mathsf{a}), \neg\mathsf{p}(\mathsf{a})\} \cup \mathfrak{T}_{\Pi_{3.3}}$.
We have $(\mathcal{A}_1, \neg\mathsf{p}(\mathsf{a})) \approx_{\mathrm{P3}} (\mathcal{A}_2, \mathsf{p}(\mathsf{a}))$, because of $\mathsf{p}(\mathsf{a}), \neg\mathsf{p}(\mathsf{a}) \notin \mathfrak{T}_{\Pi_{3.3}}$, and because, for $H \subseteq \mathfrak{T}_{\Pi_{3.3} \cup \Delta_{3.3}}$, $i \in \{1, 2\}$, $L_1 := \neg\mathsf{p}(\mathsf{a})$, and $L_2 := \mathsf{p}(\mathsf{a})$, we have the logical equivalence of $H = \{\mathsf{q}(\mathsf{a})\}$ on the one hand, and of H being a minimal simplified activation set for $(\mathcal{A}_i, L_i)$ but not for $(\emptyset, L_i)$, on the other hand. By Theorem 5.16, we also get $(\mathcal{A}_1, \neg\mathsf{p}(\mathsf{a})) \approx_{\mathrm{CP1}} (\mathcal{A}_2, \mathsf{p}(\mathsf{a}))$. This makes perfect sense because $\mathsf{q}(\mathsf{a}) \wedge \mathsf{s}(\mathsf{a})$ is not at all strictly "more precise" than $\mathsf{q}(\mathsf{a})$ in the context of $\Pi_{3.3}$.
Note that nothing is changed here if $\mathsf{s}(x) \Leftarrow \mathsf{q}(x)$ is replaced by setting $\Pi^{\mathrm{G}}_{3.3} := \{\mathsf{s}(\mathsf{a})\}$. If $\mathsf{s}(x) \Leftarrow \mathsf{q}(x)$ is replaced, however, by setting $\Pi^{\mathrm{G}}_{3.3} := \emptyset$ and $\Pi^{\mathrm{F}}_{3.3} := \{\mathsf{q}(\mathsf{a}), \mathsf{s}(\mathsf{a})\}$, then we get both $(\mathcal{A}_1, \neg\mathsf{p}(\mathsf{a})) <_{\mathrm{P3}} (\mathcal{A}_2, \mathsf{p}(\mathsf{a}))$ and $(\mathcal{A}_1, \neg\mathsf{p}(\mathsf{a})) <_{\mathrm{CP1}} (\mathcal{A}_2, \mathsf{p}(\mathsf{a}))$.

7 Relation to Other Approaches

Our new notion of specificity $\lesssim_{\mathrm{CP1}}$ follows the lines of Poole (1985). It is a transitive relation that provides us a quasi-ordering on arguments, which is as monotonic w.r.t. conjunction as can be expected (cf. Sect. 6.2). In addition, the effort for computing $\lesssim_{\mathrm{CP1}}$ is lower than that of $\lesssim_{\mathrm{P3}}$ because of $\mathfrak{T}_\Pi \subseteq \mathfrak{T}_{\Pi \cup \Delta}$, though not w.r.t. asymptotic complexity: In both cases already the number of possible (simplified) activation sets is exponential in the number of literals in the respective sets $\mathfrak{T}_\Pi$ and $\mathfrak{T}_{\Pi \cup \Delta}$, because in principle each possible subset has to be tested.

Stolzenburg et al. (2003, Definition 12) introduce the concept of pruning derivation trees because, for the case of $\lesssim_{\mathrm{P2}}$, attention cannot be restricted to derivations which make use only of the instances of defeasible rules given in the arguments. The reason for this is that the specificity notions of (Poole 1985) and (Simari and Loui 1992) admit literals L in activation sets that cannot be derived solely by strict rules, i.e. $L \in \mathfrak{T}_{\Pi \cup \Delta} \backslash \mathfrak{T}_\Pi$. Since this is not possible with the relation $\lesssim_{\mathrm{CP1}}$, this problem vanishes with our new version of specificity. See also Example 6.6.

Yet still, the new relation $\lesssim_{\mathrm{CP1}}$ inherits several properties from $\lesssim_{\mathrm{P3}}$. For instance, in general the specificity criterion requires us to compare sets of derivations, in principle all possible derivations for a given argument. This is true for both versions of the specificity relation. The reason for this complication is that we consider a very general setting of defeasible reasoning here, because — in contrast to other approaches (Gelfond and Przymusinska 1990; Dung and Son 1996; Benferhat and Garcia 1997) — we admit more than one antecedent in rules, i.e. bodies containing more than one literal, and (possibly) non-empty sets of background knowledge, namely the general rules in Π^{G} in addition to the facts in Π^{F}.

All in all, there are numerous frameworks for argumentation in logic. The overall process usually includes a dialectical process used for answering queries. Different arguments are pro or contra a certain answer. By means of an attack relation conflicts between contradicting arguments can be determined in abstract argumentation frameworks (Dung 1995; Prakken and Vreeswijk 2002). A concrete specificity or similar relation helps then to decide among conflicting arguments. There are a lot of works on abstract argumentation frameworks. However, as the discussion in this paper demonstrates, it is not that easy to find an effective concrete specificity relation. The main problem is that the orderings tend to be either computationally highly complex (Kern-Isberner and Thimm 2012) or not really appropriate for specificity (Besnard and Hunter 2001).

8 Conclusion

We would need further discussions on our most surprising new findings — after all, defeasible reasoning with Poole's notion of specificity is being applied now for over a quarter of century, and it was not to be expected that our investigations could discover a flaw in its foundations.

One remedy for the discovered lack of transitivity of $\lesssim_{\mathrm{P3}}$ could be to consider the transitive closure of the non-transitive relation $\lesssim_{\mathrm{P3}}$. Only under the condition of Theorem 5.16, the transitive closure of $\lesssim_{\mathrm{P3}}$ is a subset of $\lesssim_{\mathrm{CP1}}$, and therefore a possible choice. Moreover, it will still have all the intuitive shortcomings made obvious in Sect. 6. We do not see how this transitive closure could be decided efficiently. Furthermore, this transitive closure lacks a direct intuitive motivation, and after the first extension step from $\lesssim_{\mathrm{P3}}$ to its transitive closure, we had better take the second extension step to the more intuitive $\lesssim_{\mathrm{CP1}}$ immediately.

Finally, contrary to the transitive closure of $\lesssim_{\mathrm{P3}}$, our novel relation $\lesssim_{\mathrm{CP1}}$ also solves the problem of non-monotonicity of specificity w.r.t. conjunction (cf. Sect. 6.2) insofar as it was realized as a problem of $\lesssim_{\mathrm{P1}}$ in (Poole 1985).

Further work is needed to improve efficiency considerably. As a first step, we have narrowed the concept of $\lesssim_{\mathrm{CP1}}$ further down according to Sect. 3, resulting in a similar (no difference in any of the examples presented in this paper!), but more tractable relation $\lesssim_{\mathrm{CP2}}$. We are currently developing and testing strong methods for efficient operationalization of $\lesssim_{\mathrm{CP2}}$, which can hardly be found for any of $\lesssim_{\mathrm{P1}}, \lesssim_{\mathrm{P2}}, \lesssim_{\mathrm{P3}}, \lesssim_{\mathrm{CP1}}$.

Abstract

We provide a sound and complete axiomatization for a class of logics appropriate for reasoning about the rationality of players in games. Essentially the same axiomatization applies to a wide class of decision rules.

1 Introduction

Decision-making in an uncertain environment is a fundamental component of game theory: players must choose what to do without necessarily knowing what their opponents will do. Under certainty, decision-making is straightforward; one simply chooses the course of action that leads to the most preferred outcome. Under uncertainty, however, a player must evaluate many possible outcomes in a manner that somehow takes into account her relative degrees of belief. There are many ways to do this. The *maximin* decision rule, for example, focuses entirely on worst-case scenarios. An *expected utility maximizer*, on the other hand, weights each outcome according to her (subjective) probability and chooses the course of action that maximizes the corresponding expected value.

One can argue about which decision rules are reasonable and which are not, and the word "rational" is often invoked to denote this very divide, but this is not the notion of rationality that concerns us here. Rather, assuming that we have fixed a decision rule for a given player, we can ask whether that player is, in fact, making choices in accordance with it, and call her *rational* precisely when she is. In classical game theory, for example, rationality is typically identified with expected utility maximization: a player is rational precisely if she is acting to maximize her expected utility.

Another fundamental component of game theory is higher-order belief: what you believe your opponent will *do* is connected with what you believe your opponent *believes*. In other words, your beliefs about their beliefs matter. Many notions of equilibrium, for example, require not only that each player is rational, but also that each player believes their opponents to be rational as well. Reasoning about games therefore requires reasoning about beliefs.

Epistemic game theory takes this as its motto, and concerns itself with models expressive enough to represent the complexities of higher-order beliefs in a game-theoretic context. Formal logic furnishes a powerful and versatile class of such models; namely, modal logics of belief appropriately specialized for reasoning about games. Rationality is no less important in this setting; however, while it has been incorporated into these models both syntactically and semantically, no axiomatization of the resulting logical systems has been provided. This paper fills this gap.

We take as our point of departure axioms for rationality in the sense of expected utility maximization given in (Bjorndahl, Halpern, & Pass 2011). We extend these axioms to arbitrary decision rules, under the assumption that the players' uncertainty is represented by a probability measure. This allows us to deal with not just expected utility maximization, but other standard rules such as *maximin* and *minimax regret* (see (Halpern 2003) for a discussion of all the decision rules mentioned in this paper). We then go on to consider what happens when the players' uncertainty is represented by a *set* of probabilities, which allows us to capture well-known decision rules such as *maxmin expected utility* and *minimax expected regret*. Finally, we consider situations where a player might be uncertain about which decision rules his opponents are using.

The rest of this paper is organized as follows. In Section 2, we define the core concepts formally: games, modal logics of belief appropriate for reasoning about games, and the incorporation of rationality into these logics. Section 3 gives the axiomatization, and proves that it is sound and complete. In Section 4, we provide sound and complete axiomatizations for the cases where the players' uncertainty is represented by sets of probabilities, and where players may be uncertain about the decision rules used by other players. In Section 5 we discuss the role of language. Section 6 concludes with a discussion of future work. More detailed proofs and further discussion can be found in the full paper, which is available at http://www.math.cornell.edu/∼abjorndahl/Site/CV_files/Axiomatizing%20Rationality.pdf.

2 Reasoning about games

Given a tuple $(X_i)_{i\in I}$ over some finite index set $I = \{1,\dots,n\}$, we adopt the usual notational convention of writing $X \coloneqq \prod_{i\in I} X_i$ and $X_{-i} \coloneqq \prod_{j\neq i} X_j$. We also

Copyright © 2014, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

write $X_i' \times X_{-i}$ for

$$X_1 \times \cdots \times X_{i-1} \times X_i' \times X_{i+1} \times \cdots \times X_n$$

and similarly (x_i', x_{-i}) for $(x_1, \ldots, x_{i-1}, x_i', x_{i+1}, \ldots, x_n)$.

A **(normal-form) game** is a tuple $\Gamma = (I, (\Sigma_i)_{i \in I}, (u_i)_{i \in I})$ where $I = \{1, \ldots, n\}$ is the set of *players*, Σ_i is the (finite) set of *strategies available to player* i, and $u_i : \Sigma \to \mathbb{R}$ is *player* i*'s utility function*, where $\Sigma = \prod_i \Sigma_i$ denotes the set of *strategy profiles*.

2.1 Syntax

One way of reasoning formally about a game is to build a logical language that is expressive enough to capture the aspects of play that we are interested in analyzing. To this end, given a game Γ, we begin by defining a propositional modal language of belief and then specializing the primitive propositions to correspond to the strategies available to the players.

Given an arbitrary set Φ of primitive propositions, let $\mathcal{L}_B(\Phi)$ be the language recursively generated by the grammar

$$\varphi ::= p \mid \neg\varphi \mid \varphi \wedge \psi \mid B_i\varphi,$$

where $p \in \Phi$ and $i \in I$. As usual, we read $B_i\varphi$ as "player i believes φ". We define $\vee$, $\rightarrow$, and $\leftrightarrow$ as usual in terms of $\wedge$ and $\neg$, and write $\widehat{B}_i\varphi$ for $\neg B_i \neg\varphi$ ("player i consider it possible that φ"). We also write

$$\begin{aligned} EB^1\varphi &\equiv B_1\varphi \wedge \cdots \wedge B_n\varphi \text{ and} \\ EB^k\varphi &\equiv EB^1(EB^{k-1}\varphi) \end{aligned}$$

for "everyone believes φ" and its k-fold iteration, respectively. Set

$$\Phi_\Gamma \coloneqq \{play_i(\sigma_i) \,:\, i \in I,\, \sigma_i \in \Sigma_i\},$$

where we read $play_i(\sigma_i)$ as "player i is playing strategy σ_i"; we write

$$\begin{aligned} play(\sigma) &\equiv play_1(\sigma_1) \wedge \cdots \wedge play_n(\sigma_n) \text{ and} \\ play_{-i}(\sigma_{-i}) &\equiv \bigwedge_{j \neq i} play_j(\sigma_j) \end{aligned}$$

for "the players are playing according to the strategy profile σ" and the analogous statement regarding the players other than i. The language $\mathcal{L}_B(\Phi_\Gamma)$ is thus appropriate for reasoning about the beliefs of the players with respect to the strategies they are playing.

2.2 Semantics

A language of belief can be interpreted using Kripke-style possible world semantics, where associated to each world ω and each player i is a probability measure on the set of all worlds, used to interpret player i's beliefs at ω. In the case of a language like $\mathcal{L}_B(\Phi_\Gamma)$, we also must take care to interpret the primitive propositions appropriately.

We restrict our attention to finite models. A **finite Γ-structure** is a tuple $M = (\Omega, (Pr_i)_{i \in I}, s)$ satisfying the following conditions:

(C1) Ω is a nonempty, finite set;

(C2) Pr_i associates with each $\omega \in \Omega$ a probability measure $Pr_i(\omega)$ on Ω;

(C3) $Pr_i(\omega)(\{\omega' \in \Omega \,:\, Pr_i(\omega') = Pr_i(\omega)\}) = 1$;

(C4) $s : \Omega \to \Sigma$ satisfies $Pr_i(\omega)(\{\omega' \in \Omega \,:\, s_i(\omega') = s_i(\omega)\}) = 1$.

Conditions (C1) and (C2) set the stage to interpret player i's beliefs at ω by the measure $Pr_i(\omega)$. Condition (C3) then ensures that at each world ω, each player is sure of (i.e. assigns probability 1 to) her own beliefs. Finally, condition (C4) establishes that the *strategy function* s assigns to each world ω a strategy profile $s(\omega)$ in game Γ—intuitively, the strategy that each player is playing at ω—and moreover, that each player is sure of her own strategy.

A finite Γ-structure M induces an **interpretation** $[\![\cdot]\!]_M : \mathcal{L}_B(\Phi_\Gamma) \to 2^\Omega$ defined recursively as follows:

$$\begin{aligned} [\![play_i(\sigma_i)]\!]_M &\coloneqq \{\omega \in \Omega \,:\, s_i(\omega) = \sigma_i\} \\ [\![\varphi \wedge \psi]\!]_M &\coloneqq [\![\varphi]\!]_M \cap [\![\psi]\!]_M \\ [\![\neg\varphi]\!]_M &\coloneqq \Omega \setminus [\![\varphi]\!]_M \\ [\![B_i\varphi]\!]_M &\coloneqq \{\omega \in \Omega \,:\, Pr_i(\omega)([\![\varphi]\!]_M) = 1\}. \end{aligned}$$

Thus, the primitive propositions are interpreted in the obvious way using the strategy function (s_i denotes the ith component function of s), the Boolean connectives are interpreted classically, and the formula $B_i\varphi$ holds at all and only those worlds ω at which $Pr_i(\omega)$ assigns probability 1 to φ. As is standard, we often write $(M, \omega) \models \varphi$ or just $\omega \models \varphi$ to indicate that $\omega \in [\![\varphi]\!]_M$. Similarly, we write $M \models \varphi$ if $[\![\varphi]\!]_M = \Omega$, and when $(M, \omega) \not\models \varphi$, we say that M *refutes* φ *(at* ω*)*, or just that ω refutes φ.

2.3 Rationality

Informally, a player is *rational* if the strategy she is playing is a best response to her beliefs about the outcome of the game, given her preferences. But there is no single conception of what constitutes a "best response"; a variety of principles of decision-making have been proposed and studied.

One influential notion, particularly in game theory, is that of expected utility maximization. Given a game Γ and a probability measure μ on Σ_{-i} (thought of as representing player i's beliefs about the strategies her opponents will play), the **expected utility** of a strategy $\sigma_i \in \Sigma_i$ is just the expected value of the function $u_i(\sigma_i, \cdot) : \Sigma_{-i} \to \mathbb{R}$ with respect to μ:

$$EU_i(\sigma_i; \mu) \coloneqq \sum_{\sigma_{-i} \in \Sigma_{-i}} u_i(\sigma_i, \sigma_{-i}) \cdot \mu(\sigma_{-i}).$$

A best response for an expected utility maximizer is a strategy that maximizes this value. Abstractly, we might identify the mandate "maximize expected utility" for player i (in the game Γ) with a function $\mathfrak{d}_i^{eu}$ that takes as input a belief μ on Σ_{-i} and returns as output the set of strategies $\sigma_i \in \Sigma_i$ that maximize player i's expected utility given μ:

$$\mathfrak{d}_i^{eu}(\mu) \coloneqq \{\sigma_i \in \Sigma_i \,:\, (\forall \sigma_i' \in \Sigma_i)(EU_i(\sigma_i; \mu) \geq EU_i(\sigma_i'; \mu))\}.$$

Let $\Delta(\Sigma_{-i})$ denote the set of all probability measures on Σ_{-i}. Then, generalizing the above, we define a **decision**

rule for player i **(in** Γ**)** to be a function $\mathfrak{d}_i : \Delta(\Sigma_{-i}) \to 2^{\Sigma_i} \setminus \{\emptyset\}$. Intuitively, $\sigma_i \in \mathfrak{d}_i(\mu)$ just in case σ_i is a best response for player i to the belief μ according to the decision rule $\mathfrak{d}_i$. For example, the "maximin" mandate for player i, which says to maximize the worst-case outcome among those considered possible, corresponds to the decision rule defined as follows: let

$$WC_i(\sigma_i; \mu) \coloneqq \min\{u_i(\sigma_i, \sigma_{-i}) \ : \ \mu(\sigma_{-i}) > 0\},$$

and set

$$\mathfrak{d}_i^m(\mu) \coloneqq \{\sigma_i \in \Sigma_i \ : \ (\forall \sigma_i' \in \Sigma_i)(\, WC_i(\sigma_i; \mu) \geq \ WC_i(\sigma_i'; \mu))\}.$$

Decision rules can be interpreted in Γ-structures; roughly speaking, for each world ω, we can define the set of $\mathfrak{d}_i$-best responses for player i at ω, and thus determine whether or not player i is being $\mathfrak{d}_i$-rational (i.e., acting in accordance with the decision rule $\mathfrak{d}_i$) at ω. Formally, given a Γ-structure M, for each player i and each world ω, the probability measure $Pr_i(\omega)$ induces a probability measure $\mu_{i,\omega}$ defined on Σ_{-i} as follows:

$$\mu_{i,\omega}(\sigma_{-i}) \coloneqq Pr_i(\omega)([\![play_{-i}(\sigma_{-i})]\!]_M).$$

In fact, $\mu_{i,\omega}$ is the *pushforward* of $Pr_i(\omega)$ by s_{-i}. Since $Pr_i(\omega)$ is interpreted as representing player i's beliefs at ω, it makes sense to apply her decision rule to $\mu_{i,\omega}$. This leads us to define the set of $\mathfrak{d}_i$**-best responses for player** i **at** ω to be $\mathfrak{d}_i(\mu_{i,\omega})$. We say that player i is $\mathfrak{d}_i$**-rational at** ω just in case $s_i(\omega) \in \mathfrak{d}_i(\mu_{i,\omega})$.

Since we wish to reason formally about games using the logic developed above, and rationality is an important concept for such analyses, we expand the language to include primitive propositions denoting rationality of the players. Given a profile of decision rules $\mathfrak{d} = (\mathfrak{d}_i)_{i \in I}$, let

$$\Phi_\Gamma^{\mathfrak{d}} \coloneqq \Phi_\Gamma \cup \{RAT_i^{\mathfrak{d}_i} \ : \ i \in I\},$$

where $RAT_i^{\mathfrak{d}_i}$ is read "player i is $\mathfrak{d}_i$-rational". Henceforth, except where noted otherwise, we work with an arbitrary but fixed profile of decision rules $\mathfrak{d}$. For notational convenience, we omit the $\mathfrak{d}_i$ when possible, referring to "best responses" and "rationality" instead of "$\mathfrak{d}_i$-best responses" and "$\mathfrak{d}_i$-rationality", and writing RAT_i instead of $RAT_i^{\mathfrak{d}_i}$. We also make use of the syntactic abbreviation

$$RAT \quad \equiv \quad RAT_1 \wedge \cdots \wedge RAT_n$$

for "everyone is rational".

Given a Γ-structure M, the interpretation $[\![\cdot]\!]_M$ is extended to $\mathcal{L}_B(\Phi_\Gamma^{\mathfrak{d}})$ in the obvious way, by setting

$$[\![RAT_i]\!]_M \quad \coloneqq \quad \{\omega \in \Omega \ : \ s_i(\omega) \in \mathfrak{d}_i(\mu_{i,\omega})\}.$$

When $\mathfrak{d} = \mathfrak{d}^{eu}$, so each player's decision rule is given by expected utility maximization, we regain the traditional notion of rationality in game theory. Rationality so defined can be used to characterize several well-known solution concepts in terms of Γ-structures. For example, as shown by Tan and Werlang (1988) and Brandenburger and Dekel (1987), given a game Γ, a strategy σ_i is *rationalizable* if and only if there exists a Γ-structure M and a state ω therein such that $\omega \models play_i(\sigma_i)$ and for every $k \in \mathbb{N}$, $\omega \models EB^k(RAT)$ (i.e. it is common belief that everyone is rational).

It is worth noting that decision rules are general enough to represent processes that fall outside the traditional purview of "rationality". For example, suppose that player i is a computer system and Σ_i is a collection of actions it can execute. Suppose also that the system maintains a database consisting of estimates of the values of certain variables, which can be represented as beliefs about the strategies of "opponents". In this context, a decision rule can be thought of as a nondeterministic process that the computer system might use to choose which action to execute on the basis of the information in its database. In particular, $RAT_i^{\mathfrak{d}_i}$ asserts that the system has executed an action consistent with the nondeterministic process $\mathfrak{d}_i$.[1]

2.4 Example

In order to help solidify the framework just introduced, we present a simple example. Consider the standard Bach-or-Stravinsky game Γ (Osborne & Rubinstein 1994), in which each of two players must choose which of two concerts to attend this evening: one featuring the music of Bach, and one of Stravinsky. Player 1 prefers to attend the Bach concert, while player two prefers the Stravinsky; however, each much prefers to attend the same concert as the other. We can represent these preferences with the utility functions summarized in Table 1.

	Bach	Stravinsky
Bach	3,2	0,0
Stravinsky	0,0	2,3

Table 1: Bach or Stravinsky?

We now describe a Γ-structure in which we can reason about the beliefs and rationality of the players. Let $\Omega = \{\omega_0, \omega_1, \omega_2\}$ and let $Pr_1(\omega_0)$ be the uniform distribution on $\{\omega_1, \omega_2\}$, so player 1 considers ω_1 and ω_2 equally likely. Consider a strategy function s defined such that $s_2(\omega_1) =$ Bach and $s_2(\omega_2) =$ Stravinsky. It is easy to see that in this case, the induced measure μ_{1,ω_0} assigns probability .5 to Bach and .5 to Stravinsky. It follows easily that player 1's expected utility on choosing Bach is 1.5, while his expected utility on choosing Stravinsky is 1. Thus,

$$\omega_0 \models RAT_1^{\mathfrak{d}_1^{eu}} \leftrightarrow play_1(\text{Bach}).$$

On the other hand, the worst-case outcome for player 1 on choosing either Bach or Stravinsky yields a utility of 0, so we have

$$\omega_0 \models RAT_1^{\mathfrak{d}_1^m},$$

regardless of which strategy player 1 actually chooses at ω_0.

[1] In this sense, we can think of a decision rule as a *knowledge-based program* (Fagin *et al.* 1995). Knowledge-based programs have previously been used to characterize rationality and solution concepts (Halpern & Moses 2007).

3 Axiomatization

Although reasoning formally about beliefs and rationality has long been recognized as important to game theory (see, e.g., (**?**)), to the best of our knowledge, rationality has not been axiomatized in a logic of belief. In this section we provide an axiomatization and prove that it is sound and complete.

3.1 The axioms

While most of the axioms are easy to state and understand, two require some preliminary definitions. Fix a game Γ and a profile of decision rules $\mathfrak{d}$. Given a subset $S \subseteq \Sigma_{-i}$, let

$$\delta_{i,S} \equiv \bigwedge_{\sigma_{-i} \in S} \widehat{B}_i \, play_{-i}(\sigma_{-i}) \wedge \bigwedge_{\sigma_{-i} \notin S} \neg \widehat{B}_i \, play_{-i}(\sigma_{-i}).$$

Intuitively, the formula $\delta_{i,S}$ says that player i considers possible *all* and *only* the strategy profiles for his opponents that are elements of S. It is easy to see that for each player i and any world ω, exactly one of the formulas $\delta_{i,S}$ holds.

Given a measure μ on a finite set X, let

$$supp(\mu) \coloneqq \{x \in X \,:\, \mu(x) > 0\},$$

the **support** of μ. For each player i and each $\sigma_i \in \Sigma_i$, let $\mathcal{S}_i^+(\sigma_i)$ denote the collection of all $S \subseteq \Sigma_{-i}$ such that there exists a probability measure μ with $supp(\mu) = S$ and with respect to which σ_i is a best response; that is, $\sigma_i \in \mathfrak{d}_i(\mu)$. Similarly, define $\mathcal{S}_i^-(\sigma_i)$ to be the collection of all $S \subseteq \Sigma_{-i}$ such that there exists a probability measure μ with $supp(\mu) = S$ and $\sigma_i \notin \mathfrak{d}_i(\mu)$.

Consider the following axiom schemes:

G1. $\bigvee_{\sigma_i \in \Sigma_i} play_i(\sigma_i)$

G2. $\neg(play_i(\sigma_i) \wedge play_i(\sigma_i'))$, for $\sigma_i \neq \sigma_i'$

G3. $play_i(\sigma_i) \leftrightarrow B_i \, play_i(\sigma_i)$

G4. $RAT_i \leftrightarrow B_i(RAT_i)$

G5. $(play_i(\sigma_i) \wedge RAT_i) \rightarrow \bigvee_{S \in \mathcal{S}_i^+(\sigma_i)} \delta_{i,S}$

G6. $(play_i(\sigma_i) \wedge \neg RAT_i) \rightarrow \bigvee_{S \in \mathcal{S}_i^-(\sigma_i)} \delta_{i,S}.$

G1–G4 are straightforward. **G1** and **G2** say that, at each state, each player plays exactly one strategy. **G3** and **G4** say that each player is certain of her strategy and of whether or not she is rational. The interesting axioms are **G5** and **G6**. Intuitively, **G5** says that if RAT_i holds and player i is playing σ_i, then player i must consider possible a collection of strategy profiles[2] on which she could place a probability that would justify her playing σ_i. **G6** is interpreted analogously. Notice that player i's actual (i.e. quantitative) beliefs are not fully specified. This may be somewhat surprising, given that the semantic interpretation of RAT_i is defined in terms of the quantitative probabilities that constitute player i's beliefs. Nevertheless, as we show in Section 3.2, these axioms completely characterize the logical properties of rationality as expressible in the language $\mathcal{L}_B(\Phi_\Gamma^{\mathfrak{d}})$; we return to this point in Section 5. Axioms **G1–G4** and the specialization of axioms **G5** and **G6** to the rule of maximizing expected utility appear in (Bjorndahl, Halpern, & Pass 2011).

Let $\mathsf{GL}_\Gamma^{\mathfrak{d}}$ be the axiom system that results from adding **G1–G6** to the standard $\mathsf{KD45}$ axioms and rules of inference of belief logic (see, e.g., (Fagin *et al.* 1995)). It bears emphasizing that $\mathsf{GL}_\Gamma^{\mathfrak{d}}$ is parametrized by two variables: the underlying game Γ that determines the players, their strategies, and their preferences, and the profile of decision rules $\mathfrak{d}$ that determines the meaning of "rationality" for each player. Thus, what we are axiomatizing here is not a single logic but a class of logics.

For each fixed Γ and $\mathfrak{d}$, the corresponding axiom system $\mathsf{GL}_\Gamma^{\mathfrak{d}}$ is trivially decidable (i.e., we can effectively determine whether a formula is an instance of an axiom scheme) because $\mathsf{KD45}$ is decidable and there are only finitely-many instances of the axiom schemes **G1–G6** (the implicit quantification in these schemes ranges in some cases over players and in others over strategies, all of which are finite sets).

But there is arguably a more interesting question. Up to now we have fixed a game Γ, and considered decision rules in the game Γ. But rules like maximizing expected utility, maximin, or minimizing regret can be applied in all games in a uniform way. To capture this, we define a **decision paradigm** to be a function that maps each game Γ to a decision rule in Γ. Suppose that we are given decision paradigms $\mathcal{D}_i$ for each player associating with each game Γ a decision rule $\mathcal{D}_i(\Gamma)$ for that player in Γ. We might want to know, given the profile $\mathcal{D} = (\mathcal{D}_i)_{i \in I}$, whether the mapping

$$\Gamma \mapsto \mathsf{GL}_\Gamma^{\mathcal{D}(\Gamma)}$$

is decidable; in other words, given as input a game Γ, can we effectively determine whether a formula belongs to the axiom system $\mathsf{GL}_\Gamma^{\mathcal{D}(\Gamma)}$? For each game Γ, this requires determining membership in the sets $\mathcal{S}_i^+(\sigma_i)$ and $\mathcal{S}_i^-(\sigma_i)$, which are defined by existential quantification over simplices $\Delta(\Sigma_{-i})$, subject to constraints based on the decision rules $\mathcal{D}_i(\Gamma)$. In the case of familiar decision paradigms like maximin or expected utility maximization, computing the sets $\mathcal{S}_i^+(\sigma_i)$ and $\mathcal{S}_i^-(\sigma_i)$ boils down to solving systems of linear inequalities. In general, however, we must impose certain computability requirements on the decision paradigms in order to be able to decide whether a formula is an instance of an axiom. At this point, we have not found an interesting characterization of when we get decidability.

3.2 Soundness and completeness

Theorem 3.1: $\mathsf{GL}_\Gamma^{\mathfrak{d}}$ *is a sound axiomatization of the language* $\mathcal{L}_B(\Phi_\Gamma^{\mathfrak{d}})$ *with respect to the class of all finite* Γ*-structures.*

[2]Note that the sets $\mathcal{S}_i^+(\sigma_i)$ and $\mathcal{S}_i^-(\sigma_i)$ could be empty; by convention, we define the empty disjunction to be $\bot$ (or *false*). If, for example, $\mathcal{S}_i^+(\sigma_i) = \emptyset$, this means that σ_i is not a best response to any beliefs, in which case the corresponding axiom $(play_i(\sigma_i) \wedge RAT_i) \rightarrow \bot$ is intuitively correct.

Proof: The proof is much in the same spirit as the proof of the corresponding result in (Bjorndahl, Halpern, & Pass 2011) (except that now we consider rules more general than just maximizing expected utility). Soundness of the axioms and rules of KD45 can be proved as usual. It therefore suffices to show that **G1**–**G6** are valid in all finite Γ-structures.

Fix a finite Γ-structure $M = (\Omega, (Pr_i)_{i\in I}, s)$. Soundness of $\mathbf{G1}$ and $\mathbf{G2}$ is an immediate consequence of the fact that s is a (total) function. Soundness of $\mathbf{G3}$ is a straightforward consequence of condition (C4), while soundness of $\mathbf{G4}$ follows easily from the combination of conditions (C3) and (C4).

Now suppose that $\omega \models play_i(\sigma_i) \wedge RAT_i$; then $\sigma_i \in \mathfrak{d}_i(\mu_{i,\omega})$. Set $S := supp(\mu_{i,\omega})$, and observe that $S \in \mathcal{S}_i^+(\sigma_i)$. For each $\sigma_{-i} \in S$, it is easy to see that $\omega \models \widehat{B}_i\, play_{-i}(\sigma_{-i})$; therefore, we must have

$$\omega \models \bigwedge_{\sigma_{-i}\in S} \widehat{B}_i\, play_{-i}(\sigma_{-i}).$$

Similarly, for each $\sigma_{-i} \notin S$, we have $\omega \models \neg\widehat{B}_i\, play_{-i}(\sigma_{-i})$, so

$$\omega \models \bigwedge_{\sigma_{-i}\notin S} \neg\widehat{B}_i\, play_{-i}(\sigma_{-i}).$$

In other words, $\omega \models \delta_{i,S}$; this establishes the soundness of $\mathbf{G5}$.

Finally, suppose that $\omega \models play_i(\sigma_i) \wedge \neg RAT_i$, which implies that $\sigma_i \notin \mathfrak{d}_i(\mu_{i,\omega})$. Set $S := supp(\mu_{i,\omega})$; then $S \in \mathcal{S}_i^-(\sigma_i)$ and, as above, we have $\omega \models \delta_{i,S}$, which establishes soundness of $\mathbf{G6}$. ∎

We prove completeness by what is essentially the *canonical model method*, a standard method for proving completeness of modal logics (see, e.g., (Fagin *et al.* 1995) or any standard text on modal logic). Of course, the full canonical model is not finite (for $n > 1$), so we modify the construction by restricting attention to finite sub-languages. More precisely, given a formula $\varphi \in \mathcal{L}_B(\Phi_\Gamma^{\mathfrak{d}})$, we identify a finite sub-language of $\mathcal{L}_B(\Phi_\Gamma^{\mathfrak{d}})$ such that the corresponding canonical model refutes φ just in case $\mathsf{GL}_\Gamma^{\mathfrak{d}} \nvdash \varphi$. This technique is sometimes called *filtration*.

Fix a formula $\varphi \in \mathcal{L}_B(\Phi_\Gamma^{\mathfrak{d}})$. Let $Sub_\Gamma(\varphi)$ denote the collection of all subformulas of φ together with all subformulas of instances of the axiom schemes $\mathbf{G1}$ through $\mathbf{G6}$. Define

$$Sub_\Gamma^+(\varphi) := Sub_\Gamma(\varphi) \cup \{\neg\psi \,:\, \psi \in Sub_\Gamma(\varphi)\}.$$

Note that there are only finitely many instances of $\mathbf{G1}$ through $\mathbf{G6}$, and therefore $Sub_\Gamma^+(\varphi)$ is finite.

Let Ω^φ be the collection of all maximal, consistent (with respect to $\mathsf{GL}_\Gamma^{\mathfrak{d}}$) subsets of $Sub_\Gamma^+(\varphi)$. Clearly Ω^φ is a finite set. Given $X \subseteq \mathcal{L}_B(\Phi_\Gamma^{\mathfrak{d}})$, set

$$X^{B_i} := \{\psi \,:\, B_i\psi \in X\};$$

and, for $F \in \Omega^\varphi$, define

$$\mathrm{Bel}_i(F) := \{G \in \Omega^\varphi \,:\, G \supseteq F^{B_i} \text{ and } G^{B_i} = F^{B_i}\}.$$

For each $i \in I$ and each $F \in \Omega^\varphi$, we will define a probability measure $Pr_i^\varphi(F)$ on Ω^φ such that the support of this measure is precisely $\mathrm{Bel}_i(F)$. Loosely speaking, $\mathrm{Bel}_i(F)$ is the set of all $G \in \Omega^\varphi$ that are compatible with the beliefs of player i in F. More precisely, $G \in \mathrm{Bel}_i(F)$ if and only if:

(a) $B_i\psi \in F$ implies $\psi \in G$, and

(b) $B_i\psi \in F$ iff $B_i\psi \in G$.

Condition (a) just says that everything player i believes in F is true in G; condition (b) says that player i's beliefs in F are the same as her beliefs in G, which is reasonable in light of the fact that we are working in a system with positive and negative introspection. (In the full canonical model, (b) follows from (a); here we must impose this condition explicitly because of the way the language has been restricted.)

Since our aim is to define probability measures with the sets $\mathrm{Bel}_i(F)$ as their supports, we must show that these sets are never empty.

Lemma 3.2: *For each $i \in I$ and $F \in \Omega^\varphi$, $\mathrm{Bel}_i(F) \neq \emptyset$.*

Proof: Given $F \in \Omega^\varphi$, set

$$\begin{aligned}\Lambda \;:=\; & \{\psi \,:\, B_i\psi \in F\} \cup \{B_i\psi \,:\, B_i\psi \in F\} \\ & \cup \{\neg B_i\psi \,:\, \neg B_i\psi \in F\}.\end{aligned}$$

It is easy to see that $\Lambda \subset Sub_\Gamma^+(\varphi)$. In addition, we show that Λ is consistent. For suppose not; then

$$\begin{aligned}\mathsf{GL}_\Gamma^{\mathfrak{d}} \vdash \neg\bigwedge_{\xi\in\Lambda}\xi \;&\Longrightarrow\; \mathsf{GL}_\Gamma^{\mathfrak{d}} \vdash B_i\neg\bigwedge_{\xi\in\Lambda}\xi \\ &\Longrightarrow\; \mathsf{GL}_\Gamma^{\mathfrak{d}} \vdash \neg B_i\bigwedge_{\xi\in\Lambda}\xi \\ &\Longrightarrow\; \mathsf{GL}_\Gamma^{\mathfrak{d}} \vdash \neg\bigwedge_{\xi\in\Lambda} B_i\xi,\end{aligned}$$

which is a contradiction, since each formula $B_i\xi$ with $\xi \in \Lambda$ is logically equivalent to a formula in F, and F is consistent.

From this we can conclude that there exists a $G \in \Omega^\varphi$ such that $G \supseteq \Lambda$. It follows immediately that $G \supseteq F^{B_i}$ and that $G^{B_i} \supseteq F^{B_i}$. Moreover, if $\psi \in G^{B_i}$, then $B_i\psi \in G$ and so certainly $\neg B_i\psi \notin G$, from which it follows that $\neg B_i\psi \notin \Lambda$ and thus $\neg B_i\psi \notin F$. Maximality of F then guarantees that $B_i\psi \in F$, whence $\psi \in F^{B_i}$, and so $G^{B_i} \subseteq F^{B_i}$. This establishes that $G \in \mathrm{Bel}_i(F)$, as desired. ∎

In the classical canonical model construction, it is sufficient to define $Pr_i^\varphi(F)$ to be the uniform distribution on $\mathrm{Bel}_i(F)$. In the present context, however, we need to be more careful, since $Pr_i^\varphi(F)$ is used not only to interpret the belief modalities B_i, but also the primitive propositions RAT_i. In essence, we must define $Pr_i^\varphi(F)$ in a manner that agrees with whether or not player i is best responding to her beliefs at F; not surprisingly, this is precisely where the axiom schemes **G5** and **G6** come into play. At the same time, we have to define Pr_i^φ on Ω^φ in a systematic way so as to preserve the introspection condition (C3). What follows is a formalization of this basic recipe, for which several more lemmas and definitions are needed.

Lemma 3.3: *Let $F \in \Omega^\varphi$. If $\widehat{B}_i\psi \in F$, then there exists a $G \in \mathrm{Bel}_i(F)$ with $\psi \in G$; if $\neg\widehat{B}_i\psi \in F$, then for all $G \in \mathrm{Bel}_i(F)$ we have $\psi \notin G$.*

Proof: See the full paper. ∎

For each $\sigma_{-i} \in \Sigma_{-i}$, define

$$\mathrm{Bel}_i(F;\sigma_{-i}) \coloneqq \{G \in \mathrm{Bel}_i(F) \,:\, play_{-i}(\sigma_{-i}) \in G\}.$$

Given $F \in \Omega^\varphi$, it is easy to see, using **G1** and **G2**, that there is a unique $\sigma_i \in \Sigma_i$ with $play_i(\sigma_i) \in F$. If, in addition, $RAT_i \in F$, then by **G5** we know that for some $S \in \mathcal{S}_i^+(\sigma_i)$, $\delta_{i,S} \in F$ (or, in the case where $\mathcal{S}_i^+(\sigma_i) = \emptyset$, we know that no such F exists). Otherwise, if $RAT_i \notin F$, then by **G6** we know that for some $S \in \mathcal{S}_i^-(\sigma_i)$, $\delta_{i,S} \in F$ (or again, in the case where $\mathcal{S}_i^-(\sigma_i) = \emptyset$, that no such F exists). Thus, for each $i \in I$, there is a unique set $S_i(F) \subseteq \Sigma_{-i}$ such that $\delta_{i,S_i(F)} \in F$, and moreover, $S_i(F) \in \mathcal{S}_i^+(\sigma_i)$ if $RAT_i \in F$, and $S_i(F) \in \mathcal{S}_i^-(\sigma_i)$ if $RAT_i \notin F$.

Lemma 3.4: *The collection* $\{\mathrm{Bel}_i(F;\sigma_{-i}) \,:\, \sigma_{-i} \in \Sigma_{-i}\}$ *partitions* $\mathrm{Bel}_i(F)$*; moreover,* $\mathrm{Bel}_i(F;\sigma_{-i}) \neq \emptyset$ *if and only if* $\sigma_{-i} \in S_i(F)$.

Proof: The first statement is a straightforward consequence of **G1** and **G2**, while the second is an immediate corollary of Lemma 3.3 together with the fact that

$$\begin{aligned}\delta_{i,S_i(F)} \;\equiv\; & \textstyle\bigwedge_{\sigma_{-i} \in S_i(F)} \widehat{B}_i\, play_{-i}(\sigma_{-i}) \wedge \\ & \textstyle\bigwedge_{\sigma_{-i} \notin S_i(F)} \neg \widehat{B}_i\, play_{-i}(\sigma_{-i}) \in F. \;\blacksquare\end{aligned}$$

For each $\sigma_i \in \Sigma_i$ and $S \in \mathcal{S}_i^+(\sigma_i)$, let $\mu^+_{\sigma_i,S}$ be a fixed probability measure witnessing the fact that $S \in \mathcal{S}_i^+(\sigma_i)$; that is, $supp(\mu^+_{\sigma_i,S}) = S$ and $\sigma_i \in \mathfrak{d}_i(\mu^+_{\sigma_i,S})$. Likewise, for each $\sigma_i \in \Sigma_i$ and $S \in \mathcal{S}_i^-(\sigma_i)$, let $\mu^-_{\sigma_i,S}$ be a fixed probability measure witnessing the fact that $S \in \mathcal{S}_i^-(\sigma_i)$.

Let $F \in \Omega^\varphi$, and suppose that $play_i(\sigma_i) \in F$. In light of Lemma 3.4, we can define $Pr_i^\varphi(F)$ to be the unique probability measure on $\mathrm{Bel}_i(F)$ such that, for all $\sigma_{-i} \in \Sigma_{-i}$,

$$Pr_i^\varphi(F)(\mathrm{Bel}_i(F;\sigma_{-i})) = \begin{cases} \mu^+_{\sigma_i,S_i(F)}(\sigma_{-i}) & \text{if } RAT_i \in F \\ \mu^-_{\sigma_i,S_i(F)}(\sigma_{-i}) & \text{if } RAT_i \notin F, \end{cases}$$

and which is uniform within each (nonempty) set $\mathrm{Bel}_i(F;\sigma_{-i})$.

Proposition 3.5: *Pr_i^φ satisfies the following:*

(a) $Pr_i^\varphi(F)(G) > 0$ iff $G \in \mathrm{Bel}_i(F)$, and

(b) $G^{B_i} = F^{B_i}$ implies $Pr_i^\varphi(G) = Pr_i^\varphi(F)$.

Proof: See the full paper. ∎

Finally, we define a strategy function $s^\varphi : \Omega^\varphi \to \Sigma$ by assigning to each $F \in \Omega^\varphi$ the unique strategy profile $\sigma \in \Sigma$ such that $play(\sigma) \in F$.

Lemma 3.6: *The tuple $M^\varphi \coloneqq (\Omega^\varphi, (Pr_i^\varphi)_{i\in I}, s^\varphi)$ is a Γ-structure.*

Proof: Conditions (C1) and (C2) have already been established. By Lemma 3.5(b), in order to see that (C3) holds it suffices to observe that $Pr_i^\varphi(F)(G) > 0$ implies that $G^{B_i} = F^{B_i}$, which follows from Lemma 3.5(a). This same observation also establishes (C4), since by **G3** we know that $G^{B_i} = F^{B_i}$ implies $s_i^\varphi(G) = s_i^\varphi(F)$. ∎

Lemma 3.7: *For all formulas ψ, for all $F \in \Omega^\varphi$, if $\psi \in Sub_\Gamma^+(\varphi)$ then $F \in [\![\psi]\!]_{M^\varphi}$ if and only if $\psi \in F$.*

Proof: The proof proceeds by induction on the structure of ψ. We prove here the base cases corresponding to the primitive propositions; the inductive steps can be proved in the standard way (see, e.g., (Fagin *et al.* 1995)).

First consider the primitive proposition $play_i(\sigma_i)$. We have

$$\begin{aligned} F \in [\![play_i(\sigma_i)]\!]_{M^\varphi} \quad & \text{iff} \quad s_i^\varphi(F) = \sigma_i \\ & \text{iff} \quad play_i(\sigma_i) \in F, \end{aligned}$$

as a direct consequence of the definition of s^φ. Next consider the primitive proposition RAT_i; we have

$$\begin{aligned} F \in [\![RAT_i]\!]_{M^\varphi} \quad & \text{iff} \quad s_i^\varphi(F) \in \mathfrak{d}_i(\mu_{i,F}) \\ & \text{iff} \quad RAT_i \in F, \end{aligned}$$

the last equivalence being a consequence of the definition of Pr_i^φ, which ensures that $s_i^\varphi(F)$ is a best response to (the pushforward of) $Pr_i^\varphi(F)$ precisely when $RAT_i \in F$. This completes the proof. ∎

Theorem 3.8: $\mathsf{GL}_\Gamma^\mathfrak{d}$ *is a complete axiomatization of the language $\mathcal{L}_B(\Phi_\Gamma^\mathfrak{d})$ with respect to the class of all finite Γ-structures.*

Proof: Suppose that $\mathsf{GL}_\Gamma^\mathfrak{d} \nvdash \varphi$. Then $\{\neg\varphi\}$ is consistent and so can be extended to a maximal consistent set $F \in \Omega^\varphi$. By Lemma 3.7, this implies that $F \notin [\![\varphi]\!]_{M^\varphi}$ and so, in particular, that $M^\varphi \not\models \varphi$, as desired. ∎

4 Extensions

4.1 Belief as lower probability

In this paper we have taken for granted that each player's uncertainty is represented by a probability measure. While this is a very standard assumption, it is by no means the only framework that has been considered; see (Halpern 2003) for an overview of different ways of modeling uncertainty. Here we show that, with very minor modifications, the results of Section 3.2 hold also in the more general context where beliefs are represented using *sets* of probability measures.

Given a set $\mathcal{P}$ of probability measures, the **lower probability** of an event E, denoted $\mathcal{P}_*(E)$, is defined to be the infimum of the probabilities assigned to E by members of $\mathcal{P}$:

$$\mathcal{P}_*(E) \coloneqq \inf\{\mu(E) \,:\, \mu \in \mathcal{P}\}.$$

Fix a game Γ. A **finite lower Γ-structure** is a tuple $M = (\Omega, (\mathcal{PR}_i)_{i\in I}, s)$ satisfying the following conditions:

(L1) Ω is a nonempty, finite set;

(L2) $\mathcal{PR}_i$ associates to each $\omega \in \Omega$ a set $\mathcal{PR}_i(\omega)$ of probability measures on Ω;

(L3) $\mathcal{PR}_i(\omega)_*(\{\omega' \in \Omega \,:\, \mathcal{PR}_i(\omega') = \mathcal{PR}_i(\omega)\}) = 1$;

(L4) $s : \Omega \to \Sigma$ satisfies $\mathcal{PR}_i(\omega)_*(\{\omega' \in \Omega \,:\, s_i(\omega') = s_i(\omega)\}) = 1$.

These conditions are simply the analogues of conditions (C1) through (C4) where uncertainty is represented by sets of probability measures and certainty is identified with lower probability 1. Accordingly, we define the interpretation $[\![\cdot]\!]_M$ as before, except for the clause corresponding to the belief modalities, which is replaced by the following:

$$[\![B_i\varphi]\!]_M \quad := \quad \{\omega \in \Omega \,:\, \mathcal{PR}_i(\omega)_*([\![\varphi]\!]_M) = 1\}.$$

Finally, a **decision rule** for player i in this context is a function $\mathfrak{d}_i : 2^{\Delta(\Sigma_{-i})} \to 2^{\Sigma_i}$, since player i must make her choice based on the uncertainty given by a set of probability measures. For example, the "maximin expected utility" decision rule for player i would be given by the following:

$$\mathfrak{d}_i^{meu}(\mathcal{P}) := \big\{\sigma_i \in \Sigma_i \,:\, (\forall \sigma_i' \in \Sigma_i) \\ (\min_{\mu\in\mathcal{P}}\{EU_i(\sigma_i;\mu)\} \geq \min_{\mu\in\mathcal{P}}\{EU_i(\sigma_i';\mu)\})\big\}.$$

Other rules, such as minimax expected regret (Hayashi 2008), can also easily be defined in this setting.

As before, such decision rules makes sense in a Γ-structure M: for each player i and each world ω, the probability measures in the set $\mathcal{PR}_i(\omega)$ can be pushed forward by s_{-i} to probability measures on Σ_{-i}. Let $\mathcal{P}_{i,\omega}$ denote the set of all such pushforwards:

$$\mathcal{P}_{i,\omega} := \{\mu_{i,\omega} \,:\, \mu \in \mathcal{PR}_i(\omega)\}.$$

Then we can define $\mathfrak{d}_i$**-rationality** for player i at ω in the obvious way, namely, by the requirement that $s_i(\omega) \in \mathfrak{d}_i(\mathcal{P}_{i,\omega})$.

The axiomatization of Section 3 can be generalized as well. First observe that the dual belief modality, $\widehat{B}_i \equiv \neg B_i \neg$, is interpreted as positive *upper* probability, where the **upper probability** of an event E with respect to a set $\mathcal{P}$ of probability measures, denoted $\mathcal{P}^*(E)$, is given by

$$\mathcal{P}^*(E) := \sup\{\mu(E) \,:\, \mu \in \mathcal{P}\}.$$

Accordingly, given a set $\mathcal{P}$ of probability measures on a finite space X, we define

$$supp(\mathcal{P}) := \{x \in X \,:\, (\exists \mu \in \mathcal{P})(\mu(x) > 0)\}.$$

For each $\sigma_i \in \Sigma_i$, let $\mathcal{S}_i^+(\sigma_i)$ denote the collection of all $S \subseteq \Sigma_{-i}$ such that there exists a set of probability measures $\mathcal{P}$ with $supp(\mathcal{P}) = S$ and $\sigma_i \in \mathfrak{d}_i(\mathcal{P})$. Similarly, define $\mathcal{S}_i^-(\sigma_i)$ to be the collection of all $S \subseteq \Sigma_{-i}$ such that there exists a set $\mathcal{P}$ of probability measures with $supp(\mathcal{P}) = S$ and $\sigma_i \notin \mathfrak{d}_i(\mathcal{P})$. It is not hard to see that all of these definitions generalize what was presented in Sections 2 and 3; indeed, by considering the special case where all sets of probability measures are singletons, we recover that framework exactly. Moreover, the axiom system $\mathsf{GL}_\Gamma^{\mathfrak{d}}$, interpreted in this more general setting using the definitions above, remains sound and complete.

Theorem 4.1: $\mathsf{GL}_\Gamma^{\mathfrak{d}}$ *is a sound and complete axiomatization of the language* $\mathcal{L}_B(\Phi_\Gamma^{\mathfrak{d}})$ *with respect to the class of all finite lower* Γ*-structures.*

Proof: The proof given in Section 3.2 works here as well, modulo the obvious minor alterations in keeping with the generalized definitions given above. In particular, for each $\sigma_i \in \Sigma_i$ and $S \in \mathcal{S}_i^+(\sigma_i)$, we define $\mathcal{P}^+_{\sigma_i,S}$ to be a fixed *set* of probability measures such that $supp(\mathcal{P}^+_{\sigma_i,S}) = S$ and $\sigma_i \in \mathfrak{d}_i(\mathcal{P}^+_{\sigma_i,S})$; likewise, for each $\sigma_i \in \Sigma_i$ and $S \in \mathcal{S}_i^-(\sigma_i)$, define $\mathcal{P}^-_{\sigma_i,S}$ to be a fixed set of probability measures witnessing the fact that $S \in \mathcal{S}_i^-(\sigma_i)$. Then, given $F \in \Omega^\varphi$ with $play_i(\sigma_i) \in F$, define $\mathcal{PR}_i^\varphi(F)$ as follows: for each $\mu \in \mathcal{P}^+_{\sigma_i,S} \cup \mathcal{P}^-_{\sigma_i,S}$, let $\tilde{\mu}$ be the unique probability measure on $\mathrm{Bel}_i(F)$ such that, for all $\sigma_{-i} \in \Sigma_{-i}$,

$$\tilde{\mu}(\mathrm{Bel}_i(F;\sigma_{-i})) = \mu(\sigma_{-i}),$$

and which is uniform on each set $\mathrm{Bel}_i(F;\sigma_{-i})$; then set

$$\mathcal{PR}_i^\varphi(F) := \begin{cases} \{\tilde{\mu} \,:\, \mu \in \mathcal{P}^+_{\sigma_i,S}\} & \text{if } RAT_i \in F \\ \{\tilde{\mu} \,:\, \mu \in \mathcal{P}^-_{\sigma_i,S}\} & \text{if } RAT_i \notin F. \end{cases} \blacksquare$$

4.2 Multiple decision rules

In general, we may wish to reason about players who are uncertain about which decision rules their opponents are using. For example, player i might believe that if player j is maximizing her expected utility, she will play σ_j, but if she plays σ_j', then she might be minimizing the worst-case outcome. One way to try to model such uncertainty is to expand the logic so that there is a *set* $\mathfrak{D}_i$ of decision rules associated with each player i. Consider the collection of primitive propositions

$$\Phi_\Gamma^{\mathfrak{D}} := \Phi_\Gamma \cup \{RAT_i^{\mathfrak{d}_i} \,:\, i \in I,\, \mathfrak{d}_i \in \mathfrak{D}_i\}.$$

Interpret $RAT_i^{\mathfrak{d}_i}$ as before. Then $\mathcal{L}_B(\Phi_\Gamma^{\mathfrak{D}})$ is a language for reasoning about the strategies and beliefs of the players $i \in I$ as well as their adherence to the various decision rules $\mathfrak{d}_i \in \mathfrak{D}_i$.

To obtain a complete axiomatization of this language, it is not sufficient to simply let **G4**–**G6** range over all decision rules $\mathfrak{d}_i \in \mathfrak{D}_i$ for each player i; in general, this system is sound but not complete. Roughly speaking, this is because it is possible for both $play_i(\sigma_i) \wedge RAT_i^{\mathfrak{d}_i}$ and $play_i(\sigma_i) \wedge RAT_i^{\mathfrak{d}_i'}$ to be consistent with $\delta_{i,S}$ for some $S \subseteq \Sigma_{-i}$, yet no measure μ with $supp(\mu) = S$ is such that $\sigma_i \in \mathfrak{d}_i(\mu) \cap \mathfrak{d}_i'(\mu)$. In this case, the formula

$$play_i(\sigma_i) \wedge RAT_i^{\mathfrak{d}_i} \wedge RAT_i^{\mathfrak{d}_i'} \wedge \delta_{i,S}$$

is not satisfiable, but there is no way to prove its negation from the axioms. However, provided that each set $\mathfrak{D}_i$ is finite, we can deal with this problem by replacing **G5** and **G6** with the following collection of axioms for each player i, each strategy $\sigma_i \in \Sigma_i$, and every subset $D \subseteq \mathfrak{D}_i$:

$$\Big(play_i(\sigma_i) \wedge \bigwedge_{\mathfrak{d}_i \in D} RAT_i^{\mathfrak{d}_i} \wedge \bigwedge_{\mathfrak{d}_i \notin D} \neg RAT_i^{\mathfrak{d}_i}\Big) \to \bigvee_{S \in \mathcal{S}_i^D(\sigma_i)} \delta_{i,S},$$

where $\mathcal{S}_i^D(\sigma_i)$ is the collection of all $S \subseteq \Sigma_{-i}$ such that there exists a probability measure μ on S such that $supp(\mu) = S$ and for every $\mathfrak{d}_i \in D$, $\sigma_i \in \mathfrak{d}_i(\mu)$, and for every $\mathfrak{d}_i \notin D$, $\sigma_i \notin \mathfrak{d}_i(\mu)$. **G5** and **G6** are special cases occurring when $|\mathfrak{D}_i| = 1$, corresponding to $D = \mathfrak{D}_i$ and $D = \emptyset$, respectively.

These modified axioms give a sound and complete axiomatization of $\mathcal{L}_B(\Phi_\Gamma^{\mathfrak{D}})$ with respect to the class of all finite Γ-structures. Nevertheless, there is something unsatisfying about using this language to model players' uncertainty about decision rules: the propositions $RAT_i^{\mathfrak{d}_i}$ say that player i is playing a $\mathfrak{d}_i$-best-response, but *not* that player i is actually *using* the rule $\mathfrak{d}_i$ to decide her strategy. To see the difference, consider a player i who is trying to maximize her expected utility (i.e. using $\mathfrak{d}_i^{eu}$), and happens to also play a maximin strategy; contrast this with a scenario in which she is actively seeking to maximize the worst-case outcome (i.e. using $\mathfrak{d}_i^{m}$), and in so doing happens to play a strategy that maximizes her expected utility. Although player i is following different decision rules in these two cases, the language $\mathcal{L}_B(\Phi_\Gamma^{\mathfrak{D}})$ cannot express this difference; the formula $RAT_i^{\mathfrak{d}_i^{eu}} \wedge RAT_i^{\mathfrak{d}_i^{m}}$ holds either way. For instance, in the example presented in Section 2.4, it is not hard to check that

$$\omega_0 \models play_1(\text{Bach}) \rightarrow \left(RAT_1^{\mathfrak{d}_1^{eu}} \wedge RAT_1^{\mathfrak{d}_1^{m}}\right).$$

In sum, the propositions $RAT_i^{\mathfrak{d}_i}$ do not say anything about *how* player i is making her decision, but simply record whether or not the decision she does make is compatible with the rule $\mathfrak{d}_i$. What we want is a different kind of proposition, say $rule_i(\mathfrak{d}_i)$, that says that player i really is *using* the rule $\mathfrak{d}_i$ in deciding her strategy.

Decision rules interpreted in this sense are particularly relevant in a dynamic setting. When an opponent does something unexpected and seemingly irrational, there is the question of how to update your beliefs. One option is to abandon the belief that your opponent is rational, but this is unsatisfying both conceptually and methodologically. An alternative response is to update your beliefs about your opponent's beliefs: what they did actually was rational with respect to their beliefs, you had just misjudged what those beliefs were (see, e.g., (Battigalli & Siniscalchi 2002)). But in some cases, this too is unsatisfying or simply unavailable. However, when decision rules are formally present as objects of belief, a third option becomes available: abandon the belief that your opponent is $\mathfrak{d}_i$-rational, but not that they are behaving rationally with respect to *some* decision rule. Though an analysis of decision rules in extensive-form games is beyond the scope of this paper, the groundwork for such a study can be laid by formalizing them in a static context.

Fix a game Γ and a profile $\mathfrak{D} = (\mathfrak{D}_i)_{i\in I}$ of sets of decision rules for each player $i \in I$. Let

$$\Phi_{\Gamma,\mathfrak{D}} \coloneqq \Phi_\Gamma \cup \{rule_i(\mathfrak{d}_i) \,:\, i \in I,\, \mathfrak{d}_i \in \mathfrak{D}_i\}.$$

In order to interpret the primitive propositions $rule_i(\mathfrak{d}_i)$, we must extend the semantic model so that it associates with each world ω the decision rule that each player i is using at that world; furthermore, we must constrain the strategies used at each world so that they are compatible with the corresponding decision rules. Formally, a **Γ-structure with decision functions** is a tuple $M = (\Omega, (Pr_i)_{i\in I}, s, r)$ satisfying (C1) through (C4) as well as the following additional conditions:

(C5) $r : \Omega \rightarrow \mathfrak{D}$ satisfies $Pr_i(\omega)(\{\omega' \in \Omega \,:\, r_i(\omega') = r_i(\omega)\}) = 1$;

(C6) $s_i(\omega) \in r_i(\omega)(\mu_{i,\omega})$.

Condition (C5) says that the *decision function* r assigns to each world ω a profile of decision rules $r(\omega)$—intuitively, $r_i(\omega) \in \mathfrak{D}_i$ is the rule that player i is using at ω—and moreover, each player is sure of her own decision rule. Condition (C6) requires that, at each world ω, the strategy $s_i(\omega)$ is an $r_i(\omega)$-best response for player i; in other words, player i really is following the decision rule $r_i(\omega)$ at ω.

The language $\mathcal{L}_B(\Phi_{\Gamma,\mathfrak{D}})$ can be interpreted in a Γ-structure with decision functions M as before, with the additional clause

$$[\![rule_i(\mathfrak{d}_i)]\!]_M \;\coloneqq\; \{\omega \in \Omega \,:\, r_i(\omega) = \mathfrak{d}_i\}.$$

The resulting logic can be axiomatized using essentially the same technique as in Section 3. Consider the following axiom schemes:

P1. $\bigvee_{\sigma_i\in\Sigma_i} play_i(\sigma_i)$

P2. $\neg(play_i(\sigma_i) \wedge play_i(\sigma_i'))$, for $\sigma_i \neq \sigma_i'$

P3. $play_i(\sigma_i) \leftrightarrow B_i\, play_i(\sigma_i)$

P4. $\bigvee_{\mathfrak{d}_i\in\mathfrak{D}_i} rule_i(\mathfrak{d}_i)$

P5. $\neg(rule_i(\mathfrak{d}_i) \wedge rule_i(\mathfrak{d}_i'))$, for $\mathfrak{d}_i \neq \mathfrak{d}_i'$

P6. $rule_i(\mathfrak{d}_i) \leftrightarrow B_i\, rule_i(\mathfrak{d}_i)$

P7. $(play_i(\sigma_i) \wedge rule_i(\mathfrak{d}_i)) \rightarrow \bigvee_{S\in\mathcal{S}_i^+(\sigma_i)} \delta_{i,S}$.

Here, as before, $\mathcal{S}_i^+(\sigma_i)$ denotes the collection of all $S \subseteq \Sigma_{-i}$ such that there exists a probability measure μ with $supp(\mu) = S$ and such that $\sigma_i \in \mathfrak{d}_i(\mu)$. Note that there is no need for a symmetric axiom involving $\mathcal{S}_i^-(\sigma_i)$ for this logic, because the formula $\neg rule_i(\mathfrak{d}_i)$, unlike $\neg RAT_i$, does not say that σ_i is *incompatible* with player i's beliefs and the decision rule $\mathfrak{d}_i$; it simply says that player i did not *use* the rule $\mathfrak{d}_i$ to help choose her strategy σ_i (though she may, coincidentally, have beliefs with respect to which σ_i is a $\mathfrak{d}_i$-best response).

Let $\mathsf{GL}_{\Gamma,\mathfrak{D}}$ be the axiom system that results from adding **P1**–**P7** to the KD45 axioms and rules of inference of belief logic. Then we have the following result, the proof of which proceeds analogously to that given in Section 3.2.

Theorem 4.2: *$\mathsf{GL}_{\Gamma,\mathfrak{D}}$ is a sound and complete axiomatization of the language $\mathcal{L}_B(\Phi_{\Gamma,\mathfrak{D}})$ with respect to the class of all finite Γ-structures with decision functions.*

5 The role of language

In this section we focus on the profile of decision rules $\mathfrak{d} = \mathfrak{d}^{eu}$, with respect to which each player is rational precisely if they are playing a strategy that maximizes their expected utility. As noted, it is somewhat surprising that **G5** and **G6** are sufficient to capture this notion of rationality. Whether or not a player is maximizing their expected utility depends on their *quantitative* beliefs; however, while **G5** and **G6** specify the possible supports for player i's beliefs,

they say nothing about the actual weights placed on the individual outcomes. Nor could they—the language $\mathcal{L}_B(\Phi_\Gamma^{\mathfrak{d}})$ cannot express anything beyond such qualitative properties of the measures $Pr_i(\omega)$.

Expressivity, however, is a double-edged sword: when working with a less expressive language, though we are more limited in the possible axioms we have available, there are also fewer validities to worry about proving. This, in essence, is why $\mathsf{GL}_\Gamma^{\mathfrak{d}}$ can be a complete axiomatization: the properties of rationality it fails to encode are precisely those properties that are not expressible in the language at all.

A richer language—in particular, one with a finer-grained representation of belief—may not be axiomatizable at all, or at least not using the techniques in this paper. Consider, for example, a language with belief modalities B_i^α for each $\alpha \in [0,1]$, where $B_i^\alpha\varphi$ is interpreted as saying that player i assigns probability α to φ. In this case, $\mathsf{GL}_\Gamma^{\mathfrak{d}}$ (replacing B_i by B_i^1) is sound but certainly not complete. It can easily happen, for example, that in the game Γ it is only rational for player i to play σ_i if she assigns probability $\frac{1}{2}$ to σ_{-i}; however, the corresponding validity

$$(play_i(\sigma_i) \wedge RAT_i) \to B_i^{\frac{1}{2}}\, play_{-i}(\sigma_{-i})$$

is clearly not a theorem of $\mathsf{GL}_\Gamma^{\mathfrak{d}}$. Moreover, extending $\mathsf{GL}_\Gamma^{\mathfrak{d}}$ to this richer language runs into difficulties. The axiom schemes **G5** and **G6** essentially work by insisting that the players' beliefs be compatible with rationality or its negation, respectively. In the language $\mathcal{L}_B(\Phi_\Gamma^{\mathfrak{d}})$, this amounts to specifying the possible supports for the players' beliefs, which can be written using finite formulas since each Σ_{-i} is finite and therefore has only finitely-many subsets. By contrast, in the language with belief modalities B_i^α for every $\alpha \in [0,1]$, the "formula" that says that player i's beliefs are compatible with rationality may be infinitely long.

A still richer language, however, can circumvent these difficulties entirely. Fix a game Γ and consider the language of *linear likelihood inequalities* defined by the grammar

$$\varphi ::= p \mid \neg\varphi \mid \varphi \wedge \psi \mid a_1\ell_i(\varphi_1) + \cdots + a_k\ell_i(\varphi_k) \geq b,$$

where $p \in \Phi_\Gamma$, $i \in I$, $k \in \mathbb{N}$, and $a_1, \ldots, a_k, b \in \mathbb{R}$. The *likelihood terms* $\ell_i(\varphi)$ are meant to be read as "the probability of φ according to player i", and a likelihood formula $a_1\ell_i(\varphi_1) + \cdots + a_k\ell_i(\varphi_k) \geq b$ should be thought of as asserting the corresponding inequality. More precisely, we interpret such formulas in a Γ-structure M as follows:

$$\begin{aligned} &[\![a_1\ell_i(\varphi_1) + \cdots + a_k\ell_i(\varphi_k) \geq b]\!]_M \\ :=\ &\{\omega \in \Omega \,:\, \textstyle\sum_{j=1}^k a_j Pr_i(\omega)([\![\varphi_j]\!]_M) \geq b\}. \end{aligned}$$

For example, the formula $\ell_i(\varphi) \geq 1$ says that player i assigns probability at least (and therefore exactly) 1 to φ, while the formula $(\ell_i(\varphi) \geq \frac{1}{2}) \wedge (\ell_i(\neg\varphi) \geq \frac{1}{2})$ says that player i assigns probability $\frac{1}{2}$ to φ. See (Halpern 2003) for a thorough discussion of this and related logics; a sound and complete axiomatization is given in (Fagin, Halpern, & Megiddo 1990).

In this language, rationality in the sense of expected utility maximization can be *defined*, thus obviating the need for a separate axiomatization. Indeed, if we let $\sigma_i \succeq \sigma_i'$ be an abbreviation for the formula

$$\begin{aligned} &\textstyle\sum_{\sigma_{-i}\in\Sigma_{-i}} u_i(\sigma_i, \sigma_{-i})\ell_i(play_{-i}(\sigma_{-i})) - \\ &\quad \textstyle\sum_{\sigma_{-i}\in\Sigma_{-i}} u_i(\sigma_i', \sigma_{-i})\ell_i(play_{-i}(\sigma_{-i})) \geq 0, \end{aligned}$$

which says that the expected value according to player i of playing σ_i is no less than the expected value of playing σ_i', then it is easy to see that

$$RAT_i^{\mathfrak{d}_i^{eu}} \leftrightarrow \bigvee_{\sigma_i\in\Sigma_i} \Big(play_i(\sigma_i) \wedge \bigwedge_{\sigma_i'\in\Sigma_i} \sigma_i \succeq \sigma_i' \Big)$$

is valid. Since rationality is expressible in this language, it is axiomatized as well.

6 Further work

Equilibrium analysis in game theory is predicated on the notion of rationality: solution concepts like Nash equilibrium are formulated in terms of best responding to beliefs. As such, one natural application of a logic of rationality is to the analysis of equilibria.

The language $\mathcal{L}_B(\Phi_\Gamma)$ has formulas that represent pure strategy choices, but not mixed strategies. In the context of Nash equilibrium, this difference turns out to be (at least formally) innocuous: one can view a mixed strategy $\ell_i \in \Delta(\Sigma_i)$ either as a conscious randomization on the part of player i, or as the common conjecture of the players $j \neq i$ about what pure strategy i will choose—either way, the set of mixed strategy Nash equilibria stays the same. However, this insensitivity is, in part, dependent on that fact that rationality in the sense of expected utility maximization plays well with mixing: $\ell_i \in \Delta(\Sigma_i)$ maximizes player i's expected utility (with respect to some fixed beliefs) if and only if every pure strategy σ_i in the support of ℓ_i maximizes expected utility. But this correspondence breaks down when "expected utility maximization" is replaced with the generalized notion of rationality presented in Section 2.3: in the context of an arbitrary decision rule $\mathfrak{d}_i : \Delta(\Sigma_{-i}) \to 2^{\Sigma_i}$, there is no principled way to extend the notion of "best response" from Σ_i to $\Delta(\Sigma_i)$. This suggests that further research into the interaction between pure and mixed strategies under general decision rules may be fruitful.

One might also wonder whether there are useful logical characterizations of when a given strategy constitutes a Nash equilibrium. Similar to the above, a related line of inquiry arises by considering generalized decision rules and the correspondingly generalized notions of equilibria they induce. In principle, it makes sense to consider "$\mathfrak{d}$-Nash equilibria", defined by replacing $\mathfrak{d}^{eu}$ with an arbitrary profile of decision rules $\mathfrak{d}$ in the definition of Nash equilibrium. It is certainly too much to hope that Nash's famous existence theorem apply in full force to this wider concept; however, properties of $\mathfrak{d}$ that suffice to guarantee the existence of equilibria are of interest, and potentially admit a logical characterization. Such questions are the subject of ongoing research.

Although in this paper we focused on rationality, our approach to axiomatizing rationality applies to a wider class of properties. Define an *i-subjective property* to be any property of i that i is sure of; that is, a formula φ such that

$\varphi \leftrightarrow B_i\varphi$ is valid. Rationality is i-subjective, as is whether i is jealous (e.g., believes somebody has some property that she doesn't have, but wishes she did), whether i is cautious (e.g., assigns positive probability to all her opponents' actions), etc. We believe that the techniques developed in this paper could be used to provide a sound and complete axiomatization of any i-subjective property whose truth is determined by i's beliefs and what i plays. We hope to return to this topic in future work.

Dynamic Causal Calculus

Alexander Bochman
Computer Science Department,
Holon Institute of Technology,

Abstract

We introduce dynamic causal calculus, a nonmonotonic formalism that can be viewed as a direct logical counterpart of the action description language C+ from (Giunchiglia et al. 2004). We formulate a nonmonotonic semantics of the associated causal language, and compare this semantics with the indirect, two-stage semantics for C+, given in (Giunchiglia et al. 2004). It will be shown, in particular, that the suggested semantics allows us to alleviate syntactic distinctions between propositional atoms, maintained by C+, as well as type restrictions imposed on its causal laws. We will describe also a logical formalism of dynamic causal inference that constitutes a complete description of the logic that is adequate for this dynamic calculus.

Introduction

Unlike general descriptions of temporal dynamics in temporal logics and related logical formalisms, action theories in AI have to deal primarily with two quite specific reasoning tasks, namely the *prediction* task (what are the results of a given sequence of actions from an initial state) and the *planning* task (what sequence of actions could lead from an initial state to a target goal state). These reasoning tasks immediately lead to a triple of famous problems, known as the frame, ramification and qualification problems (see (Shanahan 1997)). It was realized quite early that classical logic and its temporal/dynamic extensions, taken by themselves, encounter difficulties in resolving these problems. More precisely, it has become clear that these problems have an essentially *nonmonotonic* character, so their proper solution requires augmenting purely logical, monotonic reasoning with an appropriate mechanism for making nonmonotonic conclusions[1].

In recent years a dominant approach to solving these problems has been based, in one form or another, on what can be broadly termed causal reasoning. Given a set of action and (causal) rules describing the domain, the causal approach employs a distinction between facts that hold in a situation versus facts that are caused (or explained) by other facts and the rules. In this context, the corresponding causal closure assumption (see. e.g., (Reiter 2001)) can be viewed as a particular form of an old philosophical principle of *universal causation*, which amounts to the requirement that all facts that hold in a situation should be either caused by other occurrent facts, or else preserve their truth-values in time (due to the accompanying *inertia* assumption). A direct incorporation of such causal assertions into the language of the situation calculus has been proposed in (Lin 1995; 1996), and has been shown to provide a natural account of both the frame and ramification problems. Subsequently, a general formal framework for this kind of causal reasoning, called a causal calculus, has been suggested in (McCain and Turner 1997).

An elaborate implementation of the above causal principles in reasoning about actions has been given in (Giunchiglia et al. 2004). The formalism of (Giunchiglia et al. 2004), however, is a multi-sorted and multi-layered representation framework. As its top layer, it employs a causal action description language C+ that provides high-level descriptions of action domains in terms of three kinds of propositional atoms (actions, simple fluents and statically determined fluents) and three different kinds of causal laws (static laws, action dynamic laws and fluent dynamic laws). Domain descriptions in this language are then instantiated by assigning temporal stamps to propositions, and incorporating the resulting descriptions into an atemporal causal calculus of (McCain and Turner 1997). The models of the resulting causal theories are viewed then as intended models of the source, higher-level action descriptions.

In this study[2] we will attempt to single out and 'streamline' the logical framework behind the language C+. To this end, we will introduce a dynamic generalization of the original causal calculus, which will be formulated, ultimately, in terms of a single basic kind of *dynamic* causal rules. This dynamic calculus will provide a direct and uniform logical description for the language C+. In addition, we will describe also a logical (monotonic) system of dynamic causal inference that will constitute a concise logical framework for causal reasoning in dynamic domains.

[1] Even the well-known "monotonic" solution to the frame problem, described in (Reiter 1991), can be seen as a result of compiling this nonmonotonic information into the successor state equivalences.

[2] Preliminary version of this paper has appeared in (Bochman 2013).

The plan of the paper is as follows. After an overview of the original (atemporal) causal calculus and its use in the framework of (Giunchiglia et al. 2004), we will introduce a dynamic causal calculus as a direct reformulation of the action description language C+. We will describe a modified nonmonotonic semantic for this dynamic causal language that is based on a comprehensive principle of universal causation, and show that this modification allows us, in particular, to alleviate most of the syntactic restrictions imposed in C+ on the form of its causal rules, as well as syntactic distinctions between the propositions of the language. Finally, we will describe a logical formalism of dynamic causal inference that constitutes an underlying logic for causal reasoning in action domains.

The Causal Calculus

Throughout this study, we will assume that our basic language is a classical propositional language with the usual connectives and constants $\{\wedge, \vee, \neg, \rightarrow, \mathbf{t}, \mathbf{f}\}$. $\models$ and Th will stand, respectively, for the classical entailment and the associated logical closure operator. In what follows, we will also identify propositional interpretations ('worlds') with the sets of propositional formulas that hold in them.

A *causal rule* is a rule of the form $A \Rightarrow B$, where A and B are classical propositions. We will informally interpret such rules as saying plainly *"A causes B"*.[3]

By a *causal theory* we will mean an arbitrary set of causal rules. For a set u of propositions and a causal theory Δ, we will denote by $\Delta(u)$ the set of all propositions that are caused by u in Δ, that is,

$$\Delta(u) = \{B \mid A \Rightarrow B \in \Delta, \text{ for some } A \in u\}$$

Then the nonmonotonic semantics of a causal theory can be defined as follows.

Definition 1. A world (= propositional interpretation) α is an *exact model* of a causal theory Δ if it is a unique model of $\Delta(\alpha)$. The set of exact models forms a *nonmonotonic semantics* of Δ.

The above semantics of causal theories coincides, in effect, with the semantics for such theories, described in (McCain and Turner 1997) and (Giunchiglia et al. 2004). It can also be verified that exact models of a causal theory are precisely the worlds that satisfy the following condition:

$$\alpha = \mathrm{Th}(\Delta(\alpha)).$$

Accordingly, exact worlds are not only closed with respect to the causal rules, but also such that any proposition that holds in them is caused (that is, explained) ultimately by other propositions.

An overview of the Language C+

The underlying propositional language of the action description language C+, introduced in (Giunchiglia et al. 2004), is somewhat more general than the standard classical propositional language in that it is based on a multi-valued propositional signature that consists of a set of constants, along with a function Dom assigning every constant c a nonempty finite set $Dom(c)$ of values. Propositional atoms in this signature are expressions of the form $c = v$, where c is a constant, while v is one of its possible values. Still, propositional formulas in this language are defined as usual combinations of atoms with the help of the ordinary classical connectives. Moreover, *Boolean* constants are defined in this setting as a special kind of constants whose domain is the set $\{\mathbf{f}, \mathbf{t}\}$ of truth values.

An *action description* in C+ is defined as a set of causal laws. There are, however, three kinds of causal laws in C+, and the differences between them are based, ultimately, on a distinction between three kinds of constants, and thereby three kinds of atoms, stipulated by the theory. First, propositional atoms are partitioned into *action* atoms and *fluent* atoms, while the latter are further partitioned into *simple* and *statically determined* fluents. A *fluent formula* is defined as a formula such that all constants occurring in it are fluent constants, whereas an *action formula* is a formula that contains at least one action constant and no fluent constants.

Granted the above syntactic distinctions among propositional atoms, the following three kinds of causal laws are defined in C+:

- *Static laws* are expressions of the form

  $$\mathbf{caused}\ F\ \mathbf{if}\ G,$$

  where F and G are fluent formulas;
- *Action dynamic laws* are expressions of the form

  $$\mathbf{caused}\ F\ \mathbf{if}\ G,$$

  where F is an action formula and G is a formula;
- *Fluent dynamic laws* are expressions of the form

  $$\mathbf{caused}\ F\ \mathbf{if}\ G\ \mathbf{after}\ H,$$

  where F is a fluent formula that does not contain statically determined constants, G is a fluent formula, and H is an arbitrary formula.

Static laws are used in C+ to talk about causal dependencies between fluents in the same state, while action dynamic laws are purported to express causal dependencies between concurrently executed actions. In accordance with their very name, statically determined fluent constants are allowed in the heads of static laws, but not in the heads of dynamic laws. As we will see in what follows, the necessity of introducing a separate syntactic sort of statically determined fluents stems from a particular definition of a state of a transition system, which has been used in interpreting action descriptions in C+.

The language C+ employs also a number of abbreviations and names for special kinds of causal laws. Two such abbreviations play an especially important role in the descriptions of action domains that serve to illustrate the general theory. If c is a simple fluent constant, then

$$\mathbf{inertial}\ c$$

[3] (Giunchiglia et al. 2004) adopted a more cautious informal reading of such rules, namely *"If A holds, then B is caused"*.

stands for the fluent dynamic laws

$$\textbf{caused } c = v \textbf{ if } c = v \textbf{ after } c = v$$

for all $v \in Dom(c)$. These laws provide an encoding of the *inertia assumption* for (simple) fluent atoms. Similarly, if c is an action constant, the expression

$$\textbf{exogenous } c$$

stands for the action dynamic laws

$$\textbf{caused } c = v \textbf{ if } c = v$$

for all $v \in Dom(c)$. These laws make action atoms exogenous in an action domain, which exempt them, in effect, from explanation.

Interpretations and models of action descriptions in C+ are defined indirectly by translating them into plain causal theories. To begin with, for every natural number m, an action description D is transformed into an atemporal causal theory D_m as follows. First, 'time stamps' i: for $i \in \{0, \ldots, m\}$ are inserted in front of every occurrence of every atom in propositional formulas. Then each static law is translated into the following set of causal rules, for every $i \leq m$:

$$i : A \Rightarrow i : B,$$

where $i : F$ is the result of inserting i: in front of every occurrence of every atom in a formula F. Similarly, any action dynamic law is translated into a set of causal rules of the same form, but only for $i < m$.

Finally, any fluent dynamic law is translated into the following set of causal rules:

$$(i : C) \wedge (i + 1 : A) \Rightarrow i + 1 : B,$$

for every $i < m$.

As a concluding step, in order to deal with the initial states, the following causal rules are added to the resulting causal theory:

$$0 : l \Rightarrow 0 : l$$

for every *simple* fluent atom l. These rules make simple fluent atoms exogenous (self-explained) in the initial state. As a result, we obtain an ordinary causal theory, and the exact models of this theory are considered to be the models of the original action description in C+. Such models can be visualized as histories of length m of the source dynamic domain. More precisely, these are histories in which the initial state is 'self-explainable', but every subsequent state is already causally explained by the preceding state and actions taken in it.

(Giunchiglia et al. 2004) contains also a more general semantic construction, according to which an action description D in C+ describes, in effect, a *transition model* (i.e., a set of states with a set of transitions among them) in which states are the models of the 'smallest' (static) causal theory D_0 (which is a theory D_m for $m = 0$)[4], while transitions correspond precisely to the models of the minimal dynamic causal theory D_1 (that is, a theory D_m for $m = 1$). It has been shown in (Giunchiglia et al. 2004, Proposition 8) that, for any $m > 0$, models of a causal theory D_m are exactly histories (paths) of length m in this transition model.

[4]Note that, by the definition of the translation, D_0 includes no dynamic laws, and only '0-stamped' static causal laws.

On statically determined fluents

The above construction of a canonical transition model for an action description implicitly relied on the property (stated as Proposition 7 in (Giunchiglia et al. 2004)) that for any transition $\langle s, e, t\rangle$ in the above sense (that is, for any model of D_1), both s and t are states (models of D_0). As has been observed in the paper, the validity of this property depends essentially on the fact that the heads of fluent dynamic laws were not allowed to contain statically determined fluent constants, which explained the very need for a *syntactic* (type) separation between simple and statically determined fluent constants in the framework of the general theory described in (Giunchiglia et al. 2004).

It should be noted, however, that, taken by itself, the distinction between simple and statically determined fluents is not as clear-cut as it may seem. Consider, for example, a fluent predicate *Safe* (for a baby), discussed first in (Myers and Smith 1988). As was observed in (Giunchiglia and Lifschitz 1995), there might be different kinds of safety in this sense. An object in question may be a heavy hammer, so it is safe for a baby only if it is far from the reach, say on a table. This is a clear example of a statically determined fluent. But the object may be a doll, in which case its safety is clearly an ordinary, simple inertial fluent. Furthermore, we can easily imagine an action like *Isolate* that wrap up a potentially non-safe hammer with a material that makes it fully safe for a baby. On an account of (Giunchiglia et al. 2004) this would require, however, a syntactic shift for this fluent from statically determined to simple one.

The distinction between simple and statically determined fluents is only a very special case of a broader distinction between inertial and non-inertial fluents. Such distinctions between fluents play an important role in reasoning about actions and change in AI, so they should not be obliterated, or neglected. Still, they need not be defined as syntactic distinctions between types of fluents. Rather, they could be viewed as a by-product of the actual ways these fluents are described, or defined, in (causal) rules. Thus, we can still maintain that a particular fluent is *statically determined* in a given action description if it happens to appear only in heads of its static rules. But this characterization could change, for example, with an addition of new dynamic rules which involve this fluent in their heads. Such a 'dynamic' characterization would be unfeasible, however, in the framework of (Giunchiglia et al. 2004) because statically determined fluents play an essential role in the definition of the very notion of a state of a transition model that determines, in turn, the semantics of C+. Accordingly, in order to make the language of C+ syntactically uniform, we should change also its semantic description. This will be done in the next section where we will describe an alternative semantics for the dynamic causal calculus that will provide a logical representation for the action descriptions in C+.

As a final note here, we should mention that there are also other, perhaps even more serious, problems with the representation of statically determined fluents in C+. Thus, many fluents of this kind are naturally defined using recursive (Prolog-like) rules. It turns out, however, that such definitions are not expressible in C+, though they are nat-

urally expressible in an alternative action description language, namely the language B (see (Gelfond and Lifschitz 1998)). As a matter of fact, representation of such recursively determined fluents creates similar difficulties also for the dynamic causal calculus, described in this study, since the latter closely follows the general semantic framework of C+[5].

Dynamic Causal Calculus

In this section we are going to describe a dynamic causal calculus that is intended to provide a direct logical reformulation of the action description language C+ and its semantics. As a first step, we will use a more convenient, 'logic-oriented' notation, namely, we will rewrite a dynamic law $\mathbf{caused}\ B\ \mathbf{if}\ A\ \mathbf{after}\ C$ as a causal rule of the form

$$C.A \Rightarrow B.$$

We will call such rules *dynamic causal rules*. Moreover, extending our previous re-interpretation of atemporal causal rules, we will assign a more 'active' informal reading to such rules, namely *"After C, A causes B"*. By the intended interpretation, a rule $C.A \Rightarrow B$ describes a dynamic transition from a state that satisfies proposition C to a subsequent state in which B is caused by A.

Remark. As a matter of fact, the above dynamic causal rules are somewhat ambiguous from a syntactic point of view. On a more abstract level, such a rule can be viewed simply as an instantiation of a primitive ternary propositional operator. There are, however, at least two other, more articulated possibilities[6]. Thus, a dynamic causal rule $C.A \Rightarrow B$ could be viewed as a plain causal rule $A \Rightarrow B$ that is conditioned by a preceding context C. In fact, this 'parsing' agrees with the informal reading of such rules, given above. Furthermore, we will see that this understanding of dynamic causal rules as conditional static rules provides a natural justification for the postulates of the associated dynamic causal inference that will be given below. Still, a different parsing possibility consists in viewing such rules as binary causal rules, though with complex premises consisting of pairs of propositions (C, A). Again, we will see later that this reading can also be given a formal support, due to a possible translation of such rules as propositions of the form $(C \circ A) \rightarrow B$ in arrow logic.

As a second step in our reformulation, we will uniformly view both static and action dynamic laws of the form $\mathbf{caused}\ B\ \mathbf{if}\ A$ as plain (static) causal rules $A \Rightarrow B$. Moreover, in the version of the dynamic causal calculus that we will present in this study, we will make one further step and identify such rules with a special kind of dynamic rules of the form $\mathbf{t}.A \Rightarrow B$, where $\mathbf{t}$ is the truth constant. In other words, we will adopt the following definition:

$$A \Rightarrow B \ \equiv_{df}\ \mathbf{t}.A \Rightarrow B.$$

According to this definition, static causal rules are precisely rules that are valid after any legitimate transition. The consequences and variations created by this identification will be discussed below.

The above reduction of static causal rules to a special kind of dynamic rules makes the dynamic causal rules the only kind of rules of the dynamic calculus. In accordance with this, a *dynamic causal theory* will be defined below simply as a set of dynamic causal rules.

Now we are going to provide a direct description of the nonmonotonic semantics of dynamic causal theories. The guiding principle behind this nonmonotonic semantics will be a thorough enforcement of the *principle of universal causation*, according to which every state of a dynamic model should be explained (i.e., caused) by a preceding state and the causal rules of the domain.

Given a dynamic causal theory Δ and worlds α, β, we will denote by $\Delta(\alpha.\beta)$ the set

$$\{C \mid A.B \Rightarrow C \in \Delta \text{ for some } A \in \alpha, B \in \beta.\}$$

For any given state β, the set $\Delta(\alpha.\beta)$ is precisely the set of propositions in β that are caused due to a transition from α.

Definition 2.(i) A pair (α, β) of worlds will be called an *exact transition* with respect to a dynamic causal theory Δ if β is the unique model of $\Delta(\alpha.\beta)$, that is

$$\beta = \mathrm{Th}(\Delta(\alpha.\beta)).$$

(ii) An *exact transition model* of a dynamic causal theory Δ is a set of worlds $\mathfrak{I}$ such that, for any $\beta \in \mathfrak{I}$ there is $\alpha \in \mathfrak{I}$ such that (α, β) is a an exact transition wrt Δ.

An exact transition is a transition between two states in which the resulting state is fully explained (caused), given the preceding state and the causal laws of the domain. It is important to note that if (α, β) is an exact transition, then the output world β is always closed with respect to the static causal rules (for our definition of the latter), namely if $A \Rightarrow B$ (that is, $\mathbf{t}.A \Rightarrow B$) belongs to Δ and $A \in \beta$, then $B \in \beta$. Note now that any world of an exact transition model is also an output of some exact transition. Accordingly, we immediately obtain the following

Lemma 1. *Any world of an exact transition model of a dynamic causal theory Δ is closed with respect to the static causal rules of Δ.*

It can be easily verified that the union of two exact transition models is also an exact transition model. Consequently, if a dynamic causal theory has at least one exact transition model, it has a unique maximal such model. We will call the latter the *canonical exact transition model* of a dynamic causal theory.

In the next section we are going to compare the above dynamic causal calculus with the theory presented in (Giunchiglia et al. 2004).

[5]Recently, (Lee, Lifschitz, and Yang 2013) have suggested a generalization of the language C+, called a language BC, that incorporates expressive capabilities of the language B. Instead of a causal interpretation, however, the authors have provided only formal translations of this language directly into the framework of logic programming.

[6]Compare with a similar compositional analysis of general and relevant conditionals, discussed in (Beall et al. 2012).

Comparisons with C+

In accordance with the reformulation procedure sketched in the preceding section, any action description in the action description language C+ can be immediately transformed into a dynamic causal theory in our sense. Despite the obvious similarities, however, this reformulation reveals also some basic differences between the two formalisms. To begin with, the language of the above dynamic causal calculus is thoroughly *uniform* in that it does not presuppose any a priori, *syntactic* distinctions between its propositional atoms, and it employs only a single form of causal rules, instead of three kinds of causal laws used in C+. On the other hand, the above notion of an exact transition model is somewhat different, and apparently more restricted, than the corresponding notion of a model for C+. In what follows we will discuss these differences in more details.

Fluents versus Actions

Many action theories in AI, as well as some general dynamic formalisms, maintain rigid semantic and syntactic distinctions between *fluent* propositions that describe particular states or situations and *actions* that describe transitions between states. Thus, the situation calculus (Reiter 2001) treats actions essentially as modifiers, or functions on situations. Similarly, Propositional Dynamic Logic (see (Harel, Kozen, and Tiuryn 2000)) interprets actions as binary relations on states.

However, in contrast to the above formalisms, it can be immediately observed that there are no *inherent* syntactic differences between fluent and action atoms in C+; both kinds are translated as (temporally indexed) propositional atoms in the underlying causal calculus. Of course, there are still important differences between these two kinds of propositions: (simple) fluents are governed by the inertia principle, while action atoms are normally treated in C+ as exogenous (see above). However, these distinctions are semantical, and they can be secured by incorporating causal rules that characterize, respectively, inertia and exogeneity for these atoms directly into the corresponding action descriptions. Once we add such rules to the action descriptions, there is no need to maintain a syntactic distinction between fluents and actions in C+, and there is no need to maintain a separate category of action dynamic laws in addition to static laws.

Remark. The treatment of actions in C+ makes the latter much similar to *temporal* formalisms for analyzing general computation processes, such as Linear Temporal Logic (LTL). In the latter, computational processes are represented as plain temporal sequences of states (which are characterized by fluent propositions), and they do not use explicit action descriptions. Still, actions are usually encoded in these formalisms by using associated 'action fluents' that appropriately constrain such temporal sequences (see, e.g., (Calvanese, De Giacomo, and Vardi 2002; De Giacomo and Vardi 2013)).

State Constraints and the Principle of Universal Causation

An exact transition model of a dynamic causal theory was defined above as a set of states in which every state is caused as a result of some exact transition. As a result, any state of such a model will be closed with respect to the static laws on our reformulation of the latter. Moreover, it can be verified that any such state will be a state in the sense of (Giunchiglia et al. 2004). Consequently, we will obtain that any exact model in our sense will correspond to a model (transition system) in the sense of (Giunchiglia et al. 2004):

Theorem 2. *If Δ is an action description in C+ and Δ_C its corresponding dynamic causal theory, then any exact transition model of Δ_C is a transition model of Δ.*

Still, our semantics for dynamic causal theories is more restrictive, since it requires that any state of the model, *including the initial state*, should be an output of some transition, whereas (Giunchiglia et al. 2004) adopted more relaxed requirements on initial states. As we have seen earlier, the construction of a causal theory for a given action description in C+ necessarily involves an addition of causal rules that make simple fluents exogenous (self-explainable) in the initial state. As a result, the framework (Giunchiglia et al. 2004) exempts to some extent initial states from the need of explanation, though it still requires that such states should be closed with respect to the static laws (which are completely separated from dynamic ones) and, moreover, that any statically determined fluent literal that holds in an initial state should still be explained (caused) by the static laws.

Remark. As a matter of fact, our definition of an exact transition almost coincides with the corresponding definition of a *causally explained transition*, given in (Giunchiglia and Lifschitz 1998) for a more restricted action description language C, a predecessor of C+[7]. In fact, the only difference between the two definitions is that (Giunchiglia and Lifschitz 1998) required further that both the initial and resulting states of such a transition should be closed with respect to the static causal laws. On our construction, this additional requirement is accounted for, respectively, as a by-product of our definition of static causal rules on the one hand (for the resulting states), and an exact transition model on the other hand (for the initial states).

In order to make a proper assessment of the above discrepancy, we should distinguish two aspects of the difference, conceptual and practical one. On the conceptual side, we believe that an ultimate reason for imposing even the above minimal restrictions on initial states in C+ stems from a broader requirement that such states should be somehow accessible in accordance with the laws of the domain. In other words, any state of a dynamic system should be consistently viewed as a result of some legitimate transition (including possible 'loops' in this state). Speaking more generally, we contend that static laws and constraints should be viewed as constraints that are effective after every legitimate transition, and vice versa, any constraint that happens to hold after any

[7] I am grateful to Vladimir Lifschitz for pointing this out (personal correspondence).

possible transition should be considered as a static law of the domain.

The suggested semantics of exact transition models allows us to treat static causal rules as a special case of general dynamic causal rules. In addition, it allows us to remove the syntactic distinction between simple and statically determined fluents. Furthermore, the principle of universal causation, used as a conceptual basis of this semantics, implies also some important consequences concerning general principles of reasoning in dynamic domains.

Generally speaking, the principle of universal causation provides logical foundations for *abductive reasoning*, namely for backward reasoning from effects to their causes (see (Bochman 2007)). This kind of reasoning constitutes an essential part of our commonsense reasoning, especially in reasoning about actions and change, and it occupies also an important part of reasoning in current action theories in AI. For example, the well-known regression method ((Reiter 2001)) can be viewed as a systematic implementation of abductive reasoning in the situation calculus.

Due to its causal foundations, abductive inference is also an essential, though implicit, part of the representation framework of C+; this is because every state of a transition model for an action description, *except the initial one*, is explained as an output of some causal transition. The associated abductive explanation may sanction, in particular, some further static constraints for such states, constraints that arise as a by-product of the fact that the state in question is a result of a particular action with some further effects. By the same token, however, the initial states in C+ are exempted from the abductive explanation of this kind, which, at least in some regular domains, may lead to a loss of important information about these states.

Persistent Action Domains

In case we don't accept the above understanding of static laws, we should maintain two separate kinds of state constraints, dynamic and purely static ones, as is actually done in (Giunchiglia et al. 2004)), as well as in many other action formalisms. This separation would allow us to include a broader class of transition models as admissible models for action descriptions, namely models that involve (initial) states that need not be a result of some transition, though they still satisfy the static laws of the domain. Moreover, we can easily construct some artificial, though logically consistent, action domains for which such a distinction would be necessary, namely action domains in which there are distinguished initial states that lack some property that holds for any state that results from a transition. Still, to find 'real-life' examples of such domains is really difficult (beyond the famous 'Big Bang' exception in Physics). This naturally brings us to the practical side of the difference between the two formalisms, namely to the question whether, and if so, how much we miss in restricting the semantics of action descriptions to exact transition models in our sense.

It turns out that for a fairly broad class of action descriptions in the language C+ (including all the examples given in (Giunchiglia et al. 2004)), we can *guarantee* in advance that any transition model of C+ that satisfies a given action description can be extended to an exact transition model in our sense. For such action descriptions, our dynamic causal calculus provides the same answers to the queries as the original theory of (Giunchiglia et al. 2004)). In what follows, we will illustrate this correspondence for a broad class of what we will call persistent action domains.

Informally speaking, a persistent action domain is a dynamic domain that does not involve involuntary, 'natural' actions that lead to unavoidable, necessary changes of some state. For such action domains, any legitimate state either remains persistent in the absence of any further actions upon it (alias after an action *Wait*), or else it can be forced to persist by using suitable (voluntary) actions.

Formally, by a *persistent action domain* we will mean any action description D in the language C+ such that for any state s of D (that is, for any model of D_0), there is a consistent transition (i.e., a model of D_1) from s to s.

It turns out to be surprisingly difficult to express the above semantic property of transition models in terms of some syntactic restrictions on action descriptions in C+. Still, it is easy to verify the validity of this persistence property for many descriptions used in action theories. Thus, in the central Monkey and Bananas example from (Giunchiglia et al. 2004) every simple fluent is inertial, so any state of the transition model can be shown to persist in the absence of actions. On the other hand, for the case of non-inertial fluents that tend to change by themselves, the corresponding action descriptions usually contain actions that make them persist. Thus, the pendulum domain from (Giunchiglia et al. 2004) involves an action *Hold* that keeps the position of the pendulum (which tends to sway otherwise).

Now, in persistent action domains, any state of a transition model can be consistently viewed as a result of some transition, which immediately leads to the following

Theorem 3. *If Δ is a persistent action description in C+ and Δ_C its corresponding dynamic causal theory, then the canonical transition model of Δ coincides with the exact transition model of Δ_C.*

As a matter of fact, the above correspondence between C+ and the dynamic causal calculus can be extended, though in a somewhat weaker form, even beyond persistent action domains. To this end, we should note that practically all queries that are usually formulated in action formalisms are 'future-oriented', namely they ask whether there is a path in a transition model from a given initial state that satisfies certain further requirements (such as whether it ends in a target goal state). Now, in many cases we can extend the source action description in C+ with some auxiliary actions that will allow us again to reconstruct any given initial state as an output of some exact transition (though in the extended action description). Moreover, this can be done without changing the future of the original states of the transition model, but only by augmenting their 'past'. As an immediate consequence, we will obtain that, for such action domains, the dynamic causal calculus will provide the same answer to such queries as the original action descriptions in C+.

Causal Inference

The framework described in the preceding section is a typical example of a nonmonotonic formalism; conclusions that can be obtained on the basis of the exact transition semantics can change non-monotonically if we add some further facts or causal rules to the original dynamic causal theory. Still, as with other formalisms for nonmonotonic reasoning (see (Bochman 2011)), the causal rules of the dynamic causal calculus presuppose a certain underlying logic that agrees with the above nonmonotonic semantics. Such a logic will provide us with a formal description of the associated dynamic causal inference.

Causal Inference Relations

The original causal calculus of (McCain and Turner 1997) has been defined only semantically, but (Bochman 2004) has described a logical formalism of causal inference relations, which has been shown to provide a complete formalization of a logical (monotonic) reasoning in causal theories. From a logical point of view, causal inference relations were defined as sets of causal rules that were required to satisfy almost all the usual postulates of classical inference, except Reflexivity $A \Rightarrow A$. The latter feature has turned out to be essential for an adequate representation of causal reasoning.

Definition 3. A *causal inference relation* is a relation $\Rightarrow$ on the set of propositions satisfying the following conditions:

(Strengthening) If $A \vDash B$ and $B \Rightarrow C$, then $A \Rightarrow C$;

(Weakening) If $A \Rightarrow B$ and $B \vDash C$, then $A \Rightarrow C$;

(And) If $A \Rightarrow B$ and $A \Rightarrow C$, then $A \Rightarrow B \wedge C$;

(Or) If $A \Rightarrow C$ and $B \Rightarrow C$, then $A \vee B \Rightarrow C$;

(Cut) If $A \Rightarrow B$ and $A \wedge B \Rightarrow C$, then $A \Rightarrow C$;

(Truth) $\mathbf{t} \Rightarrow \mathbf{t}$;

(Falsity) $\mathbf{f} \Rightarrow \mathbf{f}$.

The rule Or permits reasoning by cases; this feature can be seen as one of the main advantages of causal reasoning as compared with, say, default logic. It indicates that the causal logic is an *objective* (extensional) logical system, a system of reasoning about the world. In this respect, it is similar to classical logic, and distinct from modal (intensional) formalisms that deal primarily with beliefs and knowledge.

Yet another important feature of causal inference stems from the validity of the following rule:

(Coherence) If $A \Rightarrow \neg A$, then $A \Rightarrow \mathbf{f}$.

The above rule says that if a proposition causes propositions that are incompatible with it, then it is causally inconsistent. This feature indicates, in effect, that the above notion of causal inference is *atemporal*. For example, the rule $p \wedge q \Rightarrow \neg q$ cannot be understood as saying that p and q jointly cause $\neg q$ (afterwards) in a temporal sense; instead, by Coherence it implies $p \wedge q \Rightarrow \mathbf{f}$, which means, in effect, that $p \wedge q$ cannot hold. Just as in classical logic, however, a representation of temporal domains in this formalism can be obtained by adding explicit temporal arguments to propositions; this is what has been actually done in the action description framework of (Giunchiglia et al. 2004).

A possible worlds semantics

A semantic interpretation of causal inference relations can be given in terms of ordinary possible worlds (or Kripke) models (W, R, V), where W is a set of possible worlds, R a binary accessibility relation on W, and V a function assigning each world a propositional interpretation. Intuitively, $R\alpha\beta$ means that α is an initial state, and β a possible output state of a causal process. A Kripke model is *quasi-reflexive* if it satisfies the condition that if $R\alpha\beta$, then $R\alpha\alpha$.

Definition 4. A rule $A \Rightarrow B$ is *valid* in a Kripke model (W, R, V) if, for any worlds α, β such that $R\alpha\beta$, if A holds in α, then B holds in β.

By a set of causal rules *determined* by a Kripke model we will mean the set of rules that is valid in it. It can be verified that such a set satisfies all the postulates of causal inference. Moreover, as for other modal formalisms, a suitable construction of a canonical semantics allows us to obtain the corresponding completeness result:

Proposition 4. *A set of causal rules forms a causal inference relation if and only if it is determined by some quasi-reflexive Kripke model.*

As a by-product, the above semantics immediately sanctions a simple modal representation of causal rules. Namely, let $\Box$ be the usual modal operator definable in a possible worlds model: $\Box A$ holds in α iff A holds in all β such that $R\alpha\beta$. Then the validity of $A \Rightarrow B$ in a possible worlds model is equivalent to validity of the formula $A \rightarrow \Box B$. Consequently, causal rules are representable by modal formulas of the latter form. As a matter of fact, this modal representation has actually been used in many approaches to formalizing causation in action theories (see, e.g., (Geffner 1990; Turner 1999; Giordano, Martelli, and Schwind 2000; Zhang and Foo 2001)).

The nonmonotonic semantics of causal inference

Causal inference relations are just a special kind of causal theories, so they also possess a nonmonotonic semantics. Moreover, due to the logical properties of causal inference, the description of this nonmonotonic semantics can be simplified as follows.

To begin with, we extend causal rules to rules having arbitrary sets of propositions as premises: given a causal inference relation $\Rightarrow$ and an arbitrary set u of propositions, $u \Rightarrow A$ will be taken to hold if, for some finite $a \subseteq u$, $\bigwedge a \Rightarrow A$ belongs to $\Rightarrow$. $\mathcal{C}(u)$ will denote the set of propositions caused by u, that is $\mathcal{C}(u) = \{A \mid u \Rightarrow A\}$. Then a world α is an *exact world* of a causal inference relation if and only if

$$\alpha = \mathcal{C}(\alpha).$$

Given an arbitrary causal theory Δ, we will denote by $\Rightarrow_\Delta$ the least causal inference relation that includes Δ. It has been shown in (Bochman 2003) that Δ has the same nonmonotonic semantics as $\Rightarrow_\Delta$, which means that the rules of causal inference are adequate for causal reasoning with respect to the nonmonotonic semantics of causal theories. Moreover, it has been shown that causal inference relations constitute in this respect a maximal such logic (see (Bochman 2004) for details).

Dynamic Causal Inference

By a *dynamic causal inference relation* we will mean a set of dynamic causal rules of the form $A.B \Rightarrow C$ that satisfies the conditions described below.

The first group of postulates states that a set of dynamic causal rules with a fixed first premise (D) should satisfy the postulates of an 'ordinary' causal inference:

(Strengthening) If $A \vDash B$ and $D.B \Rightarrow C$, then $D.A \Rightarrow C$;

(Weakening) If $D.A \Rightarrow B$ and $B \vDash C$, then $D.A \Rightarrow C$;

(And) If $D.A \Rightarrow B$ and $D.A \Rightarrow C$, then $D.A \Rightarrow B \wedge C$;

(Or) If $D.A \Rightarrow C$ and $D.B \Rightarrow C$, then $D.A \vee B \Rightarrow C$;

(Cut) If $D.A \Rightarrow B$ and $D.A \wedge B \Rightarrow C$, then $D.A \Rightarrow C$;

(Truth) $\mathbf{t}.\mathbf{t} \Rightarrow \mathbf{t}$;

(Falsity) $\mathbf{t}.\mathbf{f} \Rightarrow \mathbf{f}$.

In view of the above postulates, dynamic causal rules $C.A \Rightarrow B$ can be seen as ordinary, binary causal rules $A \Rightarrow B$ that are conditioned by the preceding context C.

The next two postulates describe the logical properties of this preceding context in dynamic causal rules:

(Left-Str) If $A \vDash B$ and $B.D \Rightarrow C$, then $A.D \Rightarrow C$;

(Left-Or) If $A.D \Rightarrow C$ and $B.D \Rightarrow C$, then $A \vee B.D \Rightarrow C$.

The combined effect of the above pair of postulates is that the associated semantic interpretation of dynamic causal inference (described in the next section) will be again a kind of a possible world semantics, in which both the two premises and conclusion of a dynamic causal rule are evaluated with respect to worlds (complete states).

Finally, the last postulate is a formal expression of the requirement that any state that can be an input of some transition, is also an output state of at least one transition:

(Transition) If $\mathbf{t}.A \Rightarrow \mathbf{f}$, then $A.\mathbf{t} \Rightarrow \mathbf{f}$.

Recall that we have decided to identify static causal laws $A \Rightarrow B$ with dynamic causal laws of the form $\mathbf{t}.A \Rightarrow B$. Then the above postulate can be rewritten as

(Transition1) If $A \Rightarrow \mathbf{f}$, then $A.\mathbf{t} \Rightarrow \mathbf{f}$.

On this reformulation, the above postulate stipulates, in effect, that any input state of a consistent transition should be (statically) causally consistent. Combined with the other postulates, this will immediately imply that both the input and output state of a transition should be closed with respect to the valid static laws.

In the next section we will describe a possible-worlds semantics for the above logical formalism of dynamic inference.

A possible worlds semantics

A possible worlds semantics of dynamic causal relations can be obtained by generalizing an accessibility relation on possible worlds to ternary relations.

A *causal possible world model* of dynamic causal inference is a triple (W, R, V), where W is a set of possible worlds, R a ternary accessibility relation on W, and V a function assigning each world a propositional interpretation. The accessibility relation will be required to satisfy the following two conditions:

(Quasi-reflexivity) If $R\alpha\beta\gamma$, then $R\alpha\beta\beta$.

(Transition) If $R\alpha\beta\beta$, then $R\delta\alpha\alpha$, for some $\delta \in W$.

Definition 5. A rule $A.B \Rightarrow C$ is *valid* in a model (W, R, V) if, for any worlds α, β, γ such that $R\alpha\beta\gamma$, if A holds in α and B holds in β, then C holds in γ.

Given the above definition of validity, it is easy to verify the following

Lemma 5. *The set of dynamic causal rules valid in a causal possible world model forms a dynamic causal inference relation.*

Moreover, using a suitable construction of a canonical semantics for a dynamic causal inference relation, the following completeness result can be established:

Theorem 6. *A set of dynamic causal rules forms a dynamic causal inference relation if and only if it is determined by a causal possible world model.*

Proof. (A sketch) Due to the connection between dynamic causal rules and the original, atemporal causal rules, the proof is a relatively straightforward generalization of the corresponding completeness proof for causal inference relations, given in (Bochman 2004, Theorem 7.4). More precisely, given a dynamic causal relation $\Rightarrow$, we can construct the corresponding canonical model (W, R_c) by taking W to be the set of all maximal consistent sets of propositions, and defining R_c as follows[8]:

$$R_c\alpha\beta\gamma \;\equiv\; C(\alpha.\beta) \subseteq \beta \cap \gamma.$$

Notice that this definition directly implies quasi-reflexivity of R_c. Moreover, the use of the Transition postulate allows us to prove the transition property of R_c. Finally, it can be shown that $A.B \Rightarrow C$ holds for the source dynamic causal relation if and only if it is valid in (W, R_c). □

Remark. One of the interesting consequences of the above semantic characterization of dynamic causal inference is that, similarly to a straightforward modal translation of ordinary causal rules as formulas of the form $A \rightarrow \Box B$, dynamic causal rules can be represented as formulas of *arrow logic* (see, e.g., (Venema 1997)). As a matter of fact, one of the principal motivations behind arrow logic has also consisted in providing an abstract description of dynamic (transition) models (cf. (van Benthem 1994)). Moreover, semantic interpretation of arrow logic is also based on a possible world semantics with a ternary accessibility relation, and it can be easily verified that, by the above semantic description, a dynamic causal rule $A.B \Rightarrow C$ turns out to be equivalent to a formula

$$A \circ B \rightarrow C$$

of arrow logic, where $\circ$ is a binary 'arrow conjunction' operator having the following semantic interpretation: $A \circ B$ holds in a world α if and only if there are worlds β, γ such that $R\beta\gamma\alpha$, A holds in β and B holds in γ.

[8] See the next section for a definition of $C(\alpha.\beta)$.

Correspondences

Recall that a dynamic causal theory is an arbitrary set of dynamic causal rules. For any dynamic causal theory Δ there exists a least dynamic causal inference relation that includes Δ. We will denote it by $\Rightarrow_\Delta$. Clearly, $\Rightarrow_\Delta$ is the set of all dynamic causal rules that can be derived from Δ using the postulates of dynamic causal inference.

As before, we will extend the notation of dynamic causal rules to sets of propositional formulas in premises: for sets u, v of propositional formulas, $u.v \Rightarrow A$ will be taken to hold if $\bigwedge a. \bigwedge b \Rightarrow A$, for some finite $a \subseteq u, b \subseteq v$. In addition, $\mathcal{C}(u.v)$ will denote the set of propositions $\{A \mid u.v \Rightarrow A\}$.

Due to the logical properties of a dynamic causal inference relation, the definition of an exact transition can now be simplified, namely a pair of worlds (α, β) will be an *exact transition* with respect to a dynamic causal inference relation if and only if

$$\beta = \mathcal{C}(\alpha.\beta).$$

Then the following key result of this study shows, in effect, that the logic of causal dynamic inference is adequate for reasoning with respect to the exact semantics of dynamic causal theories, since it preserves the latter.

Theorem 7. *The exact transition models of a dynamic causal theory Δ coincide with the exact transition models of $\Rightarrow_\Delta$.*

Proof sketch. It can be shown that if C_Δ is the provability operator of $\Rightarrow_\Delta$, then, for any worlds α, β, if $C_\Delta(\alpha.\beta)$ is a consistent set, then it coincides with $\mathrm{Th}(\Delta(\alpha.\beta))$. Consequently, $\alpha = C_\Delta(\alpha.\beta)$ iff $\alpha = \mathrm{Th}(\Delta(\alpha.\beta))$, and therefore exact transitions of Δ will coincide with exact transitions of $\Rightarrow_\Delta$. Hence the result. □

Moreover, it can be shown that the logic of causal dynamic inference constitutes a maximal logic that is adequate for reasoning with exact causal models.

Definition 6. Two dynamic causal theories Δ and Γ are *strongly equivalent* if, for any set Φ of causal rules, $\Delta \cup \Phi$ has the same exact transition models as $\Gamma \cup \Phi$.

Strongly equivalent theories are 'equivalent forever', that is, they are interchangeable in any larger causal theory without changing the nonmonotonic semantics. Consequently, strong equivalence can be seen as an equivalence with respect to the background monotonic logic of causal theories. And the next result shows that this logic is precisely the logic of dynamic causal inference.

Theorem 8. *Dynamic causal theories Δ and Γ are strongly equivalent if and only if $\Rightarrow_\Delta = \Rightarrow_\Gamma$.*

The above result states that dynamic causal theories are strongly equivalent if and only if each of them can be obtained from the other using the postulates of dynamic causal inference.

Summary and Perspectives

The primary objective of this study consisted in showing that causal reasoning in dynamic action domains can be given a direct and concise logical representation. Moreover, being combined with the wealth of representation capabilities of such a reasoning, demonstrated in (Giunchiglia et al. 2004), the results of this study strongly indicate that a theory of dynamic causal inference can be viewed as a self-subsistent logical theory that provides an adequate and comprehensive representation framework for reasoning in dynamic domains. The study creates also obvious incentives for broader questions about the role and scope of causation in commonsense reasoning, as well as in knowledge representation in AI.

Causation has always been one of the most discussed concepts in the philosophy of science. It is intimately related to practically all notions that are essential both for a commonsense and scientific view of the world, such as laws, counterfactuals, explanation and abduction. On the other hand, causation and related notions have shown to be extremely elusive and problematic concepts. Efforts of many philosophers and logicians in the past have been focused on a formal, logical explication of these notions, but the task has turned out to be surprisingly difficult. Furthermore, starting with David Hume, an influential line of philosophical thought has argued, in effect, that causation should be expelled from the language of Science and Logic.

In recent years, however, we witness a revival of interest in the concept of causation, accompanied with new, more practical, insights about its role in our reasoning. Most prominent in this respect is Pearl's theory of causal reasoning (Pearl 2000) and its applications in statistics, economics, cognitive and social sciences.

An important alternative source of the new understanding of causation and its role in our reasoning comes from Artificial Intelligence, especially from theories of action and change. In these theories causation is a working concept allowing us to single out intended models of commonsense action descriptions. They make especially vivid the fact that causal reasoning, that is, asking why and seeking explanations, is germane to our reasoning about the world. However, these theories have also made evident that, though causal reasoning includes an important logical part, it is *not reducible* to a plain logical derivation in some ingenious causal logic. Instead, causal reasoning should be viewed as an important case of general nonmonotonic (assumption-based) reasoning. Accordingly, the tools and formalisms of nonmonotonic reasoning should hopefully provide us with a more adequate understanding of the concept of causation itself.

Appropriate Causal Models and Stability of Causation

Joseph Y. Halpern*
Cornell University
halpern@cs.cornell.edu

Abstract

Causal models defined in terms of structural equations have proved to be quite a powerful way of representing knowledge regarding causality. However, a number of authors have given examples that seem to show that the Halpern-Pearl (HP) definition of causality (Halpern & Pearl 2005) gives intuitively unreasonable answers. Here it is shown that, for each of these examples, we can give two stories consistent with the description in the example, such that intuitions regarding causality are quite different for each story. By adding additional variables, we can disambiguate the stories. Moreover, in the resulting causal models, the HP definition of causality gives the intuitively correct answer. It is also shown that, by adding extra variables, a modification to the original HP definition made to deal with an example of Hopkins and Pearl (2003) may not be necessary. Given how much can be done by adding extra variables, there might be a concern that the notion of causality is somewhat unstable. Can adding extra variables in a "conservative" way (i.e., maintaining all the relations between the variables in the original model) cause the answer to the question "Is $X = x$ a cause of $Y = y$?" to alternate between "yes" and "no"? Here it is shown that adding an extra variable can change the answer from "yes' to "no", but after that, it cannot cannot change back to "yes".

1 Introduction

Causal models defined in terms of structural equations have proved to be quite a powerful way of representing knowledge regarding causality. For example, they have been used to find causes of errors in software (Beer *et al.* 2012) and have been shown to be useful in predicting human attributions of responsibility (Gerstenberg & Lagnado 2010; Lagnado, Gerstenberg, & Zultan 2013). However, a number of authors authors (Glymour *et al.* 2010; Livengood 2013; Spohn 2008; Weslake 2014) have given examples that seem to show that the Halpern-Pearl (HP) definition of causality (Halpern & Pearl 2005) gives intuitively unreasonable answers. One contribution of this paper is to show that these "problematic" examples can be dealt with in a relatively uniform way, by being a little more careful about the choice of causal model.

The need to choose the causal model carefully has been pointed out frequently (Blanchard & Schaffer 2013; Hall 2007; Halpern & Pearl 2005; Halpern & Hitchcock 2010; Hitchcock 2001; 2007). A causal model is characterized by the choice of variables, the equations relating them, and which variables we choose to make exogenous and endogenous (roughly speaking, which are the variables we choose to take as given and which we consider to be modifiable). Different choices of causal model for a given situation can lead to different conclusions regarding causality. The choices are, to some extent, subjective. While some suggestions have been made for good rules of thumb for choosing random variables (e.g., in (Halpern & Hitchcock 2010)), they are certainly not definitive. Moreover, the choice of variables may also depend in part on the variables that the modeler is aware of.

In this paper, I consider the choice of representation in more detail in four examples. I show that in all these examples, the model originally considered (which I call the "naive" model) does not correctly model all the relevant features of the situation. I argue that we can see this because, in all these cases, there is another story that can be told, also consistent with the naive model, for which we have quite different intuitions regarding causality, This suggests that a more careful model is needed to disambiguate the stories. In the first four cases, what turns out to arguably be the best way to do the disambiguation is to add (quite well motivated) extra variables, which, roughly speaking, capture the mechanism of causality. In the final example, what turns out to be most relevant is the decision as to which variables to make exogenous. Once we model things more carefully, the HP approach gives the expected answer in all cases.

As already observed by Halpern and Hitchcock (2014), adding extra variables also lets us deal with two other concerns that resulted in changes to the original HP definition. In Section 4, I consider an example due Hopkins and Pearl (2003) that motivated one of the changes. After showing

how this example can be dealt with by adding an extra variable in a natural way (without modifying the original HP definition), I show that this approach generalizes: we can always add extra variables so as to get a model where the original HP definition can be used. In the full paper, I discuss an example due to Hiddleston (2005) that motivated the addition of normality considerations to the basic HP framework (see Section 2). Again, adding an extra variable deals with this example.

All these examples show that adding extra variables can result in a cause becoming a non-cause. Can adding variables also result in a non-cause becoming a cause? Of course, without constraints, this can easily happen. Adding extra variables can fundamentally change the model. However, as I show, if variables are added in a conservative way (so as to maintain all the relations between the variables in the original model), this cannot happen. If $X = x$ is not a cause of $Y = y$, then adding extra variables to the model cannot make $X = x$ a cause of $Y = y$.

The rest of this paper is organized as follows. In the next section, I review the HP definition (and the original definition) and its extension to deal with normality, as discussed in (Halpern & Hitchcock 2014). I discuss the five examples in Section 3. In Section 4, I discuss how adding extra variables can deal with the Hopkins-Pearl example and, more generally, can obviate the need to modify the original HP definition. I prove that non-causality is stable in Section 5. I conclude in Section 6 with some discussion of the implications of these results. Details of some proofs are left to the full paper (available at www.cs.cornell.edu/home/halpern/papers/causalmodeling.pdf).

2 Review

In this section, I briefly review the definitions of causal structures, the HP definition(s) of causality, and the extension that takes into account normality given by Halpern and Hitchcock. The exposition is largely taken from (Halpern 2008). The reader is encouraged to consult (Halpern & Pearl 2005), and (Halpern & Hitchcock 2014) for more details and intuition.

2.1 Causal structures

The HP approach assumes that the world is described in terms of random variables and their values. Some random variables may have a causal influence on others. This influence is modeled by a set of *structural equations*. It is conceptually useful to split the random variables into two sets: the *exogenous* variables, whose values are determined by factors outside the model, and the *endogenous* variables, whose values are ultimately determined by the exogenous variables. For example, in a voting scenario, we could have endogenous variables that describe what the voters actually do (i.e., which candidate they vote for), exogenous variables that describe the factors that determine how the voters vote, and a variable describing the outcome (who wins). The structural equations describe how the outcome is determined (e.g., majority rules).

Formally, a *causal model* M is a pair $(\mathcal{S}, \mathcal{F})$, where $\mathcal{S}$ is a *signature*, which explicitly lists the endogenous and exogenous variables and characterizes their possible values, and $\mathcal{F}$ defines a set of *modifiable structural equations*, relating the values of the variables. A signature $\mathcal{S}$ is a tuple $(\mathcal{U}, \mathcal{V}, \mathcal{R})$, where $\mathcal{U}$ is a set of exogenous variables, $\mathcal{V}$ is a set of endogenous variables, and $\mathcal{R}$ associates with every variable $Y \in \mathcal{U} \cup \mathcal{V}$ a nonempty set $\mathcal{R}(Y)$ of possible values for Y (that is, the set of values over which Y *ranges*). For simplicity, I assume here that $\mathcal{V}$ is finite, as is $\mathcal{R}(Y)$ for every endogenous variable $Y \in \mathcal{V}$. $\mathcal{F}$ associates with each endogenous variable $X \in \mathcal{V}$ a function denoted F_X such that $F_X : (\times_{U \in \mathcal{U}} \mathcal{R}(U)) \times (\times_{Y \in \mathcal{V} - \{X\}} \mathcal{R}(Y)) \rightarrow \mathcal{R}(X)$. This mathematical notation just makes precise the fact that F_X determines the value of X, given the values of all the other variables in $\mathcal{U} \cup \mathcal{V}$. If there is one exogenous variable U and three endogenous variables, X, Y, and Z, then F_X defines the values of X in terms of the values of Y, Z, and U. For example, we might have $F_X(u, y, z) = u + y$, which is usually written as $X = U + Y$.[1] Thus, if $Y = 3$ and $U = 2$, then $X = 5$, regardless of how Z is set.

The structural equations define what happens in the presence of external interventions. Setting the value of some variable X to x in a causal model $M = (\mathcal{S}, \mathcal{F})$ results in a new causal model, denoted $M_{X=x}$, which is identical to M, except that the equation for X in $\mathcal{F}$ is replaced by $X = x$.

Following (Halpern & Pearl 2005), I restrict attention here to what are called *recursive* (or *acyclic*) models. This is the special case where there is some total ordering $\prec$ of the endogenous variables (the ones in $\mathcal{V}$) such that if $X \prec Y$, then X is independent of Y, that is, $F_X(\ldots, y, \ldots) = F_X(\ldots, y', \ldots)$ for all $y, y' \in \mathcal{R}(Y)$. Intuitively, if a theory is recursive, there is no feedback. If $X \prec Y$, then the value of X may affect the value of Y, but the value of Y cannot affect the value of X. It should be clear that if M is an acyclic causal model, then given a *context*, that is, a setting $\vec{u}$ for the exogenous variables in $\mathcal{U}$, there is a unique solution for all the equations. We simply solve for the variables in the order given by $\prec$. The value of the variables that come first in the order, that is, the variables X such that there is no variable Y such that $Y \prec X$, depend only on the exogenous variables, so their value is immediately determined by the values of the exogenous variables. The values of variables later in the order can be determined once we have determined the values of all the variables earlier in the order.

2.2 A language for reasoning about causality

To define causality carefully, it is useful to have a language to reason about causality. Given a signature $\mathcal{S} = (\mathcal{U}, \mathcal{V}, \mathcal{R})$, a *primitive event* is a formula of the form $X = x$, for $X \in \mathcal{V}$ and $x \in \mathcal{R}(X)$. A *causal formula (over $\mathcal{S}$)* is one of the form $[Y_1 \leftarrow y_1, \ldots, Y_k \leftarrow y_k]\varphi$, where φ is a Boolean combination of primitive events, $Y_1, \ldots, Y_k$ are distinct variables in $\mathcal{V}$, and $y_i \in \mathcal{R}(Y_i)$. Such a formula is abbreviated as $[\vec{Y} \leftarrow \vec{y}]\varphi$. The special case where $k = 0$ is abbreviated as

[1] The fact that X is assigned $U + Y$ (i.e., the value of X is the sum of the values of U and Y) does not imply that Y is assigned $X - U$; that is, $F_Y(U, X, Z) = X - U$ does not necessarily hold.

φ. Intuitively, $[Y_1 \leftarrow y_1, \ldots, Y_k \leftarrow y_k]\varphi$ says that φ would hold if Y_i were set to y_i, for $i = 1, \ldots, k$.

A causal formula ψ is true or false in a causal model, given a context. As usual, I write $(M, \vec{u}) \models \psi$ if the causal formula ψ is true in causal model M given context $\vec{u}$. The $\models$ relation is defined inductively. $(M, \vec{u}) \models X = x$ if the variable X has value x in the unique (since we are dealing with acyclic models) solution to the equations in M in context $\vec{u}$ (that is, the unique vector of values for the exogenous variables that simultaneously satisfies all equations in M with the variables in $\mathcal{U}$ set to $\vec{u}$). The truth of conjunctions and negations is defined in the standard way. Finally, $(M, \vec{u}) \models [\vec{Y} \leftarrow \vec{y}]\varphi$ if $(M_{\vec{Y}=\vec{y}}, \vec{u}) \models \varphi$. I write $M \models \varphi$ if $(M, \vec{u}) \models \varphi$ for all contexts $\vec{u}$.

2.3 The definition(s) of causality

The HP definition of causality, like many others, is based on counterfactuals. The idea is that A is a cause of B if, if A hadn't occurred (although it did), then B would not have occurred. But there are many examples showing that this naive definition will not quite work. To take just one example, consider the following story, due to Ned Hall and already discussed in (Halpern & Pearl 2005), from where the following version is taken.

> Suzy and Billy both pick up rocks and throw them at a bottle. Suzy's rock gets there first, shattering the bottle. Since both throws are perfectly accurate, Billy's would have shattered the bottle had it not been preempted by Suzy's throw.

We would like to say that Suzy's throw is a cause of the bottle shattering, and Billy's is not. But if Suzy hadn't thrown, Billy's rock would have hit the bottle and shattered it.

The HP definition of causality is intended to deal with this example, and many others.

Definition 2.1: $\vec{X} = \vec{x}$ is an *actual cause of* φ *in* $(M, \vec{u})$ if the following three conditions hold:

AC1. $(M, \vec{u}) \models (\vec{X} = \vec{x})$ and $(M, \vec{u}) \models \varphi$.

AC2. There is a partition of $\mathcal{V}$ (the set of endogenous variables) into two subsets $\vec{Z}$ and $\vec{W}$[2] with $\vec{X} \subseteq \vec{Z}$ and a setting $\vec{x}'$ and $\vec{w}$ of the variables in $\vec{X}$ and $\vec{W}$, respectively, such that if $(M, \vec{u}) \models Z = z$ for all $Z \in \vec{Z}$ (i.e., z is the value of the random variable Z in the real world), then both of the following conditions hold:

- (a) $(M, \vec{u}) \models [\vec{X} \leftarrow \vec{x}', \vec{W} \leftarrow \vec{w}]\neg\varphi$.
- (b) $(M, \vec{u}) \models [\vec{X} \leftarrow \vec{x}, \vec{W}' \leftarrow \vec{w}, \vec{Z}' \leftarrow \vec{z}]\varphi$ for all subsets $\vec{W}'$ of $\vec{W}$ and all subsets $\vec{Z}'$ of $\vec{Z}$, where I abuse notation and write $\vec{W}' \leftarrow \vec{w}$ to denote the assignment where the variables in $\vec{W}'$ get the same values as they would in the assignment $\vec{W} \leftarrow \vec{w}$, and similarly for $\vec{Z}' \leftarrow \vec{z}$.

AC3. $\vec{X}$ is minimal; no subset of $\vec{X}$ satisfies conditions AC1 and AC2.

The tuple $(\vec{W}, \vec{w}, \vec{x}')$ is said to be a *witness* to the fact that $\vec{X} = \vec{x}$ is a cause of φ.

AC1 just says that $\vec{X} = \vec{x}$ cannot be considered a cause of φ unless both $\vec{X} = \vec{x}$ and φ actually happen. AC3 is a minimality condition, which ensures that only those elements of the conjunction $\vec{X} = \vec{x}$ that are essential are considered part of a cause; inessential elements are pruned. Without AC3, if dropping a lit cigarette is a cause of a fire then so is dropping the cigarette and sneezing.

AC2 is the core of the definition. We can think of the variables in $\vec{Z}$ as making up the "causal path" from $\vec{X}$ to φ. Intuitively, changing the value of some variable in X results in changing the value(s) of some variable(s) in $\vec{Z}$, which results in the values of some other variable(s) in $\vec{Z}$ being changed, which finally results in the value of φ changing. The remaining endogenous variables, the ones in $\vec{W}$, are off to the side, so to speak, but may still have an indirect effect on what happens. AC2(a) is essentially the standard counterfactual definition of causality, but with a twist. If we want to show that $\vec{X} = \vec{x}$ is a cause of φ, we must show (in part) that if $\vec{X}$ had a different value, then so too would φ. However, this effect of the value of $\vec{X}$ on the value of φ may not hold in the actual context; essentially, it ensures that $\vec{X}$ alone suffices to bring about the change from φ to $\neg\varphi$; setting $\vec{W}$ to $\vec{w}$ merely eliminates possibly spurious side effects that may mask the effect of changing the value of $\vec{X}$. Moreover, although the values of variables on the causal path (i.e., the variables $\vec{Z}$) may be perturbed by the change to $\vec{W}$, this perturbation has no impact on the value of φ. As I said above, if $(M, \vec{u}) \models \vec{Z} = \vec{z}$, then z is the value of the variable Z in the context $\vec{u}$ (i.e., in the actual situation). We capture the fact that the perturbation has no impact on the value of φ by saying that if some variables Z on the causal path were set to their original values in the context $\vec{u}$, φ would still be true, as long as $\vec{X} = \vec{x}$. Roughly speaking, it says that if the variables in $\vec{X}$ are reset to their original value, then φ holds, even under the contingency $\vec{W}' = \vec{w}$ and even if some variables in $\vec{Z}$ are given their original values (i.e., the values in $\vec{z}$). The fact that AC2(b) must hold even if only a subset $\vec{W}'$ of the variables in $\vec{W}$ are set to their values in $\vec{w}$ (so that the variables in $\vec{W} - \vec{W}'$ essentially act as they do in the real world) and only a subset of the variables in $\vec{Z}$ are set to their values in the actual world says that we must have φ even if some things happen as they do in the actual world. See Sections 3.1 and 4 for further discussion of and intuition for AC2(b).

The original HP paper (Halpern & Pearl 2001) used a weaker version of AC2(b). Rather than requiring that $(M, \vec{u}) \models [\vec{X} \leftarrow \vec{x}, \vec{W}' \leftarrow \vec{w}, \vec{Z}' \leftarrow \vec{z}]\varphi$ for all subsets $\vec{W}'$ of $\vec{W}$, it was required to hold only for $\vec{W}$. That is, the following condition was used instead of AC2(b).

AC2(b′) $(M, \vec{u}) \models [\vec{X} \leftarrow \vec{x}, \vec{W} \leftarrow \vec{w}, \vec{Z}' \leftarrow \vec{z}]\varphi$ for all

[2] I occasionally use the vector notation ($\vec{Z}$, $\vec{W}$, etc.) to denote a set of variables if the order of the variables matters, which it does when we consider an assignment such as $\vec{W} \leftarrow \vec{w}$.

subsets $\vec{Z}'$ of $\vec{Z}$.

The change from AC2(b′) to AC2(b) may seem rather technical, but it has some nontrivial consequences. One of the contributions of this paper is to examine whether it is necessary; see Section 4 for details.

To deal with other problems in the HP definition, various authors have added the idea of *normality* to the definition. This can be done in a number of ways. I now briefly sketch one way that this can be done, following the approach in (Halpern & Hitchcock 2014).

Take a *world* (in a model M) to be a complete assignment of values to all the endogenous variables in M.[3] We assume a partial preorder $\succeq$ on worlds, that is, a reflexive transitive relation.[4] Intuitively, if $s \succeq s'$, then s is at least as normal, or typical, as s'. We can use normality in the definition of causality in two ways. Say that a world s is a *witness world* for $\vec{X} = \vec{x}$ being a cause of φ in $(M, \vec{u})$ if there is a witness $(\vec{W}, \vec{w}, \vec{x}')$ to $\vec{X} = \vec{x}$ being a cause of φ and $s = s_{\vec{X}=\vec{x}',\vec{W}=\vec{w},\vec{u}}$, where $s_{\vec{X}=\vec{x}',\vec{W}=\vec{w},\vec{u}}$ is the world that results by setting $\vec{X}$ to $\vec{x}'$ and $\vec{W}$ to $\vec{w}$ in context $\vec{u}$. We can then modify AC2(a) so as to require that we consider $\vec{X} = \vec{x}$ to be a cause of φ in $(M, \vec{u})$ only if the witness world s for $\vec{X} = \vec{x}$ being a cause is such that $s \succeq s_{\vec{u}}$, where $s_{\vec{u}}$ is the world determined by context $\vec{u}$. This says that, in determining causality, we consider only possibilities that result from altering atypical features of a world to make them more typical, rather than vice versa. This captures an observation made by Kahneman and Miller (1986) regarding human ascriptions of causality.

A somewhat more refined use of normality is to use it to "grade" causes. Say that s is a *best witness* for $\vec{X} = \vec{x}$ being a cause of φ if s is a witness world for $\vec{X} = \vec{x}$ being a cause of φ and there is no other witness world s' for $\vec{X} = \vec{x}$ being a cause of φ such that $s' \succ s$. (Note that there may be more than one best witness.) We can then grade candidate causes according to the normality of their best witnesses (without requiring that there must be a witness s such that $s \succeq s_{\vec{u}}$). Experimental evidence suggests that people are focusing on the cause with the best witness (according to their subjective ordering on worlds); see, e.g., (Cushman, Knobe, & Sinnott-Armstrong 2008; Hitchcock & Knobe 2009; Knobe & Fraser 2008).

3 The Examples

In this section, I consider examples due to Spohn (2008), Glymour et al. (2010), and Livengood (2013). I go through these examples in turn. I set the scene by considering the rock-throwing example mentioned above.

[3] In (Halpern & Hitchcock 2014), a world is defined as a complete assignment of values to the *exogenous* variables, but this is a typo.

[4] $\succeq$ is not necessarily a partial order; in particular, it does not necessarily satisfy *antisymmetry* (i.e., $s \succeq s'$ and $s' \succeq s$ does not necessarily imply $s = s'$).

3.1 Throwing rocks at bottles

A naive model of the rock-throwing story just has binary random variables *ST*, *BT*, and *BS* (for "Suzy throws", "Billy throws", and "bottle shatters", with the value of *BS* given by the equation $BS = ST \vee BT$: the bottle shatters if one of Suzy and Billy throws. Call this model M_{RT}. Let u be the context that results in $ST = BT = 1$: Suzy and Billy both throw. M_{RT} is described in Figure 1. (Although I have included the exogenous variable here, in later figures exogenous variables are omitted for ease of presentation.)

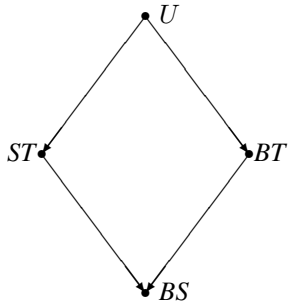

Figure 1: M_{RT}: the naive rock-throwing model.

As already pointed out by Halpern and Pearl (2005), in M_{RT} Suzy and Billy play completely symmetric roles. Not surprisingly, both $ST = 1$ and $BT = 1$ are causes of $BS = 1$ according to the HP definition. Clearly, M_{RT} cannot be used to distinguish a situation where Suzy is a cause from one where Billy is a cause.

In the story as given, people seem to agree that Suzy's throw is a cause and Billy's throw is not, since Suzy's rock hit the bottle and Billy's did not. M_{RT} does not capture this fact. Following Halpern and Pearl (2005), we extend M_{RT} so that it can express the fact that Suzy's rock hit first by adding two more variables:

- *BH* for "Billy's rock hits the (intact) bottle", with values 0 (it doesn't) and 1 (it does); and
- *SH* for "Suzy's rock hits the bottle", again with values 0 and 1.

The equations are such that $SH = ST$ (Suzy's rock hits the bottle if Suzy throws), $BH = BT \wedge \neg SH$ (Billy's rock hits an intact bottle if Billy throws and Suzy's rock does not hit), and $BS = SH \vee BH$ (the bottle shatters if either Suzy's rock or Billy's rock hit it). Now if Suzy and Bill both throw ($ST = 1$ and $BT = 1$), Suzy's rock hits the bottle ($SH = 1$), so that Billy's rock does not hit an intact bottle ($BH = 0$). Call the resulting model M'_{RT}. M'_{RT} is described in Figure 2 (with the exogenous variable omitted).

In this model $BT = 1$ is *not* a cause. For example, if we take $\vec{Z} = \{BT, BH, BS\}$ in AC2 and set $ST = 0$, then while it is the case that $BS = 0$ if $BT = 0$ and $BS = 1$ if $BT = 1$, it is not the case that $BT = 1$ if we set *BH* to its original value of 0. This example shows the necessity of allowing some variables in $\vec{Z}$ to be set to their original values in AC2(b). This captures the intuition that Billy's throw is not a cause because, in the actual world, his rock did not hit the bottle

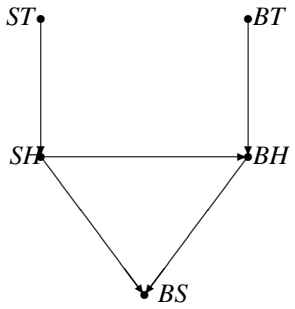

Figure 2: M'_{RT}: the better rock-throwing model.

($BH = 0$). By AC2(b), to establish $BT = 1$ as a cause of $BS = 1$, it would have to force $BS = 1$ even if $BH = 0$, which is not the case.

3.2 Spohn's example

The next example is due to Spohn (2008).

Example 3.1: There are four endogenous binary variables, A, B, C, and S, taking values 1 (on) and 0 (off). Intuitively, A and B are supposed to be alternative causes of C, and S acts as a switch. If $S = 0$, the causal route from A to C is active and that from B to C is dead; and if $S = 1$, the causal route from A to C is dead and the one from B to C is active. There are no causal relations between A, B, and S; their values are determined by the context. The equation for C is $C = (\neg S \wedge A) \vee (S \wedge B)$.

Suppose that the context is such that $A = B = S = 1$, so $C = 1$. The HP definition yields $B = 1$ and $S = 1$ as causes of $C = 1$, as we would hope. But, unfortunately, it also yields $A = 1$ as a cause of $C = 1$. The argument is that in the contingency where S is set to 0, then if $A = 0$, then $C = 0$, while if $A = 1$, then $C = 1$. This does not seem so reasonable. Intuitively, if $S = 1$, then the value of A seems irrelevant to the outcome. Considerations of normality do not help here; all worlds seem to be equally normal.

But now consider a slightly different story. This time, we view B as the switch, rather than S. If $B = 1$, then $C = 1$ if either $A = 1$ or $S = 1$; if $B = 0$, then $C = 1$ only if $A = 1$ and $S = 0$. That is, $C = (B \wedge (A \vee S)) \vee (\neg B \wedge A \wedge \neg S)$. Although this is perhaps not as natural a story as the original, such a switch is surely implementable. In any case, a little playing with propositional logic shows that, in this story, C satisfies exactly the same equation as before: $(\neg S \wedge A) \vee (S \wedge B)$ is equivalent to $(B \wedge (A \vee S)) \vee (\neg B \wedge A \wedge \neg S)$. The key point is that, unlike the first story, in the second story, it seems to me quite reasonable to say that $A = 1$ is a cause of $C = 1$ (as are $S = 1$ and $B = 1$). Having $A = 1$ is necessary for the first "mechanism" to work.

Given that we have different causal intuitions for the stories, we should model them differently. One way to distinguish them is to add two more endogenous random variables, say D and E, that describe the ways that C could be 1. In Spohn's original story, we would have the equation $D = \neg S \wedge A$, $E = S \wedge B$, and $C = D \vee E$. In this model, since $D = 0$ in the actual context, it is not hard to see that $A = 1$ is *not* a cause of $C = 1$, while $B = 1$ and $S = 1$ are, as they should be. Thus, in this model, we correctly capture our intuitions for the story.

To capture the second story, we can add variables D' and E' such that $D' = B \wedge (A \vee S)$, $E' = \neg B \wedge A \wedge S$, and $C = D' \vee E'$. In this model, it is not hard to see that all of $A = 1$, $B = 1$, and $S = 1$ are causes of $C = 1$.

This approach of adding extra variables leads to an obvious question: What is the role of these variables? I view D and E (resp., D' and E') as "structuring" variables, that help an agent "structure" a causal story. Consider Spohn's original story. We can certainly design a circuit where there is a source of power at A and B, a physical switch at S, and a bulb at C that turns on ($C = 1$) if either there is a battery at A ($A = 1$) and the switch is turned left ($S = 0$) or there is battery at B ($B = 1$) and the switch is turned right ($S = 1$). In this physical setup, there is no analogue of D and E. Nevertheless, to the extent that we view the models as a modeler's description of what is going, a modeler could usefully introduce D and E to describe the conditions under which $C = 1$, and to disambiguate this model from one where, conceptually, we might want to think of other ways that C could be 1 (as in the story with D' and E').

Note that we do not want to think of D as being *defined* to take the value 1 if $A = 1$ and $S = 0$. For then we could not intervene to set $D = 0$ if $A = 1$ and $S = 0$. Adding a variable to the model commits us to be able to intervene on it.[5] In the real world, setting D to 0 despite having $A = 1$ and $S = 0$ might correspond to the connection being faulty when the switch is turned left. Indeed, since the equation for C is the same in both stories, it is only at the level of interventions that the difference between the two stories becomes meaningful. ∎

3.3 Glymour et al.'s example

The next example is due to Glymour et al. (2010).

Example 3.2: A ranch has five individuals: $a_1, \ldots, a_5$. They have to vote on two possible outcomes: staying around the campfire ($O = 0$) or going on a round-up ($O = 1$). Let A_i be the random variable denoting a_i's vote, so $A_i = j$ if a_i votes for outcome j. There is a complicated rule for deciding on the outcome. If a_1 and a_2 agree (i.e., if $A_1 = A_2$), then that is the outcome. If $a_2, \ldots, a_5$ agree, and a_1 votes differently, then then outcome is given by a_1's vote (i.e., $O = A_1$). Otherwise, majority rules. In the actual situation, $A_1 = A_2 = 1$ and $A_3 = A_4 = A_5 = 0$, so by the first mechanism, $O = 1$. The question is what were the causes of $O = 1$.

Using the naive causal model with just the variables $A_1, \ldots, A_5, O$, and the obvious equations describing O in terms of $A_1, \ldots, A_5$, it is almost immediate that $A_1 = 1$ is a cause of $O = 1$. Changing A_1 to 0 results in $O = 0$. Somewhat surprisingly, in this naive model, $A_2 = 1$, $A_3 = 0$, $A_4 = 0$, and $A_5 = 0$ are also causes.[6] To see that $A_2 = 1$

[5] I thank Chris Hitchcock for stressing this point.

[6] Glymour et al. point out that $A_1 = 1$, $A_3 = 0$, $A_4 = 0$, and $A_5 = 0$ are causes; they do not mention that $A_2 = 1$ is also a

is a cause, consider the contingency where $A_3 = 1$. Now if $A_2 = 0$, then $O = 0$ (majority rules); if $A_2 = 1$, then $O = 1$, since $A_1 = A_2 = 1$, and $O = 1$ even if A_3 is set back to its original value of 0. To see that $A_3 = 0$ is a cause, consider the contingency where $A_2 = 0$, so that all voters but a_1 vote for 0 (staying at the campsite). If $A_3 = 1$, then $O = 0$ (majority rules). If $A_3 = 0$, then $O = 1$, by the second mechanism (a_1 is the only vote for 0), while if A_2 is set to its original value of 1, then we still have $O = 1$, now by the second mechanism.

But all this talk of mechanisms (which is also implicit in Glymour et al. (2010); in footnote 11, they say that setting A_2 back to its original value of 1 "brings out the original result, but in a different way") suggests that the mechanism should be part of the model. There are several ways of doing this. One is to add three new variables, call them M_1, M_2, and M_3. These variables have values in $\{0, 1, 2\}$, where $M_j = 0$ if mechanism j is active and suggests an outcome 0, $M_j = 1$ if mechanism j is active and suggests an outcome of 1, and $M_j = 2$ if mechanism j is not active. (We actually don't need the value $M_3 = 2$; mechanism 3 is always active, because there is always a majority with 5 voters all of whom must vote.) Note that at most one of the first two mechanisms can be active. We have obvious equations linking the value of M_1, M_2, and M_3 to the values of $A_1, \ldots, A_5$.

Now the value of O just depends on the values of M_1, M_2, and M_3: if $M_1 \neq 2$, then $O = M_1$; if $M_2 \neq 2$, then $O = M_2$, and if $M_1 = M_2 = 2$, then $O = M_3$. It is easy to see that in this model, if $A_1 = A_2 = 1$ and $A_3 = A_4 = A_5 = 0$, then none of $A_2 = 1$, $A_3 = 0$, $A_4 = 0$, and $A_5 = 0$ are causes. $A_1 = 1$ is cause, as we would expect, as is $M_2 = 1$, which seems reasonable: the second mechanism was the one that resulted in the outcome.

Now suppose that we change the description of the voting rule. We take $O = 1$ if one of the following two mechanisms applies:

- $A_1 = 1$ and it is not the case that both $A_2 = 0$ and exactly one of A_3, A_4, and A_5 is 1.
- $A_1 = 0$, $A_2 = 1$, and exactly two of A_3, A_4, and A_5 are 1.

It is not hard to check that, although the description is different, O satisfies the same equation in both stories. But now it does not seem so unreasonable that $A_2 = 1$, $A_3 = 0$, $A_4 = 0$, and $A_5 = 0$ are causes of $O = 1$. And indeed, if we construct a model in terms of these two mechanisms (i.e., add variables M_1' and M_2' that correspond to these two mechanisms), then it is not hard to see that $A_1 = 1$, $A_2 = 1$, $A_3 = 0$, $A_4 = 0$, and $A_5 = 0$ are all causes.

Here the role of the structuring variables M_1, M_2, and M_3 (resp. M_1' and M_2') as descriptors of the mechanism being invoked seems particularly clear. For example, setting $M_1 = 2$ says that the first mechanism will not be applied, even if $A_1 = A_2$; setting $M_1 = 1$ says that we act as if both a_1 and a_2 voted in favor, even if that is not the case. ∎

cause.

3.4 Livengood's voting examples

As Livengood (2013) points out, voting can lead to some apparently unreasonable causal outcomes (at least, if we model things naively). He first considers Jack and Jill, who live in an overwhelmingly Republican district. As expected, the Republican candidate wins with an overwhelming majority. Jill would normally have voted Democrat, but did not vote because she was disgusted by the process. Jack would normally have voted Republican, but did not vote because he (correctly) assumed that his vote would not affect the outcome. In the naive model, both Jack and Jill are causes of the Republican victory. For if enough of the people who voted Republican had switched to voting Democrat, then if Jack (or Jill) had voted Democrat, the Democrat would have won, while he would not have won had they abstained. Notice that, in this argument, Jack and Jill are treated the same way; their preferences make no difference.

We can easily construct a model that takes these preferences into account. One way to do so is to assume that their preferences are so strong that we may as well take them for granted. Thus, the preferences become exogenous; the only endogenous variables are whether or not they vote. In this case, Jack's not voting is not a cause of the outcome, but Jill's not voting is.

More generally, with this approach, a voter whose preference is made exogenous and is a strong supporter of the victor does not count as a cause of victory. This does not seem so unreasonable. After all, in an analysis of a close political victory in Congress, when an analyst talks about the cause(s) of victory, she points to the swing voters who voted one way or the other, not the voters that were taken to be staunch supporters of one particular side.

That said, making a variable exogenous seems like a somewhat draconian solution to the problem. It also does not allow us to take into account smaller gradations in depth of feeling. At what point should a preference switch from being endogenous to exogenous? We can achieve the same effect in an arguably more natural way by using normality considerations. In the case of Jack and Jill, we can take voting for a Democrat to be highly abnormal for Jack, and voting for a Republican to be highly abnormal for Jill. To show that either Jack (resp., Jill) is a cause of the victory, we need to consider a contingency where Jack (resp., Jill) votes for the Democratic candidate. This would be a change to a highly abnormal world in the case of Jack, but to a more normal world in the case of Jill. Thus, if we use normality as a criterion for determining causality, Jill would count as a cause, but Jack would not. If we use normality as a way of grading causes, Jack and Jill would still both count as causes for the victory, but Jill would be a much better cause. More generally, the more normal it would be for someone to vote Democratic, the better a cause that voter would be. The use of normality here allows for a more nuanced gradation of cause than the rather blunt approach of either making a variable exogenous or endogenous.

Now, following Livengood (2013), consider a vote where everyone can either vote for one of three candidates. Suppose that the actual vote is 17–2–0 (i.e., 17 vote for candidate A, 2 for candidate B, and none for candidate C). Then

not only is every vote for candidate A a cause of A winning, every vote for B is also a cause of A winning. To see this, consider a contingency where 8 of the voters for A switch to C. Then if one of the voters for B votes for C, the result is a tie; if that voter switches back to B, then A wins (even if some subset of the voters who switch from A to C switch back to A).

Is this reasonable? What makes it seem particularly unreasonable is that if it had just been a contest between A and B, with the vote 17–2, then the voters for B would not have been causes of A winning. Why should adding a third option make a difference?

In some cases it does seem reasonable that adding a third option makes a difference. For example, we speak of Nader costing Gore a victory over Bush in the 2000 election. But, as Livengood (2013) points out, we don't speak of Gore costing Nader a victory, although in a naive HP model of the situation, all the voters for Gore are causes of Nader not winning as much as the voters for Nader are causes of Gore not winning. The discussion above points a way out of this dilemma. If a sufficiently large proportion of Bush and Gore voters are taken to be such strong supporters that they will never change their minds, and we make their votes exogenous, then it is still the case that Nader caused Gore to lose, but not the case that Gore caused Nader to lose. Similar considerations apply in the case of the 17–2 vote. (Again, we can use normality considerations to give arguably more natural models of these examples.)[7]

4 Do we need AC2(b)?

In this section, I consider the extent to which we can use AC2(b$'$) rather than AC2(b), and whether this is a good thing.

4.1 The Hopkins-Pearl example

I start by examining the Hopkins-Pearl example that was intended to show that AC2(b$'$) was inappropriate. The following description is taken from (Halpern & Pearl 2005).

Example 4.1: Suppose that a prisoner dies either if A loads B's gun and B shoots, or if C loads and shoots his gun. Taking D to represent the prisoner's death and making the obvious assumptions about the meaning of the variables, we have that $D = (A \wedge B) \vee C$. Suppose that in the actual context u, A loads B's gun, B does not shoot, but C does load and shoot his gun, so that the prisoner dies. That is, $A = 1$, $B = 0$, and $C = 1$. Clearly $C = 1$ is a cause of $D = 1$. We would not want to say that $A = 1$ is a cause of $D = 1$, given that B did not shoot (i.e., given that $B = 0$). However, suppose that we take the obvious model with the random variables A, B, C, D. With AC2(b$'$), $A = 1$ is a cause of $D = 1$. For we can take $\vec{W} = \{B, C\}$ and consider the contingency where $B = 1$ and $C = 0$. It is easy to check that AC2(a) and AC2(b$'$) hold for this contingency, so under the original HP definition, $A = 1$ is a cause of $D = 1$. However, AC2(b) fails in this case, since $(M, u) \models [A \leftarrow 1, C \leftarrow 0](D = 0)$. The key point is that AC2(b) says that for $A = 1$ to be a cause of $D = 1$, it must be the case that $D = 0$ if only some of the values in $\vec{W}$ are set to $\vec{w}$. That means that the other variables get the same value as they do in the actual context; in this case, by setting only A to 1 and leaving B unset, B takes on its original value of 0, in which case $D = 0$. AC2(b$'$) does not consider this case.

Nevertheless, as pointed out by Halpern and Hitchcock (2014), we can use AC2(b$'$) if we have the "right" model. Suppose that we add a new variable E such that $E = A \wedge B$, so that $E = 1$ iff $A = B = 1$, and set $D = E \vee C$. Thus, we have captured the intuition that there are two ways that the prisoner dies. Either C shoots, or A loads and B fires (which is captured by E). It is easy to see that (using either AC2(b) or AC2(b$'$)) $B = 0$ is *not* a cause of $D = 1$. ∎

As I now show, the ideas of this example generalize. But before doing that, I define the notion of a conservative extension.

4.2 Conservative extensions

In the rock-throwing example, adding the extra variables converted $BT = 1$ from being a cause to not being a cause of $BS = 1$. Similarly, adding extra variables affected causality in all the other examples above. Of course, without any constraints, it is easy to add variables to get any desired result. For example, consider the rock-throwing model M'_{RT}. Suppose that we add a variable BH_1 with equations that set $BH_1 = BT$ and $BS = SH \vee BT \vee BH_1$. This results in a new "causal path" from BT to BS going through BH_1, independent of all other paths. Not surprisingly, in this model, $BT = 1$ is indeed a cause of $BS = 1$.

But this seems like cheating. What we want is a model where the new variable(s) are added in a way that extends what we know about the old variables. Intuitively, suppose that we had a better magnifying glass and could look more carefully at the model. We might discover new variables that were previously hidden. But we want it to be the case that any setting of the old variables results in the same observations. This is made precise in the following definition.

Definition 4.2: A causal model $M' = ((\mathcal{U}', \mathcal{V}', \mathcal{R}'), \mathcal{F}')$ is a *conservative extension* of $M = ((\mathcal{U}, \mathcal{V}, \mathcal{R}), \mathcal{F})$ if $\mathcal{U} = \mathcal{U}'$, $\mathcal{V} \subseteq \mathcal{V}'$ if, for all contexts $\vec{u}$, all variables $X \in \mathcal{V}$, and all settings $\vec{w}$ of the variables in $\vec{W} = \mathcal{V} - \{X\}$, we have $(M, \vec{u}) \models [\vec{W} \leftarrow \vec{w}](X = x)$ iff $(M', \vec{u}) \models [\vec{W} \leftarrow \vec{w}](X = x)$. That is, no matter how we set the variables other than X, X has the same value in context $\vec{u}$ in both M and M'. ∎

The following lemma gives further insight into the notion of conservative extension. It says that if M' is a conservative extension of M, then the same causal formulas involving only the variables in $\mathcal{V}$ hold in M and M'.

[7] As a separate matter, most people would agree that Nader entering the race was a cause of Gore not winning, while Gore entering the race was not a cause of Nader not winning. Here the analysis is different. If Nader hadn't entered, it seems reasonable to assume that there would have been no other strong third-party candidate, so just about all of Nader's votes would have gone to Bush or Gore, with the majority going to Gore. On the other hand, if Gore hadn't entered, there would have been another Democrat in the race replacing him, and most of Gore's votes would have gone to the new Democrat in the race, rather than Nader.

Lemma 4.3: *Suppose that M' is a conservative extension of $M = ((\mathcal{U}, \mathcal{V}, \mathcal{R}), \mathcal{F})$. Then for all causal formulas φ that mention only variables in $\mathcal{V}$ and all context u, we have $(M, u) \models \varphi$ iff $(M', u) \models \varphi$.*

Proof: See the full paper. ∎

4.3 Avoiding AC2(b)

I now show that we can always use AC2(b′) instead of AC2(b), if we add extra variables.

Theorem 4.4: *If $X = x$ is not a cause of $Y = y$ in $(M, \vec{u})$ using AC2(b), but is a cause using AC2(b′), then there is a model M' that is a conservative extension of M such that $X = x$ is not a cause of $Y = y$ using AC2(b′).*

Proof: Suppose that $(\vec{W}, \vec{w}, x')$ is a witness to $X = x$ being a cause of $Y = y$ in $(M, \vec{u})$ using AC2(b′). Let $(M, \vec{u}) \models \vec{W} = \vec{w}$. We must have $\vec{w} \neq \vec{w}^*$, for otherwise it is easy to see that $X = x$ would be a cause of $Y = y$ in $(M, \vec{u})$ using AC(2b) with witness $(\vec{W}, \vec{w}, x')$.

If M' is a conservative extension of M with additional variables $\mathcal{V}'$, and $X = x$ is a cause of $Y = y$ in $(M, \vec{u})$ with witness $(\vec{W}, \vec{w}, x')$, we say that $(\vec{W}', \vec{w}', x')$ *extends* $(\vec{W}, \vec{w}, x')$, if $\vec{W} \subseteq \vec{W}' \subseteq \vec{W} \cup \mathcal{V}'$ and $\vec{w}'$ agrees with $\vec{w}$ on the variables in $\vec{W}$.

I now construct a conservative extension M' of M in which $X = x$ is not a cause of $Y = y$ using AC2(b′) with a witness extending $(\vec{W}', \vec{w}, x')$. Of course, this just kills one witness. I then show that we can construct further extensions to kill all other witnesses to $X = x$ being a cause of $Y = y$ using AC2(b′).

Let M' be obtained from M by adding one new variable N. All the variables have the same equations in M and M' except for Y and (of course) N. The equations for N are easy to explain: if $X = x$ and $\vec{W} = \vec{w}$, then $N = 1$; otherwise, $N = 0$. The equations for Y are the same in M and M' (and do not depend on the value of N) except for two special cases. To define these cases, for each variable $Z \in \mathcal{V} - \vec{W}$, if $x'' \in \{x, x'\}$ define $z_{x'',\vec{w}}$ as the value such that $(M, \vec{u}) \models [X \leftarrow x'', \vec{W} \leftarrow \vec{w}](Z = z_{x'',\vec{w}})$. That is, $z_{x'',\vec{w}'}$ is the value taken by Z if X is set to x'' and $\vec{W}$ is set to $\vec{w}$. Let $\vec{V}'$ consist of all variables in $\mathcal{V}$ other than Y, let $\vec{v}'$ be a setting of the variables in $\vec{V}'$, and let $\vec{Z}'$ consist of all variables in $\vec{V}' - \vec{W}$ other than X. Then we want the equations for Y in M' to be such that for all $j \in \{0, 1\}$, we have

$$(M, \vec{u}) \models [\vec{V}' \leftarrow \vec{v}'](Y = y'') \text{ iff}$$
$$(M', \vec{u}) \models [\vec{V}' \leftarrow \vec{v}'; N \leftarrow j](Y = y'')$$

unless the assignment $\vec{V}' \leftarrow \vec{v}'$ results in either (a) $X = x$, $\vec{W} = \vec{w}$, $Z = z_{x,\vec{w}}$ for all $Z \in \vec{Z}'$, and $N = 0$ or (b) $X = x'$, $\vec{W} = \vec{w}$, $Z = z_{x',\vec{w}}$ for all $Z \in \vec{Z}'$, and $N = 1$. (Note that in both of these cases, the value of N is "abnormal". If $X = x$, $\vec{W} = \vec{w}$ and $Z = z_{x,\vec{w}}$ for all $z \in \vec{Z}'$, then N should be 1; if we set X to x' and change the values of the variables in $\vec{Z}'$ accordingly, then N should be 0.) If (a) holds, $Y = y'$ in M'; if (b) holds, $Y = y$.

Lemma 4.5:

(a) It is not the case that $X = x$ is a cause of $Y = y$ using AC2(b′) in M' with a witness that extends $(\vec{W}, \vec{w}, x')$.

(b) M' is a conservative extension of M.

(c) if $X = x$ is a cause of $Y = y$ in $(M', \vec{u})$ using AC2(b) (resp. AC2(b′)) with a witness extending $(\vec{W}', \vec{w}', x'')$ then $X = x$ is a cause of $Y = y$ in $(M, \vec{u})$ using AC2(b) (resp. AC2(b′)) with witness $(\vec{W}', \vec{w}', x'')$.

The proof of Lemma 4.5 and the remainder of the proof of Theorem 4.4 can be found in the full paper. ∎

4.4 Discussion

Theorem 4.4 suggests that, by adding extra variables appropriately, we can go back to the definition of causality using AC2(b′) rather than AC2(b). This has some technical advantages. For example, with AC2(b′), causes are always single conjuncts (Eiter & Lukasiewicz 2002; Hopkins 2001). As shown in (Halpern 2008), this is not in general the case with AC2(b); it may be that $X_1 = x_1 \wedge X_2 = x_2$ is a cause of $Y = y$ with neither $X_1 = x_1$ nor $X_2 = x_2$ being causes. It also seems that testing for causality is harder using AC2(b). Eiter and Lukasiewicz (2002) show that, using AC2(b′), testing for causality is NP-complete for binary models (where all random variables are binary) and Σ_2-complete in general; with AC2(b), it seems to be Σ_2-complete in the binary case and Π_3-complete in the general case (Aleksandrowicz *et al.* 2013).

On the other hand, adding extra variables may not always be a natural thing to do. For example, in Beer et al.'s (2012) analysis of software errors, the variables chosen for the analysis are determined by the program specification. Moreover, Beer et al. give examples where AC2(b) is needed to get the intuitively correct answer. Unless we are given a principled way of adding extra variables so as to be able to always use AC2(b′), it is not clear how to automate an analysis. There does not always seem to be a "natural" way of adding extra variables so that AC2(b′) suffices (even assuming that we can agree on what "natural" means!).

Adding extra variables also has an impact on complexity. Note that, in the worst case, we may have to add an extra variable for each pair (W, w) such that there is a witness (W, w, x') for $X = x$ being a cause of $Y = y$. In all the standard examples, there are very few witnesses (typically 1–2), but I have been unable to prove a nontrivial bound on the number of witnesses.

More experience is needed to determine which of AC2(b) and AC2(b′) is most appropriate. Fortunately, in many cases, the causality judgment is independent of which we use.

5 The Stability on Non-Causality

The examples in Section 3 raises a potential concern. Consider the rock-throwing example again. Adding extra variables changed $BT = 1$ from being a cause of $BS = 1$ to

not being a cause. Could adding even more variables convert $BT = 1$ back to being a cause? Could it then alternate further?

As I now show, this cannot happen. Although, as we saw with the rock-throwing example, adding variables can convert a single-variable cause to a non-cause, it cannot convert a single-variable non-cause to a cause. Non-causality is stable.

Theorem 5.1: *If $X = x$ is not a cause of φ in (M, u), and M' is a conservative extension of M, then $X = x$ is not a cause of φ in (M', u).*

Proof: Suppose, by way of contradiction, that $X = x$ is not a cause of φ in (M, u), M' is a conservative extension of M, and $\vec{X} = \vec{x}$ is a cause of φ in (M', u) with witness $(\vec{W}, \vec{w}, \vec{x}')$. Let $\vec{W}_1$ be the intersection of $\vec{W}$ with $\mathcal{V}$, the set of endogenous variables in M, let $\vec{Z}_1 = \mathcal{V} = \vec{W}$, and let $\vec{w}_1$ be the restriction of $\vec{w}$ to the variables in $\vec{W}_1$. Since $X = x$ is not a cause of φ in (M, u), it is certainly not a cause with witness $(\vec{W}_1, \vec{w}_1, x')$, so either (a) $(M, u) \models X \neq x \vee \neg\varphi$; (b) $(M, u) \models [X \leftarrow x', \vec{W}_1 \leftarrow \vec{w}_1]\varphi$, or (c) there must be subsets $\vec{W}_1'$ of $\vec{W}_1$ and $\vec{Z}_1'$ of $\vec{Z}_1$ such that if $(M, u) \models \vec{Z}_1' = \vec{z}_1$ (i.e., $\vec{z}_1$ gives the actual values of the variables in $\vec{Z}_1'$), then $(M, u) \not\models [X \leftarrow x, \vec{W}_1' \leftarrow \vec{w}_1, \vec{Z}_1' \leftarrow \vec{z}_1]\neg\varphi$. Since M' is a conservative extension of M, by Lemma 4.3, if (a) holds, then $(M', u) \models X \neq x \vee \neg\varphi$; if (b) holds, $(M', u) \models [X \leftarrow x', \vec{W}_1 \leftarrow \vec{w}_1]\varphi$; and if (c) holds, then $(M', u) \not\models [X \leftarrow x, \vec{W}_1' \leftarrow \vec{w}_1, \vec{Z}_1' \leftarrow \vec{z}_1]\neg\varphi$. Moreover, $(M', u) \models \vec{Z}_1' = \vec{z}_1$. Thus, it follows that $X = x$ is not a cause of φ with witness $(\vec{W}, \vec{w}, x')$ in (M', u). For if (a) holds, then AC1 fails; if (b) holds, then AC2(a) fails, and if (c) holds, then AC2(b) fails. ∎

Notice that this argument does not quite work if the cause involves multiple variables. If $\vec{X} = \vec{x}$ is a cause of φ in (M', u) with witness $(\vec{W}, \vec{w}, \vec{x}')$, it is possible that it is not a cause in (M, u) because AC3 fails. While I believe that stability of non-causality holds even for causes involving multiple variables, proving it remains an open problem.

It is interesting that, in the single-variable case, non-causality is stable, while causality is not. Intuitively, this says that if $X = x$ is not a cause of $Y = y$, this is somehow encoded in the variables. For example, the fact that Billy's throw is not a cause of the bottle shattering in M'_{RT} is due to the variables *BH* and *SH* encoding the fact that Suzy's rock hits and Billy's does not. This information is maintained in any extension of $M'_{|RT}$, so Billy's throw cannot become a cause again.

6 Conclusions

This paper has demonstrated the HP definition of causality is remarkably resilient, but it emphasizes how sensitive knowledge representation can be to the choice of models. The focus has been on showing that the choice of variables is a powerful modeling tool. But it is one that can be abused. One lesson that comes out clearly is the need to have variables that describe the mechanism of causality, particularly if there is more than one mechanism. However, this is hardly a general recipe. Rather, it is a heuristic for constructing a "good" model. As Hitchcock and I pointed out (Halpern & Hitchcock 2010), constructing a good model is still more of an art than a science.

∃GUARANTEENASH for Boolean Games is NEXP-Hard

Egor Ianovski and **Luke Ong**
Department of Computer Science, University of Oxford
Wolfson Building, Parks Road, Oxford, UK

Abstract

Boolean games are an expressive and natural formalism through which to investigate problems of strategic interaction in multiagent systems. Although they have been widely studied, almost all previous work on Nash equilibria in Boolean games has focused on the restricted setting of pure strategies. This is a shortcoming as finite games are guaranteed to have at least one equilibrium in mixed strategies, but many simple games fail to have pure strategy equilibria at all. We address this by showing that a natural decision problem about mixed equilibria: determining whether a Boolean game has a mixed strategy equilibrium that guarantees every player a given payoff, is NEXP-hard. Accordingly, the ϵ variety of the problem is NEXP-complete. The proof can be adapted to show coNEXP-hardness of a similar question: whether all Nash equilibria of a Boolean game guarantee every player at least the given payoff.

Introduction

A multiagent environment makes strategic considerations inevitable. Any attempt to explain the behaviour of a system consisting of self-interested agents cannot ignore the fact that agents' behaviour may be influenced or completely determined by the behaviour of other agents in the system. As the field of game theory concerns itself with precisely these issues, its concepts find fertile ground in the study of multiagent systems.

A shortcoming of game theoretical techniques is that games, being combinatorial objects, are liable to get very large very quickly. Any computational application of game theory would need alternative representations to the normal and extensive forms prominent in the economics literature. One such representation, based on propositional logic, is the Boolean game.

Boolean games were initially introduced as two player games which have an algebra isomorphic to the Lindenbaum algebra for propositional logic (Harrenstein et al. 2001). Since then Boolean games have garnered interest from the multiagent community as a simple yet expressive framework to model strategic interaction. This has led to the study of complexity issues involved in reasoning about these games. While many questions have been answered, the issue of mixed strategies remained open.

In this paper we address this lacuna and present the first complexity result about mixed equilibria in the Boolean games literature: the NEXP-hardness of ∃GUARANTEENASH, which asks whether a Boolean game has an equilibrium where each player attains at least $\boldsymbol{v}[i]$ utility, for some input vector $\boldsymbol{v}$.

Related Work

Complexity results for Boolean games were first studied in the two player case by Dunne and van der Hoek (2004) and the n-player case by Bonzon et al. (2006), where among other results the authors showed that determining the existence of a pure equilibrium is Σ_2^p-complete in the general case, and can be easier should some restrictions be placed on the goal formulae of the players. A later paper considered to what extent the interdependency of players contributed to complexity (Bonzon, Lagasquie-Schiex, and Lang 2009). Further enquiry into tractable fragments of Boolean games was carried out by Dunne and Wooldridge (2012).

Since their inception Boolean games have attracted the interest of the multiagent community, which led to increased interest about their cooperative side. The standard game theoretic notion of core was studied in a Boolean setting (Dunne et al. 2008; Bonzon, Lagasquie-Schiex, and Lang 2012), and a number of papers considered means of lining up player incentives with a central planner (Endriss et al. 2011; Kraus and Wooldridge 2012; Levit et al. 2013). in two recent papers (2013a; 2013b), Ågotnes et al. considered ways of combining Boolean games with the spiritually similar games in epistemic logic (Ågotnes et al. 2011; Ågotnes and van Ditmarsch 2011).

All the work mentioned has been in the setting of pure strategies only. Mixed strategies do arise in a cardinal extension to Boolean games dubbed weighted Boolean formula games (Mavronicolas, Monien, and Wagner 2007) or satisfiability games (Bilò 2007), but there the authors only consider a very restricted fragment of these games, and its relation to a subclass of the congestion games of Rosenthal (1973).

A very similar framework to Boolean games is that of Boolean circuit games (Schoenebeck and Vadhan 2012), building on earlier work by Feigenbaum, Koller, and Shor

(1995). There players are equipped with a Boolean circuit with k input gates and m output gates. The input gates are partitioned among the players, and a player's strategy is an assignment of values to the gates under his control. The output gates encode a binary representation of the player's utility on a given input. In this setting we do find a treatment of mixed strategies, including the complexity of ∃GUARANTEENASH.

Note that a Boolean game can be seen as a very specific type of Boolean circuit game: the players' circuits are restricted to NC^1, and the number of output gates to one. Thus easiness results for Boolean circuit games directly transfer to Boolean games, and hardness results transfer in the other direction. In particular, this means that the NEXP-completeness of ∃GUARANTEENASH for Boolean circuit games proved by Schoenebeck and Vadhan does not imply the result of this paper.

Preliminaries

While there are many breeds of games in the literature, we here restrict ourselves to what is perhaps the most widely studied class:

Definition 1. A *finite strategic game* consists of n players, each equipped with a finite set of pure strategies, S_i, and a utility function $u_i : S_1 \times \cdots \times S_n \to \mathbb{R}$.

An n-tuple of strategies is called a *strategy profile*: thus a utility function maps strategy profiles to the reals.

Example 1. In a game of *matching pennies* two players are given a coin each and may choose to display that coin heads or tails up. Player Two seeks to match the move of Player One, while player one seeks to avoid that. Hence we have $u_2(HH) = u_2(TT) = 1$, $u_1(HT) = u_1(TH) = 1$, and 0 otherwise.

Note that to represent a finite strategic game explicitly (the *normal form* of the game) we would need to list the players' utility on every possible profile. This would require on the order of $n|S_i|^n$ entries, taking S_i to mean the size of the "typical" strategy set. Such a representation is both exponential in the number of players and linear in the number of strategies - which in itself may be very large, e.g. in chess.

Ideally we would wish to avoid such a representation. If a game has some internal structure, it would be natural to ask if the game can be described in a more succinct way. In the case where the game can be interpreted as players holding propositional preferences over Boolean variables the Boolean game offers precisely that.

Definition 2. A *Boolean game* is a representation of a finite strategic game given by n disjoint sets of propositional variables, Φ_i, and n formulae of propositional logic, γ_i.

The intended interpretation is that player i controls the variables in Φ_i in an attempt to satisfy γ_i, which may depend on variables not in player i's control. Player i plays a truth assignment to Φ_i, i.e. his set of pure strategies is 2^{Φ_i}. A profile of strategies, ν, is thus a model of proposition logic and i's utility function is $\nu \mapsto 1$ if $\nu \vDash \gamma_i$, and $\nu \mapsto 0$ otherwise.

Example 2. Matching pennies can be given a Boolean representation by setting $\Phi_1 = \{p\}$, $\Phi_2 = \{q\}$, $\gamma_1 = \neg(p \leftrightarrow q)$ and $\gamma_2 = p \leftrightarrow q$.

The size of a Boolean game is thus on the order of $n(\max_i(|\Phi_i|) + \max_i(|\gamma_i|))$. In the best case γ_i is small and the resulting representation is linear in the number of players and logarithmic in the number of strategies, giving greater succinctness on both fronts.

Having defined the game representation, we now turn to reasoning about such games. The most common solution concept is the Nash equilibrium, which we define below.

Definition 3. Given a strategy profile $\boldsymbol{s}$, we use $\boldsymbol{s}_{-i}(\sigma_i')$ to mean the profile obtained by replacing the strategy of i in $\boldsymbol{s}$ with σ_i'. A *best response* for i to $\boldsymbol{s}$ is some σ_i' that maximises $u_i(\boldsymbol{s}_{-i}(\sigma_i'))$.

A strategy profile $\boldsymbol{s} = (\sigma_1, \ldots, \sigma_n)$ where every σ_i is a best response to $\boldsymbol{s}$ is a *Nash equilibrium*.

Example 3. In a game of matching pennies, T is a best response for Player One to HH, and H is a best response for Player Two, so the profile HH is not in equilibrium. In fact, the game has no equilibria in pure strategies.

The fact that games as simple as matching pennies may fail to have a pure strategy equilibrium casts doubt on its suitability as a solution concept. Fortunately, a natural extension of the framework rectifies the matter.

Definition 4. A *mixed strategy* for player i in a finite strategic game is a probability distribution over S_i.

The utility player i obtains from a profile of mixed strategies S is $\sum p(S')u_i(S')$, where $p(S')$ is the probability assigned to the pure profile S' by the mixed strategies in S.

If the idea of playing a probability distribution seems strange, the reader may instead opt to view a mixed strategy as a randomised decision procedure that leads to an outcome in the set of pure strategies, S_i. In a game of rock-paper-scissors, a mixed strategy could consist of generating a number in $[0, 1]$ then playing rock if it falls between 0 and 0.4, paper if it falls between 0.4 and 0.9 and scissors if it is above 0.9. The payoff of a mixed strategy is the expected payoff - the sum of the possible outcomes weighted by their probability.

It is in this context that Nash proved his seminal result:

Theorem 1 (Nash, 1951). *Every finite strategic game has an equilibrium in mixed strategies.*

Example 4. The unique equilibrium of matching pennies involves both players randomising over their sets of strategies by assigning a weight of 0.5 to both H and T. In this equilibrium both players attain a utility of 0.5.

In the above example the reader will observe that 0.5 is also the utility Player One would attain by deviating to the pure strategy H or the pure strategy T. This is always the case - as the payoff of a mixed strategy is a weighted sum of pure strategies, it cannot yield more utility than any of its components individually. What this means for us is that if it is possible for a player to deviate from a profile, then it is possible to deviate with a pure strategy. If we want to verify that a mixed profile is in equilibrium, we need only

check that no pure strategy for a player will lead to a better outcome.

Since every game has an equilibrium, the algorithmic question of asking whether an equilibrium exists is not relevant. This motivates decision problems based on qualified notions of equilibria, such as the one that concerns us in this paper:

∃GUARANTEENASH: Given a Boolean game G and a rational-valued vector $\boldsymbol{v} \in [0,1]^n$, does G have an equilibrium $\boldsymbol{s}$ such that $u_i(\boldsymbol{s}) \geq \boldsymbol{v}[i]$ for each player i?

For representation purposes, as the entries of $\boldsymbol{v}$ are rationals we will assume they are given as a pair of integers representing the numerator and denominator.

It is natural to also consider a problem closely related to the dual:

∀GUARANTEENASH: Given a Boolean game G and a rational-valued vector $\boldsymbol{v} \in [0,1]^n$, does every equilibrium of G, $\boldsymbol{s}$, satisfy $u_i(\boldsymbol{s}) \geq \boldsymbol{v}[i]$ for each player i?

Main Result

Our reduction will be from the following NEXP-complete problem:

NEXPTM: Given a non-deterministic Turing machine M, an integer in binary K and a string w, does M accept w in at most K steps?

Proposition 1. NEXPTM *is NEXP-complete.*

Proof. For membership in NEXP, we need only simulate the computation of M on w for K steps. Each step can be simulated in non-deterministic polynomial time, and the number of steps is exponential in $|K|$.

For hardness, let N be a non-deterministic Turing machine with an exponential time clock f. Let M be a Turing machine with an identical transition relation to N, but with no internal clock. Clearly, N accepts w if and only if M accepts w in at most $f(w)$ steps. That is, $(M, f(w), w)$ is a positive instance of NEXPTM. Moreover, the triple $(M, f(w), w)$ is polynomial in the size of N and w: $|M| \leq |N|$, $|w| = |w|$ and as $f(w) \in O(2^{p(|w|)})$, when written in binary it is of size $O(p(|w|))$. This gives us the desired reduction. □

We can now prove the hardness of ∃GUARANTEENASH. For questions of NEXP-membership, see the discussion below.

Theorem 2. ∃GUARANTEENASH *for Boolean games is NEXP-hard.*

Proof. We will give a reduction from NEXPTM. Given a triple (M, K, w) we shall construct, in polynomial time, a Boolean game G and a utility vector $\boldsymbol{v}$, such that G has an equilibrium where player i's utility is at least $\boldsymbol{v}[i]$ if and only if M accepts w in K steps or less.

For convenience, we augment M with a "do nothing" transition: if M is at an accepting state, then we allow it to move to the next computation step without moving the head, changing state, or writing anything to the tape. It is clear that augmenting M in such a fashion does not change the language accepted by M, but it ensures that the machine state is defined at all computation steps; we do not need to worry about the case where the machine accepts in under K steps, as if it does, it will still accept at step K.

Let $k = |K|$, and q be the number of states of M.

For intuition, a computation history of M on w could be seen as a $K \times K$ table, or for simplicity $2^k \times 2^k$, padding as needed. The ith row, jth column contains the contents of the jth tape cell at the ith computation step, whether or not the head is over that cell at that step and, if so, which state the machine is in. As the size of the table is 2^k by 2^k, we can index an entry by using two k-bit integers.

A way to visualise the proof is that in our game G, which consists of six players, Player One is equipped with variables that allow him to describe a single entry of this table. Player Four plays a partial matching pennies game against Player One, thereby forcing Player One to play a mixed strategy randomising over all entries of the table, and thus specifying an entire computation history with his mixed strategy. Player Two then verifies that the mixed strategy provided by Player One contains a consistent description of the head location at each computation step, and Player Three checks that every two consecutive steps are linked by exactly one transition rule. Players Five and Six play matching pennies with Players Two and Three to force them to randomise across all table entries.

To this end, let:

$$\Phi_1 = \{Zero_1, One_1, Head_1, Left_1, Right_1\} \cup \{Time_1^i\}_{1\leq i\leq k} \cup \{Tape_1^i\}_{1\leq i\leq k} \cup \{State_1^i\}_{1\leq i\leq q}.$$

The intended meaning of $Time_1^i$ (respectively $Tape_1^i$) is the value of the ith most significant bit of the integer denoting the index of the computation step (respectively tape cell) in question, given the standard convention of interpreting "true" as 1 and "false" as 0. A truth assignment by Player One can therefore be read as: at the computation step specified by $Time_1^1, \ldots, Time_1^k$ the tape cell specified by $Tape_1^1, \ldots, Tape_1^k$ contains 0 if $Zero_1$, 1 if One_1 and is blank if neither. The machine head is hovering over the cell in question if $Head_1$, and is located to the left or right of that cell respectively if $Left_1$ or $Right_1$. If the head is over the cell in question, the machine is in state i if $State_1^i$ (if the head is not over the cell, $State_1^i$ is a junk variable that has no meaning).

Player One's goal formula is a conjunction of four subformulae:

$$\gamma_1 = Init \wedge Final \wedge Cons_1 \wedge \neg\gamma_4.$$

Intuitively, $Init$ means that if the player plays the first computation step, his description of the machine must agree with the initial configuration of M on w. $Final$ means that if the player plays the last (Kth) computation step, the machine must be in an accepting state. $Cons_1$ states the description of the machine must be internally consistent. The final conjunct is to force the player to randomise across all

computation steps and tape cells, to which we will return later.

Init requires that at time zero the configuration of the machine is faithfully represented by Player One's play. This takes the form of an implication where the antecedent states that we are at step zero:

$$Init = (\bigwedge_{1 \leq i \leq k} \neg Time_1^i) \rightarrow Consequent.$$

The consequent itself is a conjunction of three further subformulae, for the head, the state and the tape.

$$Consequent = InitHead \wedge InitState \wedge InitTape.$$

The head requirement states that the head is at the leftmost cell. That is, at cell zero $Head_1$ is true, and at every other cell $Left_1$ is true:

$$InitHead = \Big((\bigwedge_{1 \leq i \leq k} \neg Tape_1^i) \rightarrow Head_1\Big) \wedge \Big(\neg(\bigwedge_{1 \leq i \leq k} \neg Tape_1^i) \rightarrow Left_1\Big).$$

The state requirement is simply M's initial state:

$$InitState = State_1^{initial}.$$

The tape requirement is a conjunction of $|w| + 1$ implications. The first $|w|$ implications state that if the tape cell chosen is within the first $|w|$ cells, then its contents must agree with w. If we use i as shorthand for the conjunction of tape variables expressing i, and $w[i]$ for $Zero_1$ or One_1 depending on the ith bit of w, this has the following form:

$$InitTape = \bigwedge_{0 \leq i < |w|} (i \rightarrow w[i]) \wedge BlankCells.$$

Note that this formula is linear in $|w|$, so the construction so far was polynomial.

The last formula in *InitTape* states that all other cells are blank.

$$BlankCells = \neg(\bigvee_{0 \leq i < |w|} i) \rightarrow (\neg Zero_1 \wedge \neg One_1).$$

Final states that at computation step K, the machine accepts. If we use K as shorthand for the appropriate conjunction of time variables, we get the following implication:

$$Final = K \rightarrow State_1^{accepting}.$$

$Cons_1$ requires that the player's description of a given computation step and cell is internally consistent. This means the cell cannot have both 0 and 1 on it, the head must be either over the cell or to one direction and the machine must be in exactly one state. It is worth noting that this says nothing about whether Player One's descriptions of different steps and cells are consistent with each other: this is the task of Players Two and Three.

For $Cons_1$, we introduce a generalised XOR symbol, which we denote $\boldsymbol{OneOf}$, with the interpretation that $\boldsymbol{OneOf}(\varphi_1, \ldots, \varphi_n)$ is true if and only if exactly one φ_i is. Such a symbol could be replaced by a propositional logic formula polynomial in the size of $\varphi_1, \ldots, \varphi_n$ - simply take the disjunction of all n admissible possibilities. This gives us the desired formula:

$$\begin{aligned} Cons_1 = {} & \neg(Zero_1 \wedge One_1) \\ & \wedge \boldsymbol{OneOf}(Head_1, Left_1, Right_1) \\ & \wedge \boldsymbol{OneOf}(\overline{State_1^i}). \end{aligned}$$

By $\overline{State_1^i}$ we mean $State_1^1, \ldots, State_1^q$.

To finish the description of γ_1, we turn to Player Four. Player Four is playing a partial matching pennies game with Player One over the time and tape variables. We thus equip her with the following:

$$\Phi_4 = \{Time_4^i\}_{1 \leq i \leq k} \cup \{Tape_4^i\}_{1 \leq i \leq k}.$$

The objective is to guess the same computation step and cell index as player one:

$$\gamma_4 = \Big(\bigwedge_{1 \leq i \leq k} (Time_1^i \leftrightarrow Time_4^i)\Big) \wedge \Big(\bigwedge_{1 \leq i \leq k} (Tape_1^i \leftrightarrow Tape_4^i)\Big).$$

Since the payoffs of Player One and Four depend only on each other, we can already describe how they will behave in any equilibrium. Player One has the power to satisfy *Init*, *Final* and $Cons_1$ unilaterally, so all that remains is $\neg\gamma_4$. To maximise the chances of this happening, Player One's best bet is to play every step/cell with probability $1/2^{2k}$ - this will ensure that Player Four will guess the same step with probability $1/2^{2k}$, whereas if Player One were to play any (i, j) with a greater probability than $1/2^{2k}$, then Player Four could play (i, j) with probability 1 and thus guess Player One's choice more often.

As such in any equilibrium play Player One will describe entry (i, j) of the computation table with probability $1/2^{2k}$.

Player Two's purpose is to verify the consistency of Player One's description of the head. This involves verifying that at a given computation step the $Head_1$ variable is true in exactly one cell, $Left_1$ is true in every cell to the right and $Right_1$ is true in every cell to the left.

Now of course, she cannot verify the entire row in one go - there are 2^k cells to check. Instead a pure strategy for her will check only a pair of consecutive cells. Player Five will then force her to randomise over *all* pairs of consecutive cells - and if Player One's description is inconsistent, there must be a witnessing pair.

Player Two controls the following variables:

$$\begin{aligned} \Phi_2 = {} & \\ & \{Head_2, sHead_2, Left_2, sLeft_2, Right_2, sRight_2\} \\ & \cup \{Tape_2^i\}_{1 \leq i \leq k} \cup \{sTape_2^i\}_{1 \leq i \leq k} \cup \{Time_2^i\}_{1 \leq i \leq k}. \end{aligned}$$

The lowercase "s" can be read as "successor". The intended meaning of these variables is that $Tape_2^1, \ldots, Tape_2^k$ name a cell and $sTape_2^1, \ldots, sTape_2^k$ the cell directly to the right of it. The other variables state the location of the head

in relation to these two cells at the computation step specified by the time variables.

Player Two's goal formula is a conjunction of four subformulae:

$$\gamma_2 = \mathit{MatchOne}_2 \wedge \mathit{Cons}_2 \wedge \boldsymbol{Succ}_2 \wedge \neg\gamma_5.$$

Intuitively, $\mathit{MatchOne}_2$ states that Player Two ought to play the same head configuration as dictated by Player One. Cons_2 requires that this configuration be internally consistent. $\boldsymbol{Succ}_2$ is to ensure that the two cells chosen are indeed consecutive.

Before we state $\mathit{MatchOne}_2$ we ought to first ask what we mean by saying that players one and two play the same head configuration. As in any given (pure) strategy profile, either player will be describing a single computation step and at most two cells; if it turns out that they are speaking about different step/cell configurations we should not be concerned about whatever claims they make - we have no way to prove they are not in agreement, so we may as well assume that they are. Only in the instance where they happen to refer to the same step/cell should we expect accord. Since Player Two is referring to two cells in any play, we require that if either of the cells she references coincides with that referenced by Player One, they must agree.

The desired formula is thus of the following form:

$$\begin{aligned}\mathit{MatchOne}_2 = \\ &\mathit{AgreeTime} \rightarrow \Big((\mathit{AgreeCell} \rightarrow \mathit{AgreeHead}) \\ &\wedge (\mathit{sAgreeCell} \rightarrow \mathit{sAgreeHead})\Big).\end{aligned}$$

The subformulae are as follows:

$$\begin{aligned}\mathit{AgreeTime} &= \bigwedge_{1\le i\le k} (\mathit{Time}_1^i \leftrightarrow \mathit{Time}_2^i).\\ \mathit{AgreeCell} &= \bigwedge_{1\le i\le k} (\mathit{Tape}_1^i \leftrightarrow \mathit{Tape}_2^i).\\ \mathit{sAgreeCell} &= \bigwedge_{1\le i\le k} (\mathit{Tape}_1^i \leftrightarrow \mathit{sTape}_2^i).\\ \mathit{AgreeHead} &= (\mathit{Head}_1 \leftrightarrow \mathit{Head}_2)\\ &\quad \wedge (\mathit{Left}_1 \leftrightarrow \mathit{Left}_2)\\ &\quad \wedge (\mathit{Right}_1 \leftrightarrow \mathit{Right}_2).\\ \mathit{sAgreeHead} &= (\mathit{Head}_1 \leftrightarrow \mathit{sHead}_2)\\ &\quad \wedge (\mathit{Left}_1 \leftrightarrow \mathit{sLeft}_2)\\ &\quad \wedge (\mathit{Right}_1 \leftrightarrow \mathit{sRight}_2).\end{aligned}$$

Internal consistency amounts simply to the conjunction of the valid combinations of claims about the head:

$$\begin{aligned}\mathit{Cons}_2 = &(\mathit{Right}_2 \wedge \mathit{sRight}_2) \vee (\mathit{Right}_2 \wedge \mathit{sHead}_2)\\ &\vee (\mathit{Head}_2 \wedge \mathit{sLeft}_2) \vee (\mathit{Left}_2 \wedge \mathit{sLeft}_2)\end{aligned}$$

Succ_2 states that the two tape locations are, in fact, consecutive. We will prove a lemma to show that this is concisely expressible in propositional logic.

Lemma 1. *Let $\boldsymbol{Succ}(p_1,\ldots,p_n;q_1,\ldots,q_n)$ be a formula that is true if and only if the binary integer encoded by $q_1,\ldots,q_n$ is the successor of the binary integer encoded by $p_1,\ldots,p_n$. As a convention, 2^n-1 has no successor.*

$\boldsymbol{Succ}(p_1,\ldots,p_n;q_1,\ldots,q_n)$ can be replaced by a propositional formula of size polynomial in $p_1,\ldots,p_n$ and $q_1,\ldots,q_n$.

Proof. We take advantage of the fact that to increment a binary integer we only need to modify the rightmost consecutive block of 1s, and there are only n such possible blocks.

Since we have a boundary condition to consider, we require that the first integer is not 2^n-1:

$$\boldsymbol{Succ}(p_1,\ldots,p_n;q_1,\ldots,q_n) = \neg(\bigwedge_{1\le i\le n} p_i) \wedge \mathit{Succ}'.$$

Succ' is then:

$$\begin{aligned}&\Big(\neg p_1 \rightarrow \big(q_1 \wedge \bigwedge_{i=2}^{n}(p_i \leftrightarrow q_i)\big)\Big)\\ &\wedge\Big((p_1 \wedge \neg p_2) \rightarrow \big(\neg q_1 \wedge q_2 \wedge \bigwedge_{i=3}^{n}(p_i \leftrightarrow q_i)\big)\Big)\\ &\wedge\Big((p_1 \wedge p_2 \wedge \neg p_3) \rightarrow \big(\neg q_1 \wedge \neg q_2 \wedge q_3 \wedge \bigwedge_{i=4}^{n}(p_i \leftrightarrow q_i)\big)\Big)\\ &\ \vdots\\ &\wedge\Big((\neg p_n \wedge \bigwedge_{i=1}^{n-1} p_i) \rightarrow \big((\bigwedge_{i=1}^{n-1} \neg q_i) \wedge q_{i+1}\big)\Big).\end{aligned}$$

This is quadratic in the number of variables, giving us the desired result. □

Succ_2 can then be stated simply:

$$\mathit{Succ}_2 = \boldsymbol{Succ}(\overline{\mathit{Tape}_2^i}; \overline{\mathit{sTape}_2^i}).$$

Finally, Player Five is trying to guess Player Two's choice of cell and computation step.

$$\begin{aligned}&\Phi_5 = \{\mathit{Time}_5^i\}_{1\le i\le k} \cup \{\mathit{Tape}_5^i\}_{1\le i\le k}.\\ &\gamma_5 = \bigwedge_{i=1}^{k}(\mathit{Tape}_2^i \leftrightarrow \mathit{Tape}_5^i) \wedge \bigwedge_{i=1}^{k}(\mathit{Time}_2^i \leftrightarrow \mathit{Time}_5^i).\end{aligned}$$

Player Three's purpose is to verify that the tape contents in successive computation steps respect the transition rules of M. Like Player Two, he does this for a small, local part of the table, and is forced to randomise over the whole table by Player Six. To do this he specifies a total of six cells and two computation steps: consecutive triples in consecutive steps. Then he verifies that the tape contents, head position

and machine state are in agreement with some rule of M.

$$\begin{aligned}\Phi_3 = \{&pHead_3, Head_3, sHead_3, npHead_3, nHead_3,\\ &nsHead_3, pZero_3, Zero_3, sZero_3, npZero_3,\\ &nZero_3, nsZero_3, pOne_3, One_3, sOne_3,\\ &npOne_3, nOne_3, nsOne_3\}\\ \cup&\{pState_3^i\}_{1\le i\le q} \cup \{State_3^i\}_{1\le i\le q}\\ \cup&\{sState_3^i\}_{1\le i\le q} \cup \{npState_3^i\}_{1\le i\le q}\\ \cup&\{nState_3^i\}_{1\le i\le q} \cup \{nsState_3^i\}_{1\le i\le q}\\ \cup&\{pTape_3^i\}_{1\le i\le k} \cup \{Tape_3^i\}_{1\le i\le k}\\ \cup&\{sTape_3^i\}_{1\le i\le k} \cup npTape_3^i\}_{1\le i\le k}\\ \cup&\{nTape_3^i\}_{1\le i\le k} \cup \{nsTape_3^i\}_{1\le i\le k}\\ \cup&\{Time_3^i\}_{1\le i\le k} \cup \{nTime_3^i\}_{1\le i\le k}.\end{aligned}$$

The "p" can be read as "predecessor", referring to the cell to the left, and "n" as "next computation step". The intended meaning is simply the state and tape contents in each of the six cells, as well as whether the head is over that cell.

Player Three's goal formula is a conjunction of five subformulae:

$$\gamma_3 = MatchOne_3 \wedge Triple \wedge Succ_3 \wedge Rules \wedge \neg\gamma_6.$$

$MatchOne_3$ states that if any of the step/cell pairs named by Player Three coincide with the one named by Player One, Player Three must agree with Player One. $Triple$ requires that the three cells named in either computation step should be a consecutive triple, and the triple at either step must be the same. $Succ_3$ requires the two computation steps named to be consecutive. $Rules$ is to verify that the configuration thus described is consistent with a rule of M.

$MatchOne_3$ is a conjunction of a total of six statements, depending on which step/cell pair coincides with that played by Player One. We will only give one such statement below, in the case that Player One named the same step as $Time_3^1, \ldots, Time_3^k$ and the same cell as $pTape_3^1, \ldots, pTape_3^k$. The other five statements are obtained in the obvious manner.

$$\begin{aligned}&\Big(\bigwedge_{i=1}^{k}(Time_1^i \leftrightarrow Time_3^i) \wedge \bigwedge_{i=1}^{k}(Tape_1^i \leftrightarrow pTape_3^i)\Big) \rightarrow\\ &\Big((Zero_1 \leftrightarrow pZero_3) \wedge (One_1 \leftrightarrow pOne_3)\\ &\quad\wedge (Head_1 \leftrightarrow pHead_3) \wedge \bigwedge_{i=1}^{q}(State_1^i \leftrightarrow pState_3^i)\Big).\end{aligned}$$

$Triple$ states that the tape cells selected are consecutive triples, and that the same triple is chosen in both steps. It is worth noting that given our previous definition of successor, if Player Three is to satisfy this conjunct then the middle cell cannot be 0 or $2^k - 1$.

$$\begin{aligned}Triple = &\boldsymbol{Succ}(\overline{pTape_3^i}; \overline{Tape_3^i})\\ &\wedge \boldsymbol{Succ}(\overline{Tape_3^i}; \overline{sTape_3^i})\\ &\wedge \boldsymbol{Succ}(\overline{npTape_3^i}; \overline{nTape_3^i})\\ &\wedge \boldsymbol{Succ}(\overline{nTape_3^i}; \overline{nsTape_3^i})\\ &\wedge \bigwedge_{1\le i\le k}(Tape_3^i \leftrightarrow nTape_3^i).\end{aligned}$$

$Succ_3$ requires that the computation steps be consecutive:

$$Succ_3 = \boldsymbol{Succ}(\overline{Time_3^i}; \overline{nTime_3^i}).$$

$Rules$ is a conjunction of four formulae: three of the formulae are conjunctions containing an implication for each $(r, s) \in Q \times \{0, 1, \perp\}$, representing the machine's behaviour if it reads s in state r and the head is over the left, centre or right cell respectively. The fourth term is $NoHead$, to handle the case where the head is not over any cell in the triple:

$$Rules = Left \wedge Centre \wedge Right \wedge NoHead.$$

We will examine $Left$ and $NoHead$, understanding that $Centre$ and $Right$ are handled in similar fashion.

$$\begin{aligned}Left = \Big(\bigwedge_{(r,s)\in Q\times\{0,1,\perp\}} &\big((pState_3^r \wedge s) \rightarrow\\ &\boldsymbol{OneOf}(\overline{Rule[(r,s) \rightarrow (r', s', D)]})\big)\Big).\end{aligned}$$

The s in the antecedent is meant to be replaced by $pZero_3$, $pOne_3$, or $\neg(pZero_3 \vee pOne_3)$ as appropriate. The intuition of the $Rules$ term is that should the machine read s in state r it should pick exactly one of the rules available to it, and if the head is not present then the tape contents should not change.

The subformula to deal with a specific rule can be broken up as follows:

$$Rule[(r, s) \rightarrow (r', s', D)] = L \wedge B.$$

L describes the behaviour of the machine if the left cell is not the leftmost cell on the tape, B deals with the boundary case where it is.

We will give an example of how $Rule[(q_3, 0) \rightarrow (q_4, 1, \mathit{left})]$ would be handled. That is, the rule that says that if the machine reads a 0 in state q_3 it may write a 1, transition to state q_4 and move the head left. All rules except "do nothing" can be handled similarly, and "do nothing" would merely assert that if the machine reads an accepting state, then nothing changes.

The L part triggers if the head is over the leftmost cell in the triple, and the leftmost cell is not cell 0. It then ensures that in the next computation step the leftmost cell contains 1 and the other cells are unchanged. Since the head leaves the

monitored triples we need no terms to account for it.

$$L = \Big(\neg(\bigwedge_{1\leq i\leq k} \neg pTape_3^i) \wedge pHead_3\Big) \rightarrow \Big(npOne_3 \wedge (Zero_3 \leftrightarrow nZero_3) \wedge (sZero_3 \leftrightarrow nsZero_3) \wedge (One_3 \leftrightarrow nOne_3) \wedge (sOne_3 \leftrightarrow nsOne_3)\Big).$$

In the boundary case the head is over the leftmost cell of the tape, so when it attempts to move left it instead stands still.

$$B = \Big((\bigwedge_{1\leq i\leq k} \neg pTape_3^i) \wedge pHead_3\Big) \rightarrow \Big(npState_3^4 \wedge npOne_3 \wedge npHead_3 (Zero_3 \leftrightarrow nZero_3) \wedge (sZero_3 \leftrightarrow nsZero_3) \wedge (One_3 \leftrightarrow nOne_3) \wedge (sOne_3 \leftrightarrow nsOne_3)\Big).$$

Finally, the $NoHead$ term asserts in the absence of a head the tape contents do not change.

$$NoHead = (\neg pHead_3 \wedge \neg Head_3 \wedge \neg sHead_3) \rightarrow \Big((pOne_3 \leftrightarrow npOne_3) \wedge (nZero_3 \leftrightarrow npZero_3) \wedge (One_3 \leftrightarrow nOne_3) \wedge (Zero_3 \leftrightarrow nZero_3) \wedge (sOne_3 \leftrightarrow nsOne_3) \wedge (sZero_3 \leftrightarrow nsZero_3)\Big).$$

This brings us to the last player, who is trying to guess the first step and central cell chosen by Player Three:

$$\Phi_6 = \{Time_6^i\}_{1\leq i\leq k} \cup \{Tape_6^i\}_{1\leq i\leq k}.$$
$$\gamma_6 = \bigwedge_{i=1}^{k}(Tape_3^i \leftrightarrow Tape_6^i) \wedge \bigwedge_{i=1}^{k}(Time_3^i \leftrightarrow Time_6^i).$$

The construction so far has been polynomial. We now claim that M having an accepting run on w in at most K steps is equivalent to the constructed game having a Nash equilibrium where Players One, Two and Three have the following guaranteed payoffs:

$$\boldsymbol{v}[1] = \frac{2^{2k}-1}{2^{2k}}.$$
$$\boldsymbol{v}[2] = \frac{2^k(2^k-1)-1}{2^k(2^k-1)}.$$
$$\boldsymbol{v}[3] = \frac{(2^k-2)(2^k-1)-1}{(2^k-2)(2^k-1)}.$$

Strictly speaking, only the payoffs of Two and Three are necessary - Player One will be able to attain $\boldsymbol{v}[1]$ utility even if M does not accept w. However, we include One's utility above as it will help us to reason about the profile being in equilibrium.

First, suppose M has an accepting run on w in at most K steps. Consider the profile where Player One randomises over all step/cell combinations with equal weight, and at each step/cell combination plays his variables in accordance to the accepting run. Player Four also randomises over all step/cell combinations with equal weight. Player Two randomises over all computation steps and the first $2^k - 1$ cells. Her other variables she plays in accordance to the run. Player Five likewise randomises over all steps and the first $2^k - 1$ cells. Player Three randomises over the first $2^k - 1$ steps and the $2^k - 2$ cells between the first and last. His other variables he plays in accordance to the run. Player Six randomises over the same $2^k - 1$ steps and the $2^k - 2$ cells.

In such a profile, Players One, Two and Three will satisfy their goals unless their step/cell combination is guessed by their opponent. Given our setup, this will happen with probabilities $1/2^{2k}$, $1/2^k(2^k-1)$ and $1/(2^k-2)(2^k-1)$ respectively, giving us the payoffs $\boldsymbol{v}[1]$, $\boldsymbol{v}[2]$ and $\boldsymbol{v}[3]$. It remains to see that this profile is in equilibrium. Recall that this is equivalent to checking that no player has a pure strategy that will grant them more utility than what they are earning already.

Let us first consider Players Four through Six. Any pure strategy by Player Four is a step/cell pair, and hence, given the play of Player One, has a $1/2^{2k}$ chance of satisfying γ_4. Player Four is thus indifferent between the current situation and any deviation. For Player Five any pure strategy using the first $2^k - 1$ cells will have a $1/2^k(2^k - 1)$ chance of satisfying γ_5, and any other pure strategy 0. Player Five thus likewise has no incentive to deviate. In the same fashion, any pure strategy for Player Six will satisfy γ_6 with probability $1/(2^k - 2)(2^k - 1)$ or 0, so she is also indifferent.

In the case of Player One, observe that no matter what pure strategy he picks, there is a $1/2^{2k}$ chance of Player Four guessing the cell/step component and thus making γ_1 false. It follows that any such strategy will yield at most a $\boldsymbol{v}[1]$ chance of satisfying γ_1. For Player Two, if she picks a pure strategy using the first $2^k - 1$ cells there will likewise be a $1/2^k(2^k-1)$ chance of her step/cell combination being guessed. If she picks a pure strategy using the last cell, she will be unable to satisfy the $Succ_2$ component of γ_2, yielding a utility of 0. For Player Three, any pure strategy using the $2^k - 1$ steps and the $2^k - 2$ cells randomised over by six will have a $1/(2^k-2)(2^k-1)$ chance of being guessed, and any other choice of pure strategy will violate either $Triple$ or $Succ_3$. This establishes that the described profile is in equilibrium.

Next, suppose that no accepting run exists. We claim that in any equilibrium Player One will still obtain a utility of $\boldsymbol{v}[1]$, but either Player Two or three will be unable to secure a payoff of $\boldsymbol{v}[2]$, $\boldsymbol{v}[3]$. For the first part, note that for any choice of step/cell by Player One, the remaining variables can be set to satisfy $Init$, $Final$ and $Cons_1$ unilaterally. It is sufficient to simply respect the initial configuration of the machine at step zero, play an accepting state at step K, and any internally consistent description elsewhere. Any strategy that does not satisfy $Init$, $Final$ and $Cons_1$ is thus dominated and can be excluded from consideration. All that remains is the choice of cell/step and it is easy to see that the only equilibrium play would involve giving every pair equal weight.

Player One's play will thus describe a sequence of 2^k con-

figurations of M, with the initial configuration at step zero and an accepting state at step K. However, as M has no accepting run on w in K steps, this sequence cannot represent a valid computation and a violation must occur somewhere.

If this violation involves the assertion of the presence of more than one head or the $Left_1$, $Right_1$ variables incorrectly specifying the location of the head, we claim that Player Two cannot obtain a utility of $\boldsymbol{v}[2]$.

Observe that in this case there must exist two consecutive cells at some time step where Player One plays one of the following combinations:

Cell i	Cell $i+1$
$Left_1$	$Right_1$
$Left_1$	$Head_1$
$Head_1$	$Head_1$
$Right_1$	$Left_1$
$Head_1$	$Right_1$

In this case, should Player Two play a strategy involving cell i, since she is committed to playing a legal head assignment she will have to disagree with Player One on either cell i or cell $i+1$. This means she will suffer a $1/2^{2k}$ chance of having $MatchOne$ falsified if Player One plays the cell in question. As there is still at least a $1/2^k(2^k-1)$ chance of having the cell/step combination guessed by Player Five, this means the maximum utility Player Two can obtain in this case is $\boldsymbol{v}[2] - 1/2^{2k} + 1/2^{2k}2^k(2^k-1)$. (The last term is to avoid double counting the case where both Player One and Player Five name the same cell/step combination.)

Of course, Player Two may opt in this case not to play any strategies involving cell i. This will however mean that she is randomising over at most (2^k-2) cells, and Player Five will randomise accordingly, meaning the highest utility she can obtain is $\frac{2^k(2^k-2)-1}{2^k(2^k-2)}$.

Suppose now that Player One does not make such a violation. The remaining possibilities for an incorrect run are:

1. The head makes an illegal transition.
2. The tape contents undergo an illegal change.
3. The state undergoes an illegal change.

Let us deal with case 1. Suppose between step t and $t+1$ the head, which is at cell i at t, performs an illegal transition. This could mean moving more than one cell in a direction, moving off the edge of the tape, staying still in a non-accepting state or moving one cell left or right without a justifying transition rule. Observe that neither of these possibilities is consistent with the $Rules$ requirement. As such, should Player Three pick step t and cell i, he will have to disagree with Player One on the movement of the head, thereby running a risk of falsifying his formula should Player One play t and i. This will prevent Player Three from obtaining v_3 utility for the same reasoning as with Player Two.

In case 2, there would exist steps t and $t+1$, and a cell i the contents of which would change without a justifying rule. This, too, would violate $Rules$. For case 3, we note that by the machine state we mean the state variable that occurs in the same cell as the head: the value of the other state variables is of no account. As such, $Rules$ again would be violated as it requires the correct state to be propagated to cell hosting the head. This completes the proof. □

We can adapt this proof to show that ∀GUARANTEENASH is coNEXP-hard. Note that this does not follow immediately: ∀GUARANTEENASH is not simply the complement of ∃GUARANTEENASH. Letting $\boldsymbol{s}$ range over equilibrium profiles, ∀GUARANTEENASH is the question whether:

$$\forall \boldsymbol{s} \,.\, \forall i \,.\, u_i(\boldsymbol{s}) \geq \boldsymbol{v}[i]$$

the complement of ∀GUARANTEENASH is then:

$$\exists \boldsymbol{s} \,.\, \exists i \,.\, u_i(\boldsymbol{s}) < \boldsymbol{v}[i].$$

To show that ∀GUARANTEENASH is coNEXP-hard we need only show that the latter problem is NEXP-hard.

Corollary 1. ∀GUARANTEENASH *is coNEXP-hard.*

Proof. We argue that the proof of Theorem 2 can be adapted to show this. Note that the utilities of Players One, Four, Five and Six did not play a rôle in the proof. Those of Four, Five and Six were omitted entirely, whereas Player One has been seen to achieve $\boldsymbol{v}[1]$ utility in every equilibrium. What remains are Two and Three, and we will argue that those players could be collapsed into a single player.

Introduce a new player into the game constructed in the proof of Theorem 2, Player Seven, with $\gamma_7 = \gamma_2 \wedge \gamma_3$ and $\Phi_7 = \emptyset$. We argue that the Turing machine M accepts w in at most K steps if and only if there exists an $\boldsymbol{s}$ for which:

$$u_7(\boldsymbol{s}) \geq 1 - \frac{(2^k-2)(2^k-1) + 2^k(2^k-1) - 1}{2^k(2^k-1)(2^k-2)(2^k-1)}.$$

This can be seen by replicating the argument in the proof: in the presence of an accepting run, the only way Player Seven can lose utility is if Player Five or Six guesses the same cell/step, which happens with probabilities $\frac{1}{2^k(2^k-1)}$ and $\frac{1}{(2^k-2)(2^k-1)}$ respectively. Adding a term for double counting and simplifying yields the quantity above.

If we call that quantity $\boldsymbol{v}[7]$, we have established that $u_7(\boldsymbol{s}) \geq \boldsymbol{v}[7]$ if and only if M accepts w in at most K steps. If we set the other entries of $\boldsymbol{v}$ to 1 to make sure they do not interfere, we demonstrate that the following question is NEXP-hard:

$$\exists \boldsymbol{s} \,.\, \exists i \,.\, u_i(\boldsymbol{s}) \geq \boldsymbol{v}[i].$$

For the next step, add Player Eight with $\gamma_8 = \neg\gamma_7$ and $\Phi_8 = \emptyset$. As $u_8 = 1 - u_7$ the following question is NEXP-hard as well, letting $\boldsymbol{v}[8] = 1 - \boldsymbol{v}[7]$ and the other entries of $\boldsymbol{v}$ be 0:

$$\exists \boldsymbol{s} \,.\, \exists i \,.\, u_i(\boldsymbol{s}) \leq \boldsymbol{v}[i].$$

It remains to show that the inequality can be made strict.

First, observe that we can increase Player Seven's score, and hence decrease Player Eight's, by an arbitrarily small ϵ of a certain form: let $\gamma_7' = \gamma_7 \vee Pennies$ where $Pennies$ is a matching pennies game over a new set of variables Φ_7' against some new player. This will give Player Seven $1/2^{|\Phi_7'|}$ additional utility, minus a double counting term.

All that remains is to show that we can identify a "sufficiently small" ϵ. By this we mean an ϵ satisfying the following:

$$\exists \boldsymbol{s} \,.\, u_8(\boldsymbol{s}) - \epsilon < \boldsymbol{v}[8] \iff \exists \boldsymbol{s} \,.\, u_8(\boldsymbol{s}) \leq \boldsymbol{v}[8].$$

To see that this is possible, recall that if M does not accept w in K steps, then Player One necessarily specifies an incorrect computation history of the machine. As we have seen in the proof of Theorem 2, such a violation decreases the maximum attainable score of Player Two or Three by a fixed amount. It is thus possible to calculate the maximum attainable utility of Player Seven in the presence of such a violation, which will give us the bounds within which ϵ may reside.

This completes the proof. □

Discussion

The preceding proof raises two related questions. To begin with, one may ask whether six players are necessary. The answer is no, as we have hinted in the proof of the corollary. The reader may convince themselves that one may reduce the number to three in a straightforward fashion by collapsing Players Two and Three, and Four, Five and Six onto each other, in a similar fashion to the proof of the corollary. We used six players to simplify the exposition of the proof. Whether it is further possible to reduce the number to two is a different matter - and an interesting one, as we will see shortly

Second: whether there is a membership result to go with the hardness. Strictly speaking, there is not. As there exist games where every equilibrium requires irrational weights on the strategies chosen (Nash 1951; Bilò and Mavronicolas 2012) we cannot rely on the intuitive approach of guessing a strategy profile and checking whether it is in equilibrium.

One way this problem is addressed in the literature is to restrict attention to two player games, where a rational equilibrium *is* guaranteed to exist (Cottle and Dantzig 1968), which brings us back to the first question. The second way is to consider the notion of an ϵ-equilibrium: a profile of strategies where no player can gain more than ϵ utility by deviating. This problem, ϵ-$\exists$GUARANTEENASH, clearly does belong to NEXP, and the reader can convince themselves that by inserting a sufficiently small ϵ into the proof above we can establish that it is NEXP-complete.

Conclusion

We have shown that the problem of determining whether a Boolean game has a Nash equilibrium which guarantees each player a certain payoff is NEXP-hard. This is the first complexity result about mixed equilibria in the Boolean games framework, and demonstrates that in this instance Boolean games are as difficult as the more general class of Boolean circuit games.

The complexity of many other natural problems remains open, most significantly that of NASH: the task of computing a mixed equilibrium. However, given the difficulty in obtaining this result for normal form games (Daskalakis, Goldberg, and Papadimitriou 2006) one could posit that it is unlikely that this can be achieved with the current tools of complexity theory. It would be interesting to see whether there is an exponential time analogue of PPAD that could lead to a solution to this problem.

Abstract

Two-way regular path queries (2RPQs) have received increased attention recently due to their ability to relate pairs of objects by flexibly navigating graph-structured data. They are present in property paths in SPARQL 1.1, the new standard RDF query language, and in the XML query language XPath. In line with XPath, we consider the extension of 2RPQs with nesting, which allows one to require that objects along a path satisfy complex conditions, in turn expressed through (nested) 2RPQs. We study the computational complexity of answering nested 2RPQs and conjunctions thereof (CN2RPQs) in the presence of domain knowledge expressed in description logics (DLs). We establish tight complexity bounds in data and combined complexity for a variety of DLs, ranging from lightweight DLs (*DL-Lite*, $\mathcal{EL}$) up to highly expressive ones. Interestingly, we are able to show that adding nesting to (C)2RPQs does not affect worst-case data complexity of query answering for any of the considered DLs. However, in the case of lightweight DLs, adding nesting to 2RPQs leads to a surprising jump in combined complexity, from P-complete to EXP-complete.

1 Introduction

Both in knowledge representation and in databases, there has been great interest recently in expressive mechanisms for querying data, while taking into account complex domain knowledge (Calvanese, De Giacomo, and Lenzerini 2008; Glimm et al. 2008). Description Logics (DLs) (Baader et al. 2003), which on the one hand underlie the W3C standard Web Ontology Language (OWL), and on the other hand are able to capture at the intensional level conceptual modeling formalisms like UML and ER, are considered particularly well suited for representing a domain of interest (Borgida and Brachman 2003). In DLs, instance data, stored in a so-called ABox, is constituted by ground facts over unary and binary predicates (*concepts* and *roles*, respectively), and hence resembles data stored in graph databases (Consens and Mendelzon 1990; Barceló et al. 2012). There is a crucial difference, however, between answering queries over graph databases and over DL ABoxes. In the former, the data is assumed to be complete, hence query answering amounts to the standard database task of query evaluation. In the latter, it is typically assumed that the data is incomplete and additional domain knowledge is provided by the DL ontology (or TBox). Hence query answering amounts to the more complex task of computing *certain answers*, i.e., those answers that are obtained from all databases that both contain the explicit facts in the ABox and satisfy the TBox constraints. This difference has driven research in different directions.

In databases, expressive query languages for querying graph-structured data have been studied, which are based on the requirement of relating objects by flexibly navigating the data. The main querying mechanism that has been considered for this purpose is that of one-way and two-way regular path queries (RPQs and 2RPQs) (Cruz, Mendelzon, and Wood 1987; Calvanese et al. 2003), which are queries returning pairs of objects related by a *path* whose sequence of edge labels belongs to a regular language over the (binary) database relations and their inverses. Conjunctive 2RPQs (C2RPQs) (Calvanese et al. 2000) are a significant extension of such queries that add to the navigational ability the possibility of expressing arbitrary selections, projections, and joins over objects related by 2RPQs, in line with conjunctive queries (CQs) over relational databases. Two-way RPQs are present in the property paths in SPARQL 1.1 (Harris and Seaborne 2013), the new standard RDF query language, and in the XML query language XPath (Berglund and others 2010). An additional construct that is present in XPath is the possibility of using *existential test operators*, also known as *nesting*, to express sophisticated conditions along navigation paths. When an existential test $\langle E \rangle$ is used in a 2RPQ E', there will be objects along the main navigation path for E' that match positions of E' where $\langle E \rangle$ appears; such objects are required to be the origin of a path conforming to the (nested) 2RPQ E. It is important to notice that existential tests in general cannot be captured even by C2RPQs, e.g., when tests appear within a transitive closure of an RPQ. Hence, adding nesting effectively increases the expressive power of 2RPQs and of C2RPQs.

In the DL community, query answering has been investigated extensively for a wide range of DLs, with much of the work devoted to CQs. With regards to the complexity of query answering, attention has been paid on the one hand to *combined complexity*, i.e., the complexity measured considering as input both the query and the DL knowledge base (constituted by TBox and ABox), and on the other

hand to *data complexity*, i.e., when only the ABox is considered as input. For expressive DLs that extend $\mathcal{ALC}$, CQ answering is typically coNP-complete in data-complexity (Ortiz, Calvanese, and Eiter 2008), and 2EXP-complete in combined complexity (Glimm et al. 2008; Lutz 2008; Eiter et al. 2009). For lightweight DLs, instead, CQ answering is in AC^0 in data complexity for *DL-Lite* (Calvanese et al. 2007), and P-complete for $\mathcal{EL}$ (Krisnadhi and Lutz 2007). For both logics, the combined complexity is dominated by the NP-completeness of CQ evaluation over plain relational databases. There has also been some work on (2)RPQs and C(2)RPQs. For the very expressive DLs $\mathcal{ZIQ}$, $\mathcal{ZOQ}$, and $\mathcal{ZOI}$, where regular expressions over roles are present also in the DL, a 2EXP upper bound has been shown via techniques based on alternating automata over infinite trees (Calvanese, Eiter, and Ortiz 2009). For the Horn fragments of $\mathcal{SHOIQ}$ and $\mathcal{SROIQ}$, P-completeness in data complexity and EXP/2EXP-completeness in combined complexity are known (Ortiz, Rudolph, and Simkus 2011). For lightweight DLs, tight bounds for answering 2RPQs and C2RPQs have only very recently been established by Bienvenu, Ortiz, and Simkus (2013): for (C)(2)RPQs, data complexity is NL-complete in *DL-Lite* and *DL-Lite*$_\mathcal{R}$, and P-complete in $\mathcal{EL}$ and $\mathcal{ELH}$. For all of these logics, combined complexity is P-complete for (2)RPQs and PSPACE-complete for C(2)RPQs.

Motivated by the expressive power of nesting in XPath and SPARQL, in this paper we significantly advance these latter lines of research on query answering in DLs, and study the impact of adding nesting to 2RPQs and C2RPQs. We establish tight complexity bounds in data and combined complexity for a variety of DLs, ranging from lightweight DLs of the *DL-Lite* and $\mathcal{EL}$ families up to the highly expressive ones of the $\mathcal{SH}$ and $\mathcal{Z}$ families. Our results are summarized in Table 1. For DLs containing at least $\mathcal{ELI}$, we are able to encode away nesting, thus showing that the worst-case complexity of query answering is not affected by this construct. Instead, for lightweight DLs (starting already from *DL-Lite*!), we show that adding nesting to 2RPQs leads to a surprising jump in combined complexity, from P-complete to EXP-complete. We then develop a sophisticated rewriting-based technique that builds on (but significantly extends) the one proposed by Bienvenu, Ortiz, and Simkus (2013), which we use to prove that the problem remains in NL for *DL-Lite*. We thus show that adding nesting to (C)2RPQs does not affect worst-case data complexity of query answering for lightweight DLs.

For lack of space, some proofs have been relegated to the appendix of the long version (Bienvenu et al. 2014).

2 Preliminaries

We briefly recall the syntax and semantics of description logics (DLs). As usual, we assume countably infinite, mutually disjoint sets $\mathsf{N_C}$, $\mathsf{N_R}$, and $\mathsf{N_I}$ of *concept names*, *role names*, and *individuals*. We typically use A for concept names, p for role names, and a, b for individuals. An *inverse role* takes the form p^- where $p \in \mathsf{N_R}$. We let $\mathsf{N_R^\pm} = \mathsf{N_R} \cup \{p^- \mid p \in \mathsf{N_R}\}$ and denote by r elements of $\mathsf{N_R^\pm}$.

A DL knowledge base (KB) consists of a *TBox* and an *ABox*, whose forms depend on the DL in question. In the DL $\mathcal{ELHI}_\bot$, a TBox is defined as a set of *(positive) role inclusions* of the form $r \sqsubseteq r'$ and *negative role inclusions* of the form $r \sqcap r' \sqsubseteq \bot$ with $r, r' \in \mathsf{N_R^\pm}$, and *concept inclusions* of the form $C \sqsubseteq D$, where C and D are *complex concepts* formed according to the following syntax:[1]

$$C ::= \top \mid \bot \mid A \mid \exists r.C \mid C \sqcap C$$

with $A \in \mathsf{N_C}$ and $r \in \mathsf{N_R^\pm}$.

Some of our results refer specifically to the *lightweight DLs* that we define next. $\mathcal{ELHI}$ is the fragment of $\mathcal{ELHI}_\bot$ that has no $\bot$. $\mathcal{ELH}$ and $\mathcal{ELI}$ are obtained by additionally disallowing inverse roles and role inclusions, respectively. *DL-Lite*$_\mathcal{R}$ is also a fragment of $\mathcal{ELHI}_\bot$, in which concept inclusions can only take the forms $B_1 \sqsubseteq B_2$ and $B_1 \sqcap B_2 \sqsubseteq \bot$, for B_i a concept name or concept of the form $\exists r.\top$ with $r \in \mathsf{N_R^\pm}$. *DL-Lite* is the fragment of *DL-Lite*$_\mathcal{R}$ that disallows (positive and negative) role inclusions.

An *ABox* is a set of assertions of the form $C(a)$ or $r(a, b)$, where C is a complex concept, $r \in \mathsf{N_R^\pm}$, and $a, b \in \mathsf{N_I}$. We use $\mathsf{Ind}(\mathcal{A})$ to refer to the set of individuals in $\mathcal{A}$.

Semantics. The semantics of DL KBs is based upon *interpretations*, which take the form $\mathcal{I} = (\Delta^\mathcal{I}, \cdot^\mathcal{I})$, where $\Delta^\mathcal{I}$ is a non-empty set and $\cdot^\mathcal{I}$ maps each $a \in \mathsf{N_I}$ to $a^\mathcal{I} \in \Delta^\mathcal{I}$, each $A \in \mathsf{N_C}$ to $A^\mathcal{I} \subseteq \Delta^\mathcal{I}$, and each $p \in \mathsf{N_R}$ to $p^\mathcal{I} \subseteq \Delta^\mathcal{I} \times \Delta^\mathcal{I}$.[2] The function $\cdot^\mathcal{I}$ can be straightforwardly extended to complex concepts and roles. In the case of $\mathcal{ELHI}_\bot$, this is done as follows: $\top^\mathcal{I} = \Delta^\mathcal{I}$, $\bot^\mathcal{I} = \emptyset$, $(p^-)^\mathcal{I} = \{(c, d) \mid (d, c) \in p^\mathcal{I}\}$, $(\exists r.C)^\mathcal{I} = \{c \mid \exists d : (c, d) \in r^\mathcal{I}, d \in C^\mathcal{I}\}$, and $(C \sqcap D)^\mathcal{I} = C^\mathcal{I} \cap D^\mathcal{I}$. An interpretation $\mathcal{I}$ satisfies an inclusion $G \sqsubseteq H$ if $G^\mathcal{I} \subseteq H^\mathcal{I}$, and it satisfies an assertion $C(a)$ (resp., $r(a, b)$) if $a^\mathcal{I} \in A^\mathcal{I}$ (resp., $(a^\mathcal{I}, b^\mathcal{I}) \in r^\mathcal{I}$). A *model* of a KB $(\mathcal{T}, \mathcal{A})$ is an interpretation $\mathcal{I}$ which satisfies all inclusions in $\mathcal{T}$ and assertions in $\mathcal{A}$.

Complexity. In addition to P and (co)NP, our results refer to the complexity classes NL (non-deterministic logarithmic space), PSPACE (polynomial space), and (2)EXP ((double) exponential time), cf. (Papadimitriou 1993).

3 Nested Regular Path Queries

We now introduce our query languages. In RPQs, nested RPQs and their extensions, *atoms* are given by (nested) regular expressions whose symbols are *roles*. The set Roles of roles contains $\mathsf{N_R^\pm}$, and all *test roles* of the forms $\{a\}?$ and $A?$ with $a \in \mathsf{N_I}$ and $A \in \mathsf{N_C}$. They are interpreted as $(\{a\}?)^\mathcal{I} = (a^\mathcal{I}, a^\mathcal{I})$, and $(A?)^\mathcal{I} = \{(o, o) \mid o \in A^\mathcal{I}\}$.

Definition 3.1. *A* nested regular expression *(NRE), denoted by E, is constructed according to the following syntax:*

$$E ::= \sigma \mid E \cdot E \mid E \cup E \mid E^* \mid \langle E \rangle$$

where $\sigma \in \mathsf{Roles}$.

[1] We slightly generalize the usual $\mathcal{ELHI}_\bot$ by allowing for negative role inclusions.

[2] Note that we do not make the *unique name assumption* (UNA), but all of our results continue to hold if the UNA is adopted.

	2RPQ		C2RPQ		N2RPQ / CN2RPQ	
	data	combined	data	combined	data	combined

Table 1: Complexity of query answering. The 'c' indicates completeness, the 'h' hardness. New results are marked in bold. For existing results, refer to (Bienvenu, Ortiz, and Simkus 2013; Pérez, Arenas, and Gutierrez 2010; Barceló Baeza 2013; Calvanese, Eiter, and Ortiz 2009; Ortiz, Rudolph, and Simkus 2011) and references therein.

We assume a countably infinite set $\mathsf{N_V}$ *of* variables *(disjoint from* $\mathsf{N_C}$*,* $\mathsf{N_R}$*, and* $\mathsf{N_I}$*). Each* $t \in \mathsf{N_V} \cup \mathsf{N_I}$ *is a* term*. An* atom *is either a* concept atom *of the form* $A(t)$*, with* $A \in \mathsf{N_C}$ *and* t *a term, or a* role atom *of the form* $E(t, t')$*, with* E *an NRE and* t, t' *two (possibly equal) terms.*

A nested two-way regular path query *(N2RPQ)* $q(x, y)$ *is an atom of the form* $E(x, y)$*, where* E *is an NRE and* x, y *are two distinct variables. A* conjunctive N2RPQ *(CN2RPQ)* $q(\vec{x})$ *with* answer variables $\vec{x}$ *has the form* $\exists \vec{y}.\varphi$*, where* φ *is a conjunction of atoms whose variables are among* $\vec{x} \cup \vec{y}$*.*

A (plain) regular expression (RE) is an NRE that does not have subexpressions of the form $\langle E \rangle$. Two-way regular path queries *(2RPQs) and* conjunctive 2RPQs *(C2RPQs) are defined analogously to N2RPQs and CN2RPQs but allowing only plain REs in atoms.*

Given an interpretation $\mathcal{I}$, the semantics of an NRE E is defined by induction on its structure:

$$(E_1 \cdot E_2)^{\mathcal{I}} = E_1^{\mathcal{I}} \circ E_2^{\mathcal{I}},$$
$$(E_1 \cup E_2)^{\mathcal{I}} = E_1^{\mathcal{I}} \cup E_2^{\mathcal{I}},$$
$$(E_1^*)^{\mathcal{I}} = (E_1^{\mathcal{I}})^*,$$
$$\langle E \rangle^{\mathcal{I}} = \{(o, o) \mid \text{there is } o' \in \Delta^{\mathcal{I}} \text{ s.t. } (o, o') \in E^{\mathcal{I}}\}.$$

A *match* for a C2NRPQ $q(\vec{x}) = \exists \vec{y}.\varphi$ in an interpretation $\mathcal{I}$ is a mapping from the terms in φ to $\Delta^{\mathcal{I}}$ such that (i) $\pi(a) = a^{\mathcal{I}}$ for every individual a of φ, (ii) $\pi(x) \in A^{\mathcal{I}}$ for every concept atom $A(x)$ of φ, and (iii) $(\pi(x), \pi(y)) \in E^{\mathcal{I}}$ for every role atom $E(x, y)$ of φ. Let $\mathsf{ans}(q, \mathcal{I}) = \{\pi(\vec{x}) \mid \pi \text{ is a match for } q \text{ in } \mathcal{I}\}$. An individual tuple $\vec{a}$ with the same arity as $\vec{x}$ is called a *certain answer* to q over a KB $\langle \mathcal{T}, \mathcal{A} \rangle$ if $(\vec{a})^{\mathcal{I}} \in \mathsf{ans}(q, \mathcal{I})$ for every model $\mathcal{I}$ of $\langle \mathcal{T}, \mathcal{A} \rangle$. We use $\mathsf{ans}(q, \langle \mathcal{T}, \mathcal{A} \rangle)$ to denote the set of all certain answers to q over $\langle \mathcal{T}, \mathcal{A} \rangle$. In what follows, by *query answering*, we will mean the problem of deciding whether $\vec{a} \in \mathsf{ans}(q, \langle \mathcal{T}, \mathcal{A} \rangle)$.

Example 3.1. We consider an ABox of advisor relationships of PhD holders[3]. We assume an *advisor* relation between nodes representing academics. There are also nodes for theses, universities, research topics, and countries, related in the natural way via roles *wrote*, *subm*(itted), *topic*, and *loc*(ation). We give two queries over this ABox.

$$q_1(x, y) = (advisor \cdot \langle wrote \cdot topic \cdot Physics? \rangle)^* (x, y)$$

[3]Our examples are inspired by the *Mathematics Genealogy Project (http://genealogy.math.ndsu.nodak.edu/)*.

Query q_1 is an N2RPQ that retrieves pairs of a person x and an academic ancestor y of x such that all people on the path from x to y (including y itself) wrote a thesis in Physics.

$$q_2(x, y, z) = advisor^-(x, z), \quad advisor^*(x, w),$$
$$advisor^- \cdot \langle wrote \cdot \langle topic \cdot DBs? \rangle \cdot subm \cdot loc \cdot \{usa\}? \rangle (y, z),$$
$$\left(advisor \cdot \langle wrote \cdot \langle topic \cdot Logic? \rangle \cdot subm \cdot loc \cdot EU? \rangle\right)^* (y, w)$$

Query q_2 is a CN2RPQ that looks for triples of individuals x, y, z such that x and y have both supervised z, who wrote a thesis on Databases and who submitted this thesis to a university in the USA. Moreover, x and y have a common ancestor w, and all people on the path from x to w, including w, must have written a thesis in Logic and must have submitted this thesis to a university in an EU country. ■

It will often be more convenient to deal with an automata-based representation of (C)N2RPQs, which we provide next.

Definition 3.2. *A* nested NFA *(n-NFA) has the form* $(\mathbf{A}, s_0, F_0)$ *where* $\mathbf{A}$ *is an indexed set* $\{\alpha_1, \ldots, \alpha_n\}$*, where each* $\alpha_l \in \mathbf{A}$ *is an automaton of the form* (S, s, δ, F)*, where* S *is a set of states,* $s \in S$ *is the initial state,* $F \subseteq S$ *is the set of final states, and*

$$\delta \subseteq S \times (\mathsf{Roles} \cup \{\langle j_1, \ldots, j_k \rangle \mid l < j_i \leq n, \text{ for } i \in \{1, \ldots, k\}\}) \times S$$

We assume that the sets of states of the automata in $\mathbf{A}$ *are pairwise disjoint, and we require that* $\{s_0\} \cup F_0$ *are states of a single automaton in* $\mathbf{A}$*. If in each transition* $(s, \langle j_1, \ldots, j_k \rangle, s')$ *of each automaton in* $\mathbf{A}$ *we have* $k = 1$*, then the n-NFA is called* reduced*.*

When convenient notationally, we will denote an *n*-NFA $(\mathbf{A}, s_0, F_0)$ by $\mathbf{A}_{s_0, F_0}$. Moreover, we will use S_i, δ_i, and F_i to refer to the states, transition relation, and final states of α_i.

Definition 3.3. *Given an interpretation* $\mathcal{I}$*, we define* $\mathbf{A}^{\mathcal{I}}_{s_0, F_0}$ *inductively as follows. Let* α_l *be the (unique) automaton in* $\mathbf{A}$ *such that* $\{s_0\} \cup F_0 \subseteq S_l$*. Then* $(o, o') \in \mathbf{A}^{\mathcal{I}}_{s_0, F_0}$ *if there is a sequence* $s_0 o_0 s_1 \cdots o_{k-1} s_k o_k$*, for* $k \geq 0$*, such that* $o_0 = o$*,* $o_k = o'$*,* $s_k \in F_0$*, and for* $i \in \{1, \ldots, k\}$ *there is a transition* $(s_{i-1}, \sigma_i, s_i) \in \delta_l$ *such that either*

- $\sigma_i \in \mathsf{Roles}$ *and* $(o_{i-1}, o_i) \in \sigma_i^{\mathcal{I}}$*, or*
- $\sigma_i = \langle j_1, \ldots, j_k \rangle$ *such that, for every* $m \in \{1, \ldots, k\}$*, there exists* $o_m \in \Delta^{\mathcal{I}}$ *with* $(o_i, o_m) \in \mathbf{A}^{\mathcal{I}}_{s', F'}$*, where* s' *and* F' *are the initial and final states of* α_{j_m} *respectively.*

Note that an n-NFA $\mathbf{A}_{s_0,F_0}$ such that there are no transitions of the form $(s, \langle j_1, \ldots, j_k \rangle, s')$ in the unique α_l with $\{s_0\} \cup F_0 \subseteq S_l$ is equivalent to a standard NFA.

For every NRE E one can construct in polynomial time an n-NFA $\mathbf{A}_{s_0,F_0}$ such that $E^{\mathcal{I}} = \mathbf{A}^{\mathcal{I}}_{s_0,F_0}$ for every interpretation $\mathcal{I}$. This is an almost immediate consequence of the correspondence between regular expressions and finite state automata. Moreover, any n-NFA can be transformed into an equivalent reduced n-NFA by introducing linearly many additional states. In the following, unless stated otherwise, we assume all n-NFAs are reduced.

4 Upper Bounds via Reductions

In this section, we derive some upper bounds on the complexity of answering (C)N2RPQs in different DLs, by means of reductions to other problems. For simplicity, we assume in the rest of this section that query atoms do not employ test roles of the form $\{a\}?$. This is without loss of generality, since each symbol $\{a\}?$ can be replaced by $A_a?$ for a fresh concept name A_a, by adding the ABox assertion $A_a(a)$.

We start by showing that answering CN2RPQs can be polynomially reduced to answering non-nested C2RPQs using TBox axioms that employ inverses, conjunction on the left, and qualified existential restrictions.

Proposition 4.1. *For each CN2RPQ q, one can compute in polynomial time an $\mathcal{ELI}$ TBox $\mathcal{T}'$ and C2RPQ q' such that $\mathsf{ans}(q, \langle \mathcal{T}, \mathcal{A} \rangle) = \mathsf{ans}(q', \langle \mathcal{T} \cup \mathcal{T}', \mathcal{A} \rangle)$ for every KB $\langle \mathcal{T}, \mathcal{A} \rangle$.*

Proof. Let q be an arbitrary CN2RPQ whose role atoms are given by n-NFAs, that is, they take the form $\mathbf{A}_{s_0,F_0}(x, y)$.

For each atom $\mathbf{A}_{s_0,F_0}(x, y)$ in q and each $\alpha_i \in \mathbf{A}$, we use a fresh concept name A_s for each state $s \in S_i$, and define a TBox $\mathcal{T}_{\alpha_i}$ that contains:

- $\top \sqsubseteq A_f$ for each $f \in F_i$,
- $\exists r.A_{s'} \sqsubseteq A_s$ for each $(s, r, s') \in \delta_i$ with $r \in \mathsf{N}_\mathsf{R}^\pm$,
- $A_{s'} \sqcap A \sqsubseteq A_s$ for each $(s, A?, s') \in \delta_i$ with $A \in \mathsf{N}_\mathsf{C}$, and
- $A_{s'} \sqcap A_{s_j} \sqsubseteq A_s$ for each $(s, \langle j \rangle, s') \in \delta_i$, with s_j the initial state of α_j.

We denote by $\mathcal{T}_\mathbf{A}$ the union of all $\mathcal{T}_{\alpha_i}$ with $\alpha_i \in \mathbf{A}$, and define $\mathcal{T}'$ as the union of $\mathcal{T}_\mathbf{A}$ for all atoms $\mathbf{A}_{s_0,F_0}(x, y) \in q$. To obtain the query q' we replace each atom $\mathbf{A}_{s_0,F_0}(x, y)$ by the atom $\alpha'_i(x, y)$, where α_i is the unique automaton in $\mathbf{A}$ with $\{s_0\} \cup F_0 \subseteq S_i$, and α'_i is obtained from α_i by replacing each transition of the form $(s, \langle j \rangle, s') \in \delta_i$ with $(s, A_{s_j}?, s')$, for s_j the initial state of α_j. Note that each α'_i is a standard NFA. We show in the appendix that $\mathsf{ans}(q, \langle \mathcal{T}, \mathcal{A} \rangle) = \mathsf{ans}(q', \langle \mathcal{T} \cup \mathcal{T}', \mathcal{A} \rangle)$, for every KB $\langle \mathcal{T}, \mathcal{A} \rangle$. □

It follows that in every DL that contains $\mathcal{ELI}$, answering CN2RPQs is no harder than answering plain C2RPQs. From existing upper bounds for C2RPQs (Calvanese, Eiter, and Ortiz 2009; Ortiz, Rudolph, and Simkus 2011), we obtain:

Corollary 4.2. *Answering CN2RPQs is:*

- *in* 2EXP *in combined complexity for all DLs contained in $\mathcal{SHIQ}$, $\mathcal{SHOI}$, $\mathcal{ZIQ}$, or $\mathcal{ZOI}$.*
- *in* EXP *in combined complexity and* P *in data complexity for all DLs contained in Horn-$\mathcal{SHOIQ}$.*

We point out that the 2EXP upper bound for expressive DLs can also be inferred, without using the reduction above, from the existing results for answering C2RPQs in $\mathcal{ZIQ}$ and $\mathcal{ZOI}$ (Calvanese, Eiter, and Ortiz 2009).[4] Indeed, these DLs support regular role expressions as concept constructors, and a nested expression $\langle E \rangle$ in a query can be replaced by a concept $\exists E.\top$ (or by a fresh concept name A_E if the axiom $\exists E.\top \sqsubseteq A_E$ is added to the TBox). Hence, in $\mathcal{ZIQ}$ and $\mathcal{ZOI}$, nested expressions provide no additional expressiveness and CN2RPQs and C2RPQs coincide.

The construction used in Proposition 4.1 also allows us to reduce the evaluation of a N2RPQ to standard reasoning in any DL that contains $\mathcal{ELI}$.

Proposition 4.3. *For every N2RPQ q and every pair of individuals a, b, one can compute in polynomial time an $\mathcal{ELI}$ TBox $\mathcal{T}'$, and a pair of assertions $A_b(b)$ and $A_s(a)$ such that $(a, b) \in \mathsf{ans}(q, \langle \mathcal{T}, \mathcal{A} \rangle)$ iff $\langle \mathcal{T} \cup \mathcal{T}', \mathcal{A} \cup \{A_b(b)\} \rangle \models A_s(a)$, for every DL KB $\langle \mathcal{T}, \mathcal{A} \rangle$.*

From this and existing upper bounds for instance checking in DLs, we easily obtain:

Corollary 4.4. *Answering N2RPQs is in* EXP *in combined complexity for every DL that contains $\mathcal{ELI}$ and is contained in $\mathcal{SHIQ}$, $\mathcal{SHOI}$, $\mathcal{ZIQ}$, or $\mathcal{ZOI}$.*

5 Lower Bounds

The upper bounds we have stated in Section 4 are quite general, and in most cases worst-case optimal.

The 2EXP upper bound stated in the first item of Corollary 4.2 is optimal already for C2RPQs and $\mathcal{ALC}$. Indeed, the 2EXP hardness proof for conjunctive queries in $\mathcal{SH}$ by Eiter et al. (2009) can be adapted to use an $\mathcal{ALC}$ TBox and a C2RPQ. Also the EXP bounds in Corollaries 4.2 and 4.4 are optimal for all DLs that contain $\mathcal{ELI}$, because standard reasoning tasks like satisfiability checking are already EXP-hard in this logic (Baader, Brandt, and Lutz 2008). For the same reasons, the P bound for data complexity in Corollary 4.2 is tight for $\mathcal{EL}$ and its extensions (Calvanese et al. 2006).

However, for the lightweight DLs *DL-Lite*$_\mathcal{R}$ and $\mathcal{EL}$, the best combined complexity lower bounds we have are NL (resp., P) for N2RPQs and PSPACE for CN2RPQs, inherited from the lower bounds for (C)NRPQs (Bienvenu, Ortiz, and Simkus 2013). This leaves a significant gap with respect to the EXP upper bounds in Corollaries 4.2 and 4.4.

We show next that these upper bounds are tight. This is the one of the core technical results of this paper, and probably the most surprising one: already evaluating one N2RPQ in the presence of a *DL-Lite* or $\mathcal{EL}$ TBox is EXP-hard.

Theorem 5.1. *In DL-Lite and $\mathcal{EL}$, N2RPQ answering is* EXP*-hard in combined complexity.*

Proof. We provide a reduction from the word problem for *Alternating Turing Machines (ATMs)* with polynomially

[4] For queries that do not contain inverse roles, that is, (1-way) CRPQs, the same applies to $\mathcal{ZOQ}$ and its sublogics.

bounded space, which is known to be EXP-hard (Chandra, Kozen, and Stockmeyer 1981). An ATM is given as a tuple $M = (\Sigma, S_\exists, S_\forall, \delta, s_{init}, s_{acc}, s_{rej})$, where Σ is an *alphabet*, $S_\exists$ is a set of *existential states*, $S_\forall$ is a set of *universal states*, $\delta \subseteq (S_\exists \cup S_\forall) \times \Sigma \cup \{\mathfrak{b}\} \times (S_\exists \cup S_\forall) \times \Sigma \cup \{\mathfrak{b}\} \times \{-1, 0, +1\}$ is a *transition relation*, $\mathfrak{b}$ is the blank symbol, and $s_{init}, s_{acc}, s_{rej} \in S_\exists$ are the *initial state*, the *acceptance state* and the *rejection state*, respectively.

Consider a word $w \in \Sigma^*$. We can w.l.o.g. assume that $\Sigma = \{0, 1\}$, that M uses only $|w|$ tape cells and that $|w| \geq 1$. Let $m = |w|$, and, for each $1 \leq i \leq m$, let $w(i)$ denote the ith symbol of w. Let $S = S_\exists \cup S_\forall$. We make the following further assumptions:

(i) The initial state is not a final state: $s_{init} \notin \{s_{acc}, s_{rej}\}$.
(ii) Before entering a state s_{acc} or s_{rej}, M writes $\mathfrak{b}$ in all m tape cells.
(iii) There exist functions $\delta_1, \delta_2 : S \times \Sigma \cup \{\mathfrak{b}\} \to S \times \Sigma \cup \{\mathfrak{b}\} \times \{-1, 0, +1\}$ such that $\{\delta_1(s, \sigma), \delta_2(s, \sigma)\} = \{(s', \sigma', d) \mid (s, \sigma, s', \sigma', d) \in \delta\}$ for every $s \in S \setminus \{s_{acc}, s_{rej}\}$ and $\sigma \in \Sigma \cup \{\mathfrak{b}\}$. In other words, non-final states of M give rise to exactly two successor configurations described by the functions δ_1, δ_2.

Note that the machine M can be modified in polynomial time to ensure (i-iii), while preserving the acceptance of w.

We next show how to construct in polynomial time a *DL-Lite* KB $\mathcal{K} = (\mathcal{T}, \mathcal{A})$ and a query q such that M accepts w iff $a \in \mathsf{ans}(q, \mathcal{K})$ (we return to $\mathcal{EL}$ later). The high-level idea underlying the reduction is to use a KB to enforce a tree that contains all possible computations of M on w. The query q selects a computation in this tree and verifies that it corresponds to a proper, error-free, accepting run.

Generating the tree of transitions. First we construct $\mathcal{K}$, which enforces a tree whose edges correspond to the possible transitions of M. More precisely, each edge encodes a transition together with the resulting position of the read/write head of M, and indicates whether the transition is given by δ_1 or δ_2. This is implemented using role names $r_{p,t,i}$, where $p \in \{1, 2\}$, $t \in \delta$, and $0 \leq i \leq m + 1$. To mark the nodes that correspond to the initial (resp., a final) configuration of M, we employ the concept name A_{init} (resp., A_{final}), and we use $A_\exists$ and $A_\forall$ to store the transition type.

We let $\mathcal{A} = \{A_{init}(a), A_\exists(a)\}$, and then we initiate the construction of the tree by including in $\mathcal{T}$ the axiom

$$A_{init} \sqsubseteq \exists r_{p,(s_{init},\sigma,s',\sigma',d),1+d}. \tag{1}$$

for each $\sigma \in \Sigma \cup \{\mathfrak{b}\}$ and $p \in \{1, 2\}$ such that $\delta_p(s_{init}, \sigma) = (s', \sigma', d)$. To generate further transitions, $\mathcal{T}$ contains

$$\exists r^-_{p,(s,\sigma,s',\sigma',d),i} \sqsubseteq \exists r_{p',(s',\sigma^*,s'',\sigma'',d'),i+d'} \tag{2}$$

for each $(s, \sigma, s', \sigma', d) \in \delta$, $1 \leq i \leq m$, $\sigma^* \in \Sigma \cup \{\mathfrak{b}\}$ and $p, p' \in \{1, 2\}$ such that $\delta_{p'}(s', \sigma^*) = (s'', \sigma'', d')$. Note that a transition $t' = (s', \sigma^*, s'', \sigma'', d') \in \delta$ can follow $t = (s, \sigma, s', \sigma', d) \in \delta$ only if σ^* is the symbol written on tape cell i, for i the position of the read/write head after executing t. This is not guaranteed by (2). Instead, we "overestimate" the possible successive transitions, and use the query q to select paths that correspond to a proper computation.

We complete the definition of $\mathcal{T}$ by adding inclusions to label the nodes according to the type of states resulting from transitions. For each $1 \leq i \leq m$, $p \in \{1, 2\}$ and transition $(s, \sigma, s', \sigma', d) \in \delta$, we have the axiom

$$\exists r^-_{p,(s,\sigma,s',\sigma',d),i} \sqsubseteq A_Q, \text{ where}$$

- $A_Q = A_{final}$ if $s' \in \{s_{acc}, s_{rej}\}$,
- $A_Q = A_\exists$, if $s' \in S_\exists \setminus \{s_{acc}, s_{rej}\}$, and
- $A_Q = A_\forall$, if $s' \in S_\forall \setminus \{s_{acc}, s_{rej}\}$.

We turn to the construction of the query q, for which we employ the *n*-NFA representation. We construct an *n*-NFA $\alpha_q = (\mathbf{A}, s, F)$ where $\mathbf{A}$ has $m+1$ automata $\{\alpha_0, \ldots, \alpha_m\}$. Intuitively, the automaton α_0 will be responsible for traversing the tree representing candidate computation paths. At nodes corresponding to the end of a computation path, α_0 launches $\alpha_1, \ldots, \alpha_m$ which "travel" back to the root of the tree and test for the absence of errors along the way. We start by defining the tests $\alpha_1, \ldots, \alpha_m$. Afterwards we define α_0, which selects a set of paths that correspond to a full computation, and launches these tests at the end of each path.

Testing the correctness of a computation path. For each $1 \leq l \leq m$, the automaton $\alpha_l = (S_l, s_l, \delta_l, F_l)$ is built as follows. We let $S_l = \{\sigma_l \mid \sigma \in \Sigma\} \cup \{\mathfrak{b}_l\} \cup \{s'_l\}$. That is, S_l contains a copy of $\Sigma \cup \{\mathfrak{b}\}$ plus the additional state s'_l. We define the initial state as $s_l = \mathfrak{b}_l$ and let $F_l = \{s'_l\}$. Finally, the transition relation δ_l contains the following tuples:

(T1) $(\sigma_l, r^-_{p,(s,\sigma,s',\sigma',d),i}, \sigma_l)$ for all $1 \leq i \leq m$, $p \in \{1, 2\}$, all transitions $(s, \sigma, s', \sigma', d) \in \delta$, and each $\sigma_l \in S_l \setminus \{s'_l\}$ with $l \neq i - d$;
(T2) $(\sigma'_l, r^-_{p,(s,\sigma,s',\sigma',d),i}, \sigma_l)$ for all $1 \leq i \leq m$, $s \in S$ and $p \in \{1, 2\}$ with $\delta_p(s, \sigma) = (s', \sigma', d)$ and $l = i - d$;
(T3) $(\sigma_l, A_{init}?, s'_l)$ for $\sigma = w(l)$.

The working of α_l can be explained as follows. Each state $\sigma_l \in S_l \setminus \{s'_l\}$ corresponds to one of the symbols that may be written in position l of the tape during a run of M. When α_l is launched at some node in a computation tree induced by $\mathcal{K}$, it attempts to travel up to the root node, and the only reason it may fail is when a wrong symbol is written in position l at some point in the computation path. Recall that in each final configuration of M, all symbols are set to the blank symbol, and thus the initial state of α_l is $\mathfrak{b}_l$.

Consider a word $w' \in \mathsf{Roles}^*$ of the form

$$r^-_{p_k,t_k,i_k} \cdots r^-_{p_1,t_1,i_1} \cdot A_{init}? \tag{3}$$

that describes a path from some node in the tree induced by $\mathcal{K}$ up to the root node a. We claim that w' is accepted by every α_l ($1 \leq l \leq m$) just in the case that $t_1, \ldots, t_k$ is a correct sequence of transitions. To see why, first suppose that every α_l accepts w', and let $(pos_0, st_0, tape_0)$ be the tuple with $pos_0 = 1$, $st_0 = s_{init}$ and $tape_0$ contains for each $1 \leq l \leq m$, the symbol σ_l corresponding to the state of α_l when reading A_{init}. Clearly, due to (T3), the tuple $(pos_0, st_0, tape_0)$ describes the initial configuration of M on input w. For $1 \leq j \leq k$, if $t_j = (s, \sigma, s', \sigma', d)$, then we define $(pos_j, st_j, tape_j)$ as follows: $pos_j = i_j$, $st_j = s'$, and $tape_j$ contains for each $1 \leq i \leq m$, the state of α_i when reading $r^-_{p_j,t_j,i_j}$. A simple inductive argument

shows that for every $1 \leq j \leq k$, the tuple $(pos_j, st_j, tape_j)$ describes the configuration of M after applying the transitions $t_1, \ldots, t_j$ from the initial configuration. Indeed, let us assume that $(pos_{j-1}, st_{j-1}, tape_{j-1})$ correctly describes the configuration after executing $t_1, \ldots, t_{j-1}$ and $t_j = (s, \sigma, s', \sigma', d)$. After executing t_j, the read/write head is in position $pos_{j-1} + d$ and the state is s'. Since the only way to enforce an $r^-_{p_j,t_j,i_j}$-edge is via axioms (1) and (2), we must have $pos_j = pos_{j-1} + d$ and $st_j = s'$. It remains to show that $tape_j$ describes the tape contents after executing t_j. Consider some position $1 \leq l \leq m$. There are two cases:

1. $l \neq i_j - d$. In this case, we know that the symbol in position l is not modified by executing t_j. We have to show that $\sigma_l \in tape_{j-1}$ implies $\sigma_l \in tape_j$. This follows from the construction of α_l. In particular, when reading $r_{p_j,t_j,i_j}{}^-$, it must employ a transition from (T1).
2. $l = i_j - d$. In this case, after executing t_j, we must have σ' in position l. We have to show that $\sigma_l \in tape_{j-1}$ implies $\sigma'_l \in tape_j$. This again follows from the construction of α_l. In particular, when reading $r_{p_j,t_j,i_j}{}^-$, there is only one possible transition available in (T2), namely $(\sigma'_l, r_{p_j,t_j,i_j}{}^-, \sigma_l)$.

Conversely, it is easy to see that any word of the form (3) that appears in the tree induced by $\mathcal{K}$ and represents a correct computation path will be accepted by all of the α_l.

Selecting a proper computation. It remains to define α_0, which selects a subtree corresponding to a full candidate computation of M, and then launches the tests defined above at the end of each path. We let $\alpha_0 = (S_0, s_0, \delta_0, F_0)$, where $S_0 = \{s_\downarrow, c_L, c_R, s_\uparrow, s_\updownarrow, s_{test}, s_f\}$, $s_0 = s_\downarrow$, $F_0 = \{s_f\}$, and δ_0 is defined next.

The automaton operates in two main modes: moving down the tree away from the root and moving back up towards the root. Depending on the type of the state of M, in state $s_\downarrow$ the automaton either selects a child node to process next, or chooses to launch the test automata. If the tests are successful, it switches to moving up. To this end, δ_0 has the following transitions:

$$(s_\downarrow, A_\exists?, c_L), (s_\downarrow, A_\exists?, c_R), (s_\downarrow, A_\forall?, c_L),$$
$$(s_\downarrow, A_{final}?, s_{test}), \text{ and } (s_{test}, \langle 1, \ldots, m\rangle, s_\uparrow).$$

The transitions that implement a step down or up are:

- $(c_L, r_{1,t,i}, s_\downarrow)$ for every $1 \leq i \leq m$ and $t \in \delta$,
- $(c_R, r_{2,t,i}, s_\downarrow)$ for every $1 \leq i \leq m$ and $t \in \delta$,
- $(s_\uparrow, r^-_{1,t,i}, s_\updownarrow)$ for every $1 \leq i \leq m$ and $t \in \delta$, and
- $(s_\uparrow, r^-_{2,t,i}, s_\uparrow)$ for every $1 \leq i \leq m$ and $t \in \delta$.

After making a step up from the state $s_\uparrow$ via an $r^-_{1,t,i}$-edge, the automaton enters the state $s_\updownarrow$. Depending on the encountered state of M, the automaton decides either to verify the existence of a computation tree for the alternative transition, to keep moving up, or to accept the word. This is implemented using the following transitions of δ_0:

$$(s_\updownarrow, ?A_\forall, c_R), (s_\updownarrow, ?A_\exists, s_\uparrow), \text{ and } (s_\updownarrow, ?A_{init}, s_f).$$

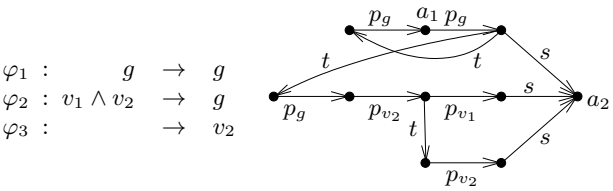

Figure 1: Example ABox in the proof of Theorem 5.2

To conclude the definition of $\alpha_q = (\mathbf{A}, s, F)$, set $s = s_\downarrow$ and $F = \{s_f\}$. Note that α_q has a constant number of states, so it can be converted into an equivalent NRE E_q in polynomial time. The desired query is $q(x, y) = E_q(x, y)$.

The above *DL-Lite* TBox $\mathcal{T}$ can be easily rephrased in $\mathcal{EL}$. Indeed, we simply take a fresh concept name $A_{p,t,i}$ for each role $r_{p,t,i}$, and replace every axiom $C \sqsubseteq \exists r_{p,t,i}$ by $C \sqsubseteq \exists r_{p,t,i}.A_{p,t,i}$ and every axiom $\exists r^-_{p,t,i} \sqsubseteq C$ by $A_{p,t,i} \sqsubseteq C$. $\square$

The above lower bound for answering N2RPQs hinges on the support for existential concepts in the right-hand-side of inclusions. If they are disallowed, then one can find a polynomial time algorithm (Pérez, Arenas, and Gutierrez 2010). However, it was open until now whether the polynomial-time upper bound is optimal. We next prove P-hardness of the problem, already for plain graph databases.

Theorem 5.2. *Given as input an N2RPQ q, a finite interpretation $\mathcal{I}$ and a pair $(o, o') \in \Delta^\mathcal{I} \times \Delta^\mathcal{I}$, it is* P*-hard to check whether $(o, o') \in \mathsf{ans}(q, \mathcal{I})$.*

Proof. To simplify the presentation, we prove the lower bound for a slight reformulation of the problem. In particular, we show P-hardness of deciding $\vec{c} \in \mathsf{ans}(q, \langle \emptyset, \mathcal{A}\rangle)$, where q is an N2RPQ and $\mathcal{A}$ is an ABox with assertions only of the form $A(a)$ or $r(a, b)$, where $A \in \mathsf{N_C}$ and $r \in \mathsf{N_R}$.

We provide a logspace reduction from the classical P-complete problem of checking entailment in propositional definite Horn theories. Assume a set $T = \{\varphi_1, \ldots, \varphi_n\}$ of definite clauses over a set of propositional variables V, where each φ_i is represented as a rule $v_1 \wedge \ldots \wedge v_m \rightarrow v_{m+1}$.

Given a variable $g \in V$, we define an ABox $\mathcal{A}$, an N2RPQ q, and tuple (a_1, a_2) such that $T \models g$ iff $(a_1, a_2) \in \mathsf{ans}(q, \langle \emptyset, \mathcal{A}\rangle)$. We may assume w.l.o.g. that $\varphi_1 = g \rightarrow g$. We define the desired ABox as $\mathcal{A} = \mathcal{A}_1 \cup \mathcal{A}_2$, using the role names s, t, and p_v, where $v \in V$. The ABox $\mathcal{A}_1$ simply encodes T and contains for every $\varphi_i = v_1 \wedge \ldots \wedge v_m \rightarrow v_{m+1}$, the following assertions:

$$p_{v_{m+1}}(e^i_{m+1}, e^i_m), \ldots, p_{v_1}(e^i_1, e^i_0), s(e^i_0, f).$$

The ABox $\mathcal{A}_2$ links variables in rule bodies with their occurrences in rule heads. For every pair of rules $\varphi_i = v_1 \wedge \ldots \wedge v_m \rightarrow v_{m+1}$ and $\varphi_j = w_1 \wedge \ldots \wedge w_n \rightarrow w_{n+1}$, and each $1 \leq l \leq m$ with $v_l = w_{n+1}$, it contains the assertion $t(e^i_{l-1}, e^j_{n+1})$. See Figure 1 for an example.

The existence of a proof tree for g, which can be limited to depth $|V|$, is expressed using the query $q(x, y) = E_{|V|}(x, y)$, with $E_1, E_2, \ldots, E_{|V|}$ defined inductively:

$$E_1 = \bigcup_{v \in V} (p_v \cdot t \cdot p_v) \cdot s$$

$$E_i = \bigcup_{v \in V} \big(p_v \cdot t \cdot p_v\big) \cdot \big(\langle E_{i-1} \rangle \cdot \bigcup_{v \in V} p_v\big)^* \cdot s \qquad (i > 1)$$

Finally, we let $a_1 = e_1^1$ and $a_2 = f$. □

6 Concrete Approach for Horn DLs

Our complexity results so far leave a gap for the data complexity of the *DL-Lite* family: we inherit NL-hardness from plain RPQs, but we only have the P upper bound stemming from Proposition 4.1. In this section, we close this gap by providing an NL upper bound.

This section has an additional goal. We recall that the upper bounds in Corollaries 4.2 and 4.4 rely on reductions to answering (C)2RPQs in extensions of $\mathcal{ELI}$, like Horn-$\mathcal{SHOIQ}$, $\mathcal{ZIQ}$, and $\mathcal{ZOI}$. Unfortunately, known algorithms for C2RPQ answering in these logics use automata-theoretic techniques that are best-case exponential and not considered suitable for implementation. Hence, we want to provide a direct algorithm that may serve as a basis for practicable techniques. To this end, we take an existing algorithm for answering C2RPQs in $\mathcal{ELH}$ and *DL-Lite*$_\mathcal{R}$ due to Bienvenu et al. (2013) and show how it can be extended to handle CN2RPQs and $\mathcal{ELHI}_\bot$ KBs.

For presenting the algorithm in this section, it will be useful to first recall the canonical model property of $\mathcal{ELHI}_\bot$.

Canonical Models

We say that an $\mathcal{ELHI}_\bot$ TBox $\mathcal{T}$ is in *normal form* if all of its concept inclusions are of one of the following forms:

$$A \sqsubseteq \bot \quad A \sqsubseteq \exists r.B \quad \top \sqsubseteq A \quad B_1 \sqcap B_2 \sqsubseteq A \quad \exists r.B \sqsubseteq A$$

with $A, B, B_1, B_2 \in \mathsf{N_C}$ and $r \in \mathsf{N_R^\pm}$.

By introducing fresh concept names to stand for complex concepts, every TBox $\mathcal{T}$ can be transformed in polynomial time into a TBox $\mathcal{T}'$ in normal form that is a model-conservative extension of $\mathcal{T}$. Hence, in what follows, we assume that $\mathcal{ELHI}_\bot$ TBoxes are in normal form.

The domain of the canonical model $\mathcal{I}_{\mathcal{T},\mathcal{A}}$ of a consistent KB $\langle \mathcal{T}, \mathcal{A} \rangle$ consists of all sequences $ar_1C_1 \dots r_nC_n$ ($n \geq 0$) such that:

- $a \in \mathsf{Ind}(\mathcal{A})$ and $r_i \in \mathsf{N_R^\pm}$ for each $1 \leq i \leq n$;
- each C_i is a finite conjunction of concept names;
- if $n \geq 1$, then $\mathcal{T}, \mathcal{A} \models (\exists r_1.C_1)(a)$;
- for $1 \leq i < n$, $\mathcal{T} \models C_i \sqsubseteq \exists r_{i+1}.C_{i+1}$.

For an $o \in \Delta^{\mathcal{I}_{\mathcal{T},\mathcal{A}}} \setminus \mathsf{Ind}(\mathcal{A})$, we use $\mathsf{tail}(o)$ to denote its final concept. The interpretation $\mathcal{I}_{\mathcal{T},\mathcal{A}}$ is then defined as follows:

$$\begin{aligned}
a^{\mathcal{I}_{\mathcal{T},\mathcal{A}}} &= a \text{ for all } a \in \mathsf{Ind}(\mathcal{A}) \\
A^{\mathcal{I}_{\mathcal{T},\mathcal{A}}} &= \{a \in \mathsf{Ind}(\mathcal{A}) \mid \mathcal{T}, \mathcal{A} \models A(a)\} \\
&\quad \cup \{o \in \Delta^{\mathcal{I}_{\mathcal{T},\mathcal{A}}} \setminus \mathsf{Ind}(\mathcal{A}) \mid \mathcal{T} \models \mathsf{tail}(o) \sqsubseteq A\} \\
p^{\mathcal{I}_{\mathcal{T},\mathcal{A}}} &= \{(a,b) \mid p(a,b) \in \mathcal{A}\} \cup \\
&\quad \{(o_1,o_2) \mid o_2 = o_1 r\, C \text{ and } \mathcal{T} \models r \sqsubseteq p\} \cup \\
&\quad \{(o_2,o_1) \mid o_2 = o_1 r\, C \text{ and } \mathcal{T} \models r \sqsubseteq p^-\}
\end{aligned}$$

Observe that $\mathcal{I}_{\mathcal{T},\mathcal{A}}$ is composed of a core part containing the individuals from $\mathcal{A}$ and an *anonymous part* consisting of (possibly infinite) trees rooted at the ABox individuals. We use $\mathcal{I}_{\mathcal{T},\mathcal{A}}|_o$ to denote the restriction of $\mathcal{I}_{\mathcal{T},\mathcal{A}}$ to domain elements having o as a prefix.

It is well-known that the canonical model of a consistent $\mathcal{ELHI}_\bot$ KB $\mathcal{I}_{\mathcal{T},\mathcal{A}}$ can be homomorphically embedded into any model of $\langle \mathcal{T}, \mathcal{A} \rangle$. Since CN2RPQs are preserved under homomorphisms, we have:

Lemma 6.1. *For every consistent $\mathcal{ELHI}_\bot$ KB $\langle \mathcal{T}, \mathcal{A} \rangle$, CN2RPQ q, and tuple $\vec{a}$ of individuals: $\vec{a} \in \mathsf{ans}(q, \langle \mathcal{T}, \mathcal{A} \rangle)$ if and only if $\vec{a} \in \mathsf{ans}(q, \mathcal{I}_{\mathcal{T},\mathcal{A}})$.*

Computing Jump and Final Transitions

A crucial component of our algorithm is to compute relevant partial paths in a subtree $\mathcal{I}_{\mathcal{T},\mathcal{A}}|_o$ rooted at an object o in the anonymous part of $\mathcal{I}_{\mathcal{T},\mathcal{A}}$. Importantly, we also need to remember which parts of the nested automata that have been partially navigated below o still need to be continued. This will allow us to 'forget' the tree below o.

In what follows, it will be convenient use *runs* to talk about the semantics of *n*-NFAs.

Definition 6.1. *Let $\mathcal{I}$ be an interpretation, and let $(\mathbf{A}, s_0, F_0)$ be an n-NFA. Then a* partial run for $\mathbf{A}$ on $\mathcal{I}$ *is a finite node-labelled tree (T, ℓ) such that every node is labelled with an element from $\Delta^\mathcal{I} \times (\bigcup_i S_i)$ and for each non-leaf node v having label $\ell(v) = (o, s)$ with $s \in S_i$, one of the following holds:*

- *v has a unique child v' with $\ell(v') = (o', s')$, and there exists $(s, \sigma, s') \in \delta_i$ such that $\sigma \in \mathsf{Roles}$ and $(o, o') \in \sigma^\mathcal{I}$;*
- *v has exactly two children v' and v'' with $\ell(v') = (o, s')$ and $\ell(v'') = (o, s'')$, with s'' the initial state of α_j, and there exists a transition $(s, \langle j \rangle, s') \in \delta_i$.*

*If T has root labelled (o_1, s_1) and a leaf node labelled (o_2, s_2) with s_1, s_2 states of the same α_i, then (T, ℓ) is called an (o_1, s_1, o_2, s_2)-*run*, and it is* full *if every leaf label $(o', s') \neq (o_2, s_2)$ is such that $s' \in F_k$ for some k.*

Full runs provide an alternative characterization of the semantics of *n*-NFAs in Definition 3.3.

Fact 6.2. *For every interpretation $\mathcal{I}$, $(o_1, o_2) \in (\mathbf{A}_{s_1,\{s_2\}})^\mathcal{I}$ if and only if there is a full (o_1, s_1, o_2, s_2)-run for $\mathbf{A}$ in $\mathcal{I}$.*

We use partial runs to characterize when an *n*-NFA $\mathbf{A}$ can be partially navigated inside a tree $\mathcal{I}_{\mathcal{T},\mathcal{A}}|_o$ whose root satisfies some conjunction of concepts C. Intuitively, $\mathsf{JumpTrans}(\mathbf{A}, \mathcal{T})$ stores pairs s_1, s_2 of states of some $\alpha \in \mathbf{A}$ such that a path from s_1 to s_2 exists, while $\mathsf{FinalTrans}(\mathbf{A}, \mathcal{T})$ stores states s_1 for which a path to some final state exists, no matter where the final state is reached. Both $\mathsf{JumpTrans}(\mathbf{A}, \mathcal{T})$ and $\mathsf{FinalTrans}(\mathbf{A}, \mathcal{T})$ store a set Γ of states s of other automata nested in α, for which a path from s to a final state remains to be found.

Definition 6.2. *Let $\mathcal{T}$ be an $\mathcal{ELHI}_\bot$ TBox in normal form and $(\mathbf{A}, s_0, F_0)$ an n-NFA. The set $\mathsf{JumpTrans}(\mathbf{A}, \mathcal{T})$ consists of tuples (C, s_1, s_2, Γ) where C is either $\top$ or a conjunction of concept names from $\mathcal{T}$, s_1 and s_2 are states from $\alpha_i \in \mathbf{A}$, and $\Gamma \subseteq \bigcup_{j>i} S_j$. A tuple (C, s_1, s_2, Γ) belongs to $\mathsf{JumpTrans}(\mathbf{A}, \mathcal{T})$ if there exists a partial run (T, ℓ) of $\mathbf{A}$ in the canonical model of $\langle \mathcal{T}, \{C(a)\} \rangle$ that satisfies the following conditions:*

- *the root of T is labelled (a, s_1);*
- *there is a leaf node v with $\ell(v) = (a, s_2)$;*
- *for every leaf node v with $\ell(v) = (o, s) \neq (a, s_2)$, either $s \in F_j$ for some $j > i$, or $o = a$ and $s \in \Gamma$.*

The set $\mathsf{FinalTrans}(\mathbf{A}, \mathcal{T})$ contains all tuples (C, s_1, F, Γ) there is a partial run (T, ℓ) of $\mathbf{A}$ in the canonical model of $\langle \mathcal{T}, \{C(a)\}\rangle$ that satisfies the following conditions:

- *the root of T is labelled (a, s_1);*
- *there is a leaf node v with $\ell(v) = (o, s_f)$ and $s_f \in F$;*
- *for every leaf node v with $\ell(v) = (o, s)$, either s is a final state in some α_k, or $o = a$ and $s \in \Gamma$.*

Proposition 6.3. *It can be decided in exponential time if a tuple belongs to $\mathsf{JumpTrans}(\mathbf{A}, \mathcal{T})$ or $\mathsf{FinalTrans}(\mathbf{A}, \mathcal{T})$.*

Proof idea. We first show how to use TBox reasoning to decide whether $(C, s_1, s_2, \Gamma) \in \mathsf{JumpTrans}(\mathbf{A}, \mathcal{T})$. For every $\alpha_j \in \mathbf{A}$, we introduce a fresh concept name A_s for each state $s \in S_j$. Intuitively, A_s expresses that there is an outgoing path that starts in s and reaches a final state. If $\{s_1, s_2\} \subseteq S_i$, then we add the following inclusions to $\mathcal{T}$:

- $\top \sqsubseteq A_s$, for every $s \in F_j$ with $j > i$;
- $\exists r.A_{s'} \sqsubseteq A_s$, whenever $(s, r, s') \in \delta_i$ with $r \in \mathsf{N}_\mathsf{R}^\pm$;
- $A_{s'} \sqcap B \sqsubseteq A_s$, whenever $(s, B?, s') \in \delta_i$;
- $A_{s'} \sqcap A_{s''} \sqsubseteq A_s$, whenever $(s, \langle j \rangle, s') \in \delta_i$ and s'' is the initial state of α_j.

Let $\mathcal{T}'$ be the resulting TBox. In the long version, we show that $(C, s_1, s_2, \Gamma) \in \mathsf{JumpTrans}(\mathbf{A}, \mathcal{T})$ iff

$$\mathcal{T}' \models (C \sqcap A_{s_2} \sqcap \prod_{s \in \Gamma} A_s) \sqsubseteq A_{s_1}.$$

To decide if $(C, s_1, F, \Gamma) \in \mathsf{FinalTrans}(\mathbf{A}, \mathcal{T})$, we must also include in $\mathcal{T}'$ the following inclusions:

- $\top \sqsubseteq A_s$, for every $s \in F$.

We then show that $(C, s_1, F, \Gamma) \in \mathsf{FinalTrans}(\mathbf{A}, \mathcal{T})$ iff

$$\mathcal{T}' \models (C \sqcap \prod_{s \in \Gamma} A_s) \sqsubseteq A_{s_1}.$$

To conclude the proof, we simply note that both problems can be decided in single-exponential time, as TBox reasoning in $\mathcal{ELHI}_\bot$ is known to be EXP-complete. □

Query Rewriting

The core idea of our query answering algorithm is to rewrite a given CN2RPQ q into a set of queries Q such that the answers to q and the union of the answers for all $q' \in Q$ coincide. However, for evaluating each $q' \in Q$, we only need to consider mappings from the variables to the individuals in the core of $\mathcal{I}_{\mathcal{T},\mathcal{A}}$. Roughly, a rewriting step makes some assumptions about the query variables that are mapped deepest into the anonymous part and, using the structure of the canonical model, generates a query whose variables are matched one level closer to the core. Note that, even when we assume that no variables are mapped below some element o in $\mathcal{I}_{\mathcal{T},\mathcal{A}}$, the satisfaction of the regular paths may require to go below o and back up in different ways. This is handled using jump and final transitions. The query rewriting algorithm is an adaptation of the algorithm for C2RPQs in (Bienvenu, Ortiz, and Simkus 2013), to which the reader may refer for more detailed explanations and examples.

The query rewriting algorithm is presented in Figure 2. In the algorithm, we use atoms of the form $\langle A_{s,F} \rangle(x)$, which are semantically equivalent to $A_{s,F}(x, z)$ for a variable z not occurring anywhere in the query. This alternative notation will spare us additional variables and make the complexity arguments simpler. To slightly simplify the notation, we may write $\mathbf{A}_{s,s'}$ instead of $\mathbf{A}_{s,\{s'\}}$.

The following proposition states the correctness of the rewriting procedure. Its proof follows the ideas outlined above and can be found in the appendix of the long version. Slightly abusing notation, we will also use $\mathsf{Rewrite}(q, \mathcal{T})$ to denote the set all of queries that can be obtained by an execution of the rewriting algorithm on q and $\mathcal{T}$.

Proposition 6.4. *Let $\langle \mathcal{T}, \mathcal{A} \rangle$ be an $\mathcal{ELHI}_\bot$ KB and $q(\vec{x})$ a C2NRPQ. Then $\vec{a} \in \mathsf{ans}(q, \langle \mathcal{T}, \mathcal{A} \rangle)$ iff there exists $q' \in \mathsf{Rewrite}(q, \mathcal{T})$ and a match π for q' in $\mathcal{I}_{\mathcal{T},\mathcal{A}}$ such that $\pi(\vec{x}) = \vec{a}$ and $\pi(y) \in \mathsf{Ind}(\mathcal{A})$ for every variable y in q'.*

We note that the query rewriting does not introduce fresh terms. Moreover, it employs an at most quadratic number of linearly sized *n*-NFAs, obtained from the *n*-NFAs of the input query. Thus, the size of each $q' \in \mathsf{Rewrite}(q, \mathcal{T})$ is polynomial in the size of q and $\mathcal{T}$. Given that all the employed checks in Figure 2 can be done in exponential time (see Proposition 6.3), we obtain the following.

Proposition 6.5. *The set $\mathsf{Rewrite}(q, \mathcal{T})$ can be computed in exponential time in the size of q and $\mathcal{T}$.*

Query Evaluation

In Figure 3, we present an algorithm EvalAtom for evaluating N2RPQs. The idea is similar to the standard nondeterministic algorithm for deciding reachability: we guess a sequence $(c_0, s_0)(c_1, s_1) \cdots (c_m, s_m)$ of individual-state pairs, keeping only two successive elements in memory at any time. Every element (c_{i+1}, s_{i+1}) must be reached from the preceding element (c_i, s_i) by a single normal, jump, or final transition. Moreover, in order to use a jump or final transition, we must ensure that its associated conditions are satisfied. To decide if the current individual belongs to C, we can employ standard reasoning algorithms, but to determine whether an outgoing path exists for one of the states in Γ, we must make a recursive call to EvalAtom. Importantly, these recursive calls involve "lower" automata, and so the depth of recursion is bounded by the number of automata in the N2RPQ (and so is independent of $\mathcal{A}$). It follows that the whole procedure can be implemented in non-deterministic logarithmic space in $|\mathcal{A}|$, if we discount the concept and role membership tests. By exploiting known complexity results for instance checking in *DL-Lite*$_\mathcal{R}$ and $\mathcal{ELHI}_\bot$, we obtain:

Proposition 6.6. EvalAtom *is a sound and complete procedure for N2RPQ evaluation over satisfiable $\mathcal{ELHI}_\bot$ KBs. It can be implemented so as to run in non-deterministic logarithmic space (resp., polynomial time) in the size of the ABox for DL-Lite*$_\mathcal{R}$ *(resp., $\mathcal{ELHI}_\bot$) KBs.*

PROCEDURE Rewrite

Input: CN2RPQ q, $\mathcal{ELHI}_\bot$ TBox $\mathcal{T}$ in normal form

1. Choose either to output q or to continue.
2. Choose a non-empty set $\mathsf{Leaf} \subseteq \mathsf{vars}(q)$ and $y \in \mathsf{Leaf}$. Rename all variables in Leaf to y.
3. Choose a conjunction C of concept names from $\mathcal{T}$ such that $\mathcal{T} \models C \sqsubseteq B$ whenever $B(y)$ is an atom of q. Drop all such atoms from q.
4. For each atom $at \in q$ of the form $\langle \mathbf{A}_{s_0,F} \rangle(t)$ or $\mathbf{A}_{s_0,F}(t,t')$ with $y \in \{t,t'\}$:
   (a) let $\alpha_i \in \mathbf{A}$ be the automaton containing s_0, F
   (b) choose a sequence $s_1, \dots, s_{n-1}$ of distinct states from S_i and some $s_n \in F$
   (c) replace at by the atoms $\mathbf{A}_{s_0,s_1}(t,y)$, $\mathbf{A}_{s_1,s_2}(y,y)$, $\dots$, $\mathbf{A}_{s_{n-2},s_{n-1}}(y,y)$, and
   - $\mathbf{A}_{s_{n-1},s_n}(y,t')$ if $at = \mathbf{A}_{s_0,F}(t,t')$, or
   - $\langle \mathbf{A}_{s_{n-1},s_n} \rangle(y)$ if $at = \langle \mathbf{A}_{s_0,F} \rangle(y)$.
5. For each atom at_j of the form $\mathbf{A}_{s_j,s_{j+1}}(y,y)$ or $\langle \mathbf{A}_{s_j,s_{j+1}} \rangle(y)$ in q, either do nothing, or:
   - Choose some $(C, s_j, s_{j+1}, \Gamma) \in \mathsf{JumpTrans}(\mathbf{A}, \mathcal{T})$ if $at_j = \mathbf{A}_{s_j,s_{j+1}}(y,y)$.
   - Choose some $(C, s_j, \{s_{j+1}\}, \Gamma) \in \mathsf{FinalTrans}(\mathbf{A}, \mathcal{T})$ if $at_j = \langle \mathbf{A}_{s_j,s_{j+1}} \rangle(y)$.
   - Replace at_j by $\{\langle \mathbf{A}_{u,F_k} \rangle(y) \mid u \in \Gamma \cap S_k, \}$.
6. Choose a conjunction D of concept names from $\mathcal{T}$ and $r, r_1, r_2 \in \mathsf{N}_\mathsf{R}^\pm$ such that:
   (a) $\mathcal{T} \models D \sqsubseteq \exists r.C$, $\mathcal{T} \models r \sqsubseteq r_1$, and $\mathcal{T} \models r \sqsubseteq r_2$.
   (b) For each atom $\mathbf{A}_{u,U}(y,t)$ of q with $u \in S_i$, there exists $v \in S_i$ such that $(u, r_1^-, v) \in \delta_i$
   (c) For each atom $\mathbf{A}_{u,U}(t,y)$ of q with $u \in S_i$, there exists $v \in S_i$ and $v' \in U$ with $(v, r_2, v') \in \delta_i$.
   (d) For each atom $\langle \mathbf{A}_{u,U} \rangle(y)$ of q with $u \in S_i$, there exists $v \in S_i$ such that $(u, r_1^-, v) \in \delta_i$.

   For atoms $\mathbf{A}_{u,U}(y,y)$, both (b) and (c) apply.
7. Replace
   - each atom $\mathbf{A}_{u,U}(y,t)$ with $t \neq y$ by $\mathbf{A}_{v,U}(y,t)$,
   - each atom $\mathbf{A}_{u,U}(t,y)$ with $t \neq y$ by $\mathbf{A}_{u,v}(y,t)$,
   - each atom $\mathbf{A}_{u,U}(y,y)$ by atom $\mathbf{A}_{v,v'}(y,y)$, and
   - each atom $\langle \mathbf{A}_{u,U} \rangle(y)$ by atom $\langle \mathbf{A}_{v,U} \rangle(y)$

   with v, v' as in Step 6.
8. Add $A(y)$ to q for each $A \in D$ and return to Step 1.

Figure 2: Query rewriting procedure Rewrite.

We present in Figure 4 the complete procedure EvalQuery for deciding CN2RPQ entailment.

Theorem 6.7. EvalQuery *is a sound and complete procedure for deciding CN2RPQ entailment over $\mathcal{ELHI}_\bot$ KBs. In the case of DL-Lite$_\mathcal{R}$ KBs, it runs in non-deterministic logarithmic space in the size of the ABox.*

Proof idea. Soundness, completeness, and termination of

PROCEDURE EvalAtom

Input: n-NFA $(\mathbf{A}, s_0, F_0)$, $\mathcal{ELHI}_\bot$ KB $\mathcal{K} = \langle \mathcal{T}, \mathcal{A} \rangle$ in normal form, $(a,b) \in \mathsf{Ind}(\mathcal{A}) \times (\mathsf{Ind}(\mathcal{A}) \cup \{\mathsf{anon}\})$

1. Let i be such that $s_0 \in S_i$, and set $\mathsf{max} = |\mathcal{A}| \times |S_i| + 1$.
2. Initialize $\mathsf{current} = (a, s_0)$ and $\mathsf{count} = 0$.
3. While $\mathsf{count} < \mathsf{max}$ and $\mathsf{current} \neq (b, s_f)$ for $s_f \in F_0$
   (a) Let $\mathsf{current} = (c, s)$.
   (b) Guess a pair $(d, s') \in (\mathsf{Ind}(\mathcal{A}) \cup \{\mathsf{anon}\}) \times S_i$ such that one of the following holds:
      i. $d \in \mathsf{Ind}(\mathcal{A})$ and there exists $(s, \sigma, s') \in \delta_i$ with $\sigma \in \mathsf{Roles}$ such that $(c,d) \in \sigma^{\mathcal{I}_{\mathcal{T},\mathcal{A}}}$
      ii. $d = c$ and $\mathsf{JumpTrans}(\mathbf{A}, \mathcal{T})$ contains a tuple (C, s, s', Γ) such that $c \in C^{\mathcal{I}_{\mathcal{T},\mathcal{A}}}$ and for every $j > i$ and every $u \in \Gamma \cap S_j$,
      $$\mathsf{EvalAtom}((\mathbf{A}, u, F_j), \mathcal{K}, (c, \mathsf{anon})) = \mathtt{yes}$$
      iii. $d = \mathsf{anon}$, $s' \in F_0$, and $\mathsf{FinalTrans}(\mathbf{A}, \mathcal{T})$ contains a tuple (C, s, F_0, Γ) such that $c \in C^{\mathcal{I}_{\mathcal{T},\mathcal{A}}}$ and for every $j > i$ and every $u \in \Gamma \cap S_j$,
      $$\mathsf{EvalAtom}((\mathbf{A}, u, F_j), \mathcal{K}, (c, \mathsf{anon})) = \mathtt{yes}$$
   (c) Set $\mathsf{current} = (d, s')$ and increment count.
4. If $\mathsf{current} = (d, s_f)$ for some $s_f \in F_0$, and either $b = d$ or $b = \mathsf{anon}$, return yes. Else return no.

Figure 3: N2RPQ evaluation procedure EvalAtom.

PROCEDURE EvalQuery

Input: Boolean CN2RPQ q, $\mathcal{ELHI}_\bot$ KB $\mathcal{K} = \langle \mathcal{T}, \mathcal{A} \rangle$ in normal form

1. Test whether $\mathcal{K}$ is satisfiable, output yes if not.
2. Set $Q = \mathsf{Rewrite}(q, \mathcal{T})$. Replace all atoms in Q of types $C(a)$, $R(a,b)$ by equivalent atoms of type $\mathbf{A}_{s_0,F_0}(a,b)$.
3. Guess some $q' \in Q$ and an assignment $\vec{a}$ of individuals to the quantified variables $\vec{v}$ in q'
   - Let q'' be obtained by substituting $\vec{a}$ for $\vec{v}$.
   - For every atom $\mathbf{A}_{s_0,F_0}(a,b)$ in q''
     check if $\mathsf{EvalAtom}((\mathbf{A}, s_0, F_0), \mathcal{K}, (a,b)) = \mathtt{yes}$
   - If all checks succeed, return yes.
4. Return no.

Figure 4: CN2RPQ entailment procedure EvalQuery.

EvalQuery follow easily from the corresponding properties of the component procedures Rewrite and EvalAtom (Propositions 6.4, 6.5, and 6.6). In *DL-Lite$_\mathcal{R}$*, KB satisfiability is known to be NL-complete in data complexity. Since the rewriting step is ABox-independent, the size of queries in $\mathcal{Q}$ can be treated as a constant. It follows that the query q' and assignment $\vec{a}$ guessed in Step 3 can be stored in logarithmic space in $|\mathcal{A}|$. By Theorem 6.7, each call to EvalAtom runs in non-deterministic logarithmic space. □

Corollary 6.8. *CN2RPQ entailment over DL-Lite$_\mathcal{R}$ knowl-*

edge bases is NL*-complete in data complexity.*

7 Conclusions and Future Work

We have studied the extension of (C)2RPQs with a nesting construct inspired by XPath, and have characterized the data and combined complexity of answering nested 2RPQs and C2RPQs for a wide range of DLs. The only complexity bound we leave open is whether the coNP lower-bound in data complexity for expressive DLs is tight; indeed, the automata-theoretic approach used to obtain optimal bounds in combined complexity for these logics does not seem to provide the right tool for tight bounds in data complexity.

In light of the surprising jump from P to EXP in the combined complexity of answering N2RPQs in lightweight DLs, a relevant research problem is to identify classes of N2RPQs that exhibit better computational properties. We are also interested in exploring whether the techniques developed in Section 6 can be extended to deal with additional query constructs, such as existential "loop-tests" or forms of role-value maps. Finally, containment of N2RPQs has been studied very recently (Reutter 2013), but only for plain graph databases, so it would be interesting to investigate containment also in the presence of DL constraints.

Decidable Gödel Description Logics without the Finitely-Valued Model Property*

Stefan Borgwardt and **Felix Distel** and **Rafael Peñaloza**†
Theoretical Computer Science, TU Dresden, Germany
{stefborg,felix,penaloza}@tcs.inf.tu-dresden.de

Abstract

In the last few years, there has been a large effort for analyzing the computational properties of reasoning in fuzzy description logics. This has led to a number of papers studying the complexity of these logics, depending on the chosen semantics. Surprisingly, despite being arguably the simplest form of fuzzy semantics, not much is known about the complexity of reasoning in fuzzy description logics w.r.t. witnessed models over the Gödel t-norm. We show that in the logic G-$\mathfrak{I}\mathcal{ALC}$, reasoning cannot be restricted to finitely-valued models in general. Despite this negative result, we also show that all the standard reasoning problems can be solved in exponential time, matching the complexity of reasoning in classical $\mathcal{ALC}$.

1 Introduction

Fuzzy Description Logics (DLs) have been studied as a means of representing vague or imprecise knowledge in a formal and well-understood manner. As for classical DLs (Baader et al. 2007), knowledge is expressed with the help of *concepts* and *roles*. What distinguishes fuzzy DLs from classical DLs are their semantics, which are based on *fuzzy sets*. Fuzzy sets associate every element of the domain of interest with a number from the interval $[0, 1]$, which intuitively represents the *degree* to which the element belongs to the fuzzy set.

When defining a fuzzy DL, one must also decide how to interpret the logical constructors, such as conjunction and implication, to handle the truth degrees. The simplest approach is to use the *minimum* operator to generalize intersection to fuzzy sets. Thus, the degree of membership of a conjunction is interpreted as the minimum of the membership degrees of the conjuncts. This operation, also known as the *Gödel t-norm*, can be used as a base to interpret all other logical constructors in a formally justified manner (Klement, Mesiar, and Pap 2000; Hájek 2001). The quantifiers $\forall$ and $\exists$ are interpreted as infima and suprema of truth values, respectively. To avoid issues arising from having infinitely many truth values, reasoning in fuzzy DLs is usually restricted to so-called *witnessed models* (Hájek 2007).

The study of fuzzy DLs underwent a large change in recent years, after some relatively inexpressive fuzzy DLs were shown to be undecidable when reasoning w.r.t. general ontologies (Baader and Peñaloza 2011a; 2011b; Cerami and Straccia 2013). Since then, the limits of decidability have been explored, yielding very expressive decidable logics on the one hand (Borgwardt, Distel, and Peñaloza 2012), and inexpressive undecidable logics on the other (Borgwardt and Peñaloza 2012). Despite being widely regarded as the simplest t-norm, surprisingly little is known about fuzzy DLs based on Gödel semantics. It is generally believed that—at least w.r.t. witnessed models—these logics are decidable, but no proof exists to support this claim. The only results for similar logics restrict reasoning *a priori* to a finite subset of $[0, 1]$; in this case, a reduction to classical reasoning then yields decidability (Bobillo et al. 2009; 2012).

All existing approaches for reasoning in fuzzy DLs depend on limiting models to use only finitely many different truth degrees. Indeed, for these approaches to work, one must either (i) restrict the semantics to a finite set of truth degrees (Bobillo et al. 2009; 2012; Bobillo and Straccia 2011; 2013; Borgwardt and Peñaloza 2013a; 2013b; Straccia 2006); (ii) prove that reasoning can be restricted to a finite set of degrees (Bobillo, Delgado, and Gómez-Romero 2008; Borgwardt, Distel, and Peñaloza 2012; Straccia 2001); or (iii) prove that models can be built from a finite pattern (Stoilos et al. 2007; Straccia and Bobillo 2007). In all three cases, the proofs of correctness of these algorithms imply the *finitely-valued model property*: an ontology has a model iff it has a model using only finitely many truth values. Conversely, the proofs of undecidability (Baader and Peñaloza 2011a; 2011b; Borgwardt and Peñaloza 2012; Cerami and Straccia 2013) construct a model that uses infinitely many truth degrees. Thus, this *finitely-valued model property* appears to be a good indicator of the decidability of a fuzzy DL.

In this paper we study the standard reasoning problems for the DL G-$\mathfrak{I}\mathcal{ALC}$, a fuzzy extension of $\mathcal{ALC}$ based on the Gödel semantics w.r.t. witnessed models. First, we show that

this logic does not have the finitely-valued model property. In fact, we provide very simple consistent ontologies that only have infinitely-valued models (see Section 3). The absence of the finitely-valued model property for these logics is a surprising result in itself, contradicting the common lore of the field. In contrast, we show in Sections 4 and 5 that consistency is decidable in exponential time for this logic. Our algorithm is based on the insight that under Gödel semantics, it is only necessary to know an ordering between the relevant truth degrees, rather the precise values they take. This idea has already been used for deciding validity of formulae in propositional Gödel logic (Guller 2012). We then extend our algorithm to also compute best subsumption degrees and best satisfiability degrees w.r.t. an ontology. The last section provides some pointers to future work.

2 Preliminaries

Before introducing fuzzy description logics, we briefly consider the operators of Gödel fuzzy logic and introduce auxiliary notions that will be useful for the reasoning procedures described in the following sections.

The two basic operators of Gödel fuzzy logic are conjunction and implication, interpreted by the *Gödel t-norm* and *residuum*, respectively. The Gödel t-norm of two fuzzy degrees $x, y \in [0,1]$ is defined as minimum function $\min(x,y)$. The residuum $\Rightarrow$ is uniquely defined by the equivalence $\min(x,y) \leq z$ iff $y \leq (x \Rightarrow z)$ for all $x, y, z \in [0,1]$, and can be computed as

$$x \Rightarrow y = \begin{cases} 1 & \text{if } x \leq y, \\ y & \text{otherwise.} \end{cases}$$

For a deeper introduction to t-norms and t-norm-based fuzzy logics, see (Cintula, Hájek, and Noguera 2011; Hájek 2001; Klement, Mesiar, and Pap 2000).

A *total preorder* over a set S is a transitive and total binary relation $\lesssim_* \subseteq S \times S$. For $x, y \in S$, we write $x \equiv_* y$ if $x \lesssim_* y$ and $y \lesssim_* x$. Notice that $\equiv_*$ is an equivalence relation on S. Similarly, we write $x <_* y$ if $x \lesssim_* y$, but not $y \lesssim_* x$. By the symbol $\bowtie$ we denote an arbitrary element of $\{=, \geq, >, \leq, <\}$, and by $\bowtie_*$ the corresponding relation induced by the total preorder $\lesssim_*$, i.e. $\equiv_*$, $\gtrsim_*$, $>_*$, $\lesssim_*$, or $<_*$. Subscripts are used to distinguish these relations for different total preorders over the same carrier set S.

An *order structure* S is a finite set containing at least the numbers 0 and 1, together with an involutive unary operation $\mathrm{inv}\colon S \to S$ such that $\mathrm{inv}(x) = 1 - x$ for all $x \in S \cap [0,1]$. For an order structure S, $\mathrm{order}(S)$ denotes the set of all total preorders $\lesssim_*$ over S that

- have 0 and 1 as least and greatest element, respectively,
- preserve the order of real numbers on $S \cap [0,1]$, and
- satisfy $x \lesssim_* y$ iff $\mathrm{inv}(y) \lesssim_* \mathrm{inv}(x)$ for all $x, y \in S$.

Given $\lesssim_* \in \mathrm{order}(S)$, the following functions on S that mimic the operators of Gödel fuzzy logic over $[0,1]$ are well-defined since $\lesssim_*$ is total:

$$\min_*(x,y) := \begin{cases} x & \text{if } x \lesssim_* y \\ y & \text{otherwise,} \end{cases}$$

Table 1: Semantics of G-$\mathfrak{I}\mathcal{ALC}$

Constructor	Syntax	Semantics
top concept	$\top$	1
involutive negation	$\neg C$	$1 - C^{\mathcal{I}}(x)$
conjunction	$C \sqcap D$	$\min(C^{\mathcal{I}}(x), D^{\mathcal{I}}(x))$
implication	$C \to D$	$C^{\mathcal{I}}(x) \Rightarrow D^{\mathcal{I}}(x)$
existential restriction	$\exists r.C$	$\sup_{y \in \Delta^{\mathcal{I}}} \min(r^{\mathcal{I}}(x,y), C^{\mathcal{I}}(y))$
value restriction	$\forall r.C$	$\inf_{y \in \Delta^{\mathcal{I}}} r^{\mathcal{I}}(x,y) \Rightarrow C^{\mathcal{I}}(y)$

$$\mathrm{res}_*(x,y) := \begin{cases} 1 & \text{if } x \lesssim_* y \\ y & \text{otherwise.} \end{cases}$$

It is easy to see that these operators agree with $\min$ and $\Rightarrow$ on the set $S \cap [0,1]$.

The fuzzy description logic G-$\mathfrak{I}\mathcal{ALC}$ is based on concepts and roles, which are interpreted as (fuzzy) unary and binary relations, respectively. Given the mutually disjoint sets $\mathsf{N_I}$, $\mathsf{N_R}$, and $\mathsf{N_C}$ of *individual*, *role*, and *concept names*, respectively, G-$\mathfrak{I}\mathcal{ALC}$ *concepts* are built through the rule

$$C ::= A \mid \top \mid \neg C \mid C \sqcap C \mid C \to C \mid \exists r.C \mid \forall r.C,$$

where $A \in \mathsf{N_C}$ and $r \in \mathsf{N_R}$. We call concepts of the form $\exists r.C$ or $\forall r.C$ *quantified concepts*. The semantics of this logic is given by means of interpretations. An *interpretation* is a pair $\mathcal{I} = (\Delta^{\mathcal{I}}, \cdot^{\mathcal{I}})$, where $\Delta^{\mathcal{I}}$ is a non-empty *domain*, and $\cdot^{\mathcal{I}}$ is a function that maps every $a \in \mathsf{N_I}$ to an element $a^{\mathcal{I}} \in \Delta^{\mathcal{I}}$, every $A \in \mathsf{N_C}$ to a fuzzy set $A^{\mathcal{I}}\colon \Delta^{\mathcal{I}} \to [0,1]$, and every role name $r \in \mathsf{N_R}$ to a fuzzy binary relation $r^{\mathcal{I}}\colon \Delta^{\mathcal{I}} \times \Delta^{\mathcal{I}} \to [0,1]$. This function is extended to arbitrary concepts using the Gödel operators as shown in Table 1.

Notice that we have not introduced an explicit constructor for the *residual negation* $\ominus x := x \Rightarrow 0$ or disjunction, as they are expressible using $\top$, $\neg$, $\sqcap$, and $\to$. The residual negation is often used in fuzzy logics, but under Gödel semantics it is much less expressive than the involutive negation since we have $\ominus 0 = 1$ and $\ominus x = 0$ for all $x \in (0,1]$.

In the literature on fuzzy DLs, interpretations are usually restricted to be witnessed (Hájek 2005), which means that existential and value restrictions must be interpreted as maxima and minima, respectively. More formally, an interpretation $\mathcal{I}$ is *witnessed* if for every existential restriction $\exists r.C$ and every $x \in \Delta^{\mathcal{I}}$ there is a *witness* $y \in \Delta^{\mathcal{I}}$ such that $(\exists r.C)^{\mathcal{I}}(x) = \min(r^{\mathcal{I}}(x,y), C^{\mathcal{I}}(y))$, and similarly for value restrictions. We also adopt this restriction here, and for the rest of this paper consider only witnessed interpretations. For brevity, we call them simply *interpretations*.

The knowledge of a domain is represented using axioms that restrict the class of interpretations that are relevant for the different reasoning tasks.

Definition 1 (axioms). A *crisp assertion* is either a *concept assertion* of the form $a\colon C$ or a *role assertion* of the form $(a,b)\colon r$ for a concept C, $r \in \mathsf{N_R}$, and $a, b \in \mathsf{N_I}$. An *(order) assertion* is of the form $\langle \alpha \bowtie \beta \rangle$, where α is a crisp assertion and β is either a crisp assertion or a value from $[0,1]$. An interpretation $\mathcal{I}$ *satisfies* an order assertion $\langle \alpha \bowtie \beta \rangle$ if $\alpha^{\mathcal{I}} \bowtie \beta^{\mathcal{I}}$, where $(a\colon C)^{\mathcal{I}} := C^{\mathcal{I}}(a^{\mathcal{I}})$,

$((a,b):r)^{\mathcal{I}} := r^{\mathcal{I}}(a^{\mathcal{I}}, b^{\mathcal{I}})$, and $q^{\mathcal{I}} := q$ for all $q \in [0,1]$. An *ordered ABox* $\mathcal{A}$ is a finite set of order assertions. An interpretation is a *model* of $\mathcal{A}$ if it satisfies all order assertions in $\mathcal{A}$.

A *general concept inclusion (GCI)* is an expression of the form $\langle C \sqsubseteq D \geq q \rangle$ for concepts C, D, and $q \in [0,1]$. An interpretation $\mathcal{I}$ satisfies this GCI if $C^{\mathcal{I}}(x) \Rightarrow D^{\mathcal{I}}(x) \geq q$ holds for all $x \in \Delta^{\mathcal{I}}$. A *TBox* is a finite set of GCIs. An *ontology* is a pair $\mathcal{O} = (\mathcal{A}, \mathcal{T})$, where $\mathcal{A}$ is an ordered ABox and $\mathcal{T}$ is a TBox. An interpretation is a *model* of a TBox $\mathcal{T}$ if it satisfies all GCIs in $\mathcal{T}$, and it is a *model* of an ontology $\mathcal{O} = (\mathcal{A}, \mathcal{T})$ if it is a model of both $\mathcal{A}$ and $\mathcal{T}$.

We will usually abbreviate $\langle C \sqsubseteq D \geq 1 \rangle$ as $\langle C \sqsubseteq D \rangle$. Ordered ABoxes are more expressive than ABoxes usually considered for fuzzy DLs (Straccia 2001) since they allow to state order relations between concepts. This more general kind of ABox is better suited for our algorithms.

We denote by $\mathsf{sub}(\mathcal{O})$ the closure under negation of the set of all subconcepts appearing in an ontology $\mathcal{O}$. The concepts $\neg\neg C$ and C are equivalent, and we regard them here as equal, which means that $\mathsf{sub}(\mathcal{O})$ is always finite. We further denote by $\mathcal{V}_{\mathcal{O}}$ the closure of the set of all truth degrees appearing in $\mathcal{O}$, together with 0, 0.5, and 1, under the operator $x \mapsto 1 - x$. Since this operator is involutive, $\mathcal{V}_{\mathcal{O}}$ is also always finite. We often denote the elements of $\mathcal{V}_{\mathcal{O}} \subseteq [0,1]$ as $0 = q_0 < q_1 < \cdots < q_k = 1$.

As with classical DLs, the most basic reasoning task in G-$\mathfrak{I}\mathcal{ALC}$ is to decide whether a given ontology has a (witnessed) model. However, one might also be interested in computing the degree to which an entailment holds.

Definition 2 (reasoning). An ontology $\mathcal{O}$ is *consistent* if it has a model. Given $p \in [0,1]$, a concept C is *p-satisfiable* w.r.t. $\mathcal{O}$ if there is a model $\mathcal{I}$ of $\mathcal{O}$ and an $x \in \Delta^{\mathcal{I}}$ with $C^{\mathcal{I}}(x) \geq p$. The *best satisfiability degree* of C w.r.t. $\mathcal{O}$ is the supremum over all p such that C is p-satisfiable w.r.t. $\mathcal{O}$. Furthermore, C is *p-subsumed* by a concept D w.r.t. $\mathcal{O}$ if all models of $\mathcal{O}$ satisfy the GCI $\langle C \sqsubseteq D \geq p \rangle$. The *best subsumption degree* of C and D w.r.t. $\mathcal{O}$ is the supremum over all p such that C is p-subsumed by D w.r.t. $\mathcal{O}$.

If consistency is decidable, then satisfiability and subsumption can be restricted without loss of generality to ontologies containing an empty ABox: if $\mathcal{O}$ is inconsistent, then these two problems are trivial, and if $\mathcal{O}$ is consistent, then the ABox assertions cannot contradict the p-satisfiability of C, and therefore C is p-satisfiable w.r.t. $\mathcal{O} = (\mathcal{A}, \mathcal{T})$ iff it is p-satisfiable w.r.t. $(\emptyset, \mathcal{T})$. A similar argument can be made for subsumptions.

We show in Section 5 that ontology consistency has the same complexity in G-$\mathfrak{I}\mathcal{ALC}$ as in classical $\mathcal{ALC}$: it is ExpTime-complete. As a first step, we establish the complexity of consistency for the special case of ontologies with so-called *local* ordered ABoxes in Section 4, adapting an automata-based technique known from classical and finitely-valued DLs (Baader, Hladik, and Peñaloza 2008; Borgwardt and Peñaloza 2013a). We later lift these results to the satisfiability and subsumption problems. But first, we illustrate why the naïve approach of restricting reasoning to finitely-valued reasoning cannot work in this logic.

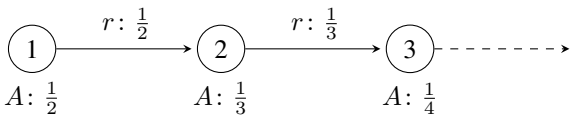

Figure 1: The model $\mathcal{I}_1$ from Example 3

3 Restricting to Finitely Many Values

It is a simple observation that any set of truth values that contains 0 and 1 is closed w.r.t. the Gödel connectives. Owing to this observation, it is common to restrict reasoning in fuzzy DLs with Gödel semantics to the finitely many truth values occurring in the ontology (Bobillo et al. 2012; Bobillo and Straccia 2013). This restriction is also sometimes justified by the "limited precision of computers" (Bobillo et al. 2009).

Earlier works have, however, neglected to study whether the restriction to a fixed finite set of values preserves the semantics of the logic. We now show that this is not the case, even for the simple description logics G-$\mathcal{AL}$, which allows only $\exists$, $\forall$, $\sqcap$, and $\top$. and G-$\mathfrak{IEL}$, where concepts are built using only $\exists$, $\sqcap$, $\rightarrow$, and $\top$. We show even stronger results: reasoning in these logics cannot, without loss of generality, be restricted to *finitely-valued* models, i.e. models that only use values from an arbitrary finite subset of $[0,1]$. We note that for the related *Zadeh semantics*, which differ from the Gödel semantics only in the operator used for implications, reasoning can be restricted to finitely-valued models without loss of generality (Straccia 2001; Bobillo, Delgado, and Gómez-Romero 2008).

Example 3. Let $\mathcal{T}_1$ be the G-$\mathcal{AL}$ TBox

$$\mathcal{T}_1 = \{\langle \forall r.A \sqsubseteq A \geq 1 \rangle,\ \langle \exists r.\top \sqsubseteq A \geq 1 \rangle\}.$$

We show that $\top$ is *not* 1-subsumed by A w.r.t. the ontology $\mathcal{O} = (\emptyset, \mathcal{T}_1)$, but every finitely-valued model of this ontology also satisfies $\langle \top \sqsubseteq A \geq 1 \rangle$.

For the former, we construct a model $\mathcal{I}_1$ of $\mathcal{T}_1$ as follows (see Figure 1). Let $\Delta^{\mathcal{I}_1}$ be the set of all natural numbers. We define $A^{\mathcal{I}_1}(n) := r^{\mathcal{I}_1}(n, n+1) := \frac{1}{n+1}$ for all $n \in \mathbb{N}$ and $r^{\mathcal{I}_1}(n,m) := 0$ if $m \neq n+1$. It is straightforward to check that this is a witnessed model of $\mathcal{T}_1$ that violates $\langle \top \sqsubseteq A \geq 1 \rangle$. Thus, $\top$ is not 1-subsumed by A w.r.t. $\mathcal{O}$. In fact, the best subsumption degree of $\top$ and A w.r.t. $\mathcal{O}$ is 0.

Assume now that there is a witnessed model $\mathcal{I}$ of $\mathcal{T}_1$ using only finitely many truth values that violates $\langle \top \sqsubseteq A \geq 1 \rangle$. Since $\mathcal{I}$ uses only finitely many truth values, there exists an element $y \in \Delta^{\mathcal{I}}$ for which $A^{\mathcal{I}}(y)$ is minimal, that is, $A^{\mathcal{I}}(y) \leq A^{\mathcal{I}}(x)$ holds for all $x \in \Delta^{\mathcal{I}}$. Furthermore, since $\mathcal{I}$ violates $\langle \top \sqsubseteq A \geq 1 \rangle$ there must be some $x_0 \in \Delta^{\mathcal{I}}$ satisfying $A^{\mathcal{I}}(x_0) < 1$. In particular, this yields $A^{\mathcal{I}}(y) < 1$.

As $\mathcal{I}$ is witnessed, there must exist a $z \in \Delta^{\mathcal{I}}$ such that $(\forall r.A)^{\mathcal{I}}(y) = r^{\mathcal{I}}(y,z) \Rightarrow A^{\mathcal{I}}(z)$. The first axiom of $\mathcal{T}_1$ entails $r^{\mathcal{I}}(y,z) \Rightarrow A^{\mathcal{I}}(z) \leq A^{\mathcal{I}}(y) < 1$, and in particular

$$r^{\mathcal{I}}(y,z) > A^{\mathcal{I}}(z). \tag{1}$$

The second axiom from $\mathcal{T}_1$ yields

$$r^{\mathcal{I}}(y,z) = \min(r^{\mathcal{I}}(y,z), 1) \leq (\exists r.\top)^{\mathcal{I}}(y) \leq A^{\mathcal{I}}(y). \tag{2}$$

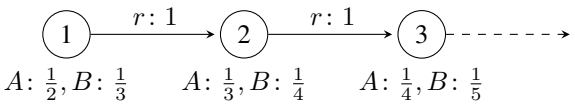

Figure 2: The model $\mathcal{I}_2$ from Example 4

From (1) and (2) we obtain $A^{\mathcal{I}}(y) > A^{\mathcal{I}}(z)$, contradicting the minimality of $A^{\mathcal{I}}(y)$. We have thus shown that a witnessed model of $\mathcal{T}_1$ with only finitely many truth values cannot violate $\langle \top \sqsubseteq A \geq 1 \rangle$. That is, $\mathcal{T}_1$ entails $\langle \top \sqsubseteq A \geq 1 \rangle$ when reasoning is restricted to finite sets of values.

It is thus not possible to restrict reasoning in G-$\mathcal{AL}$ to only finitely-valued models without changing the consequences. A similar example shows that this also holds for G-$\mathfrak{IEL}$.

Example 4. Consider the TBox

$$\mathcal{T}_2 = \{\langle B \sqsubseteq A \rangle, \langle A \to B \sqsubseteq B \rangle, \langle \top \sqsubseteq \exists r.\top \rangle, \langle \exists r.A \sqsubseteq B \rangle\}.$$

As in Example 3, one can show that $\top$ is not 1-subsumed by A w.r.t. $\mathcal{O} := (\emptyset, \mathcal{T}_2)$, but every finitely-valued model of $\mathcal{O}$ satisfies $\langle \top \sqsubseteq A \geq 1 \rangle$. A witnessed model $\mathcal{I}_2$ of $\mathcal{T}_2$ can be built as follows (see Figure 2). Let $\Delta^{\mathcal{I}_2}$ be the set of all natural numbers. Set $A^{\mathcal{I}_2}(n) := \frac{1}{n+1}$, $B^{\mathcal{I}_2}(n) := \frac{1}{n+2}$, $r^{\mathcal{I}_2}(n, n+1) := 1$ for all $n \in \mathbb{N}$, and $r^{\mathcal{I}_2}(n, m) := 0$ if $m \neq n+1$. It is straightforward to check that this is indeed a witnessed model of $\mathcal{T}_2$ that violates $\langle \top \sqsubseteq A \geq p \rangle$ for every $p > 0$; in particular for $p = 1$. Using a proof by contradiction similar to Example 3 it can be shown that no witnessed model of $\mathcal{T}_2$ with only finitely many truth values can violate $\langle \top \sqsubseteq A \geq 1 \rangle$. All details can be found in (Borgwardt, Distel, and Peñaloza 2013).

Recall that a (fuzzy) DL has the *finite model property* if every consistent ontology has a model with finite domain. A simple consequence of the last two examples is that G-$\mathcal{AL}$ and G-$\mathfrak{IEL}$ do not have the finite model property. Indeed, each $\mathcal{I}_i$ is a model of the ontology $(\{\langle a : A = 0.5 \rangle\}, \mathcal{T}_i)$ if we interpret the individual name a as $a^{\mathcal{I}_i} := 1$. This shows that these ontologies are consistent. However, any finite model $\mathcal{I}$ of $\mathcal{T}_i$ uses only finitely many truth degrees. As shown in the examples, such an interpretation must satisfy $A^{\mathcal{I}}(x) = 1$ for all $x \in \Delta^{\mathcal{I}}$, and hence violate the assertion $\langle a : A = 0.5 \rangle$. We thus obtain the following result.

Theorem 5. *G-$\mathcal{AL}$ and G-$\mathfrak{IEL}$ do not have the finite model property or the finitely-valued model property.*

The lack of the finitely-valued model property implies that some of the standard techniques used for reasoning in fuzzy DLs cannot be directly applied to any logic that contains G-$\mathcal{AL}$ or G-$\mathfrak{IEL}$. For example, termination of the tableaux-based approach (Stoilos et al. 2007; Straccia and Bobillo 2007) relies on the existence of finitely many *types* that can describe domain elements by specifying the membership degrees for all relevant concepts, while any sound and complete reduction to crisp reasoning (Bobillo, Delgado, and Gómez-Romero 2008; Bobillo et al. 2012) implies the finitely-valued model property.

Moreover, all known undecidability proofs for fuzzy DLs (Baader and Peñaloza 2011a; 2011b; Borgwardt and Peñaloza 2012; Cerami and Straccia 2013) are based on the fact that one can enforce models to have infinitely many values. One could thus be inclined to believe that consistency in G-$\mathfrak{IALC}$ is also undecidable. In the rest of this paper, we show that this is not the case, providing EXPTIME automata-based algorithms that decide consistency, subsumption, and satisfiability.

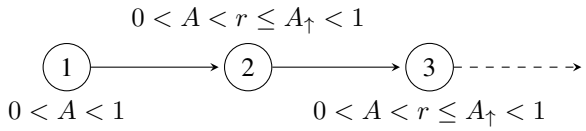

Figure 3: An abstract description of $\mathcal{I}_1$ from Example 3

4 Deciding Local Consistency

In this section, we consider only the special case where the ontology $\mathcal{O} = (\mathcal{A}, \mathcal{T})$ is such that $\mathcal{A}$ is a *local* ordered ABox, which means that it contains no role assertions and uses only a single individual name a. In Section 5, we extend the approach to handle arbitrary ontologies.

The algorithm is based on the observation that the axioms and the semantics of the constructors only introduce restrictions on the *order* of the values that models can assign to concepts, not on the values themselves. For example, an interpretation $\mathcal{I}$ satisfies an assertion $\langle a : (A \to B) = p \rangle$ iff $A^{\mathcal{I}}(a^{\mathcal{I}}) > B^{\mathcal{I}}(a^{\mathcal{I}})$ and $B^{\mathcal{I}}(a^{\mathcal{I}}) = p$. Thus, rather than building a model directly, we first create an abstract representation of a model that encodes for each domain element only the order between concepts.

Example 6. Consider again the TBox $\mathcal{T}_1$ from Example 3. When trying to construct a model violating $\langle \top \sqsubseteq A \geq 1 \rangle$, we start with a domain element satisfying the restriction that the value of A is strictly smaller than 1 (see Figure 3). The second axiom implies that the degree of any outgoing r-connection is bounded by the value of A. Moreover, the first axiom states that the witness of $\forall r.A$ must satisfy A to a degree strictly smaller than the value of the r-connection, and thus strictly smaller than the original value of A.

This yields an abstract description of two domain elements in terms of order relations between values of concepts at the current node and the parent node (denoted by a subscript $\uparrow$). Applying the same argument to the new element yields another element with the same restrictions. In order to construct a model, it is easy to see that the value of A at all considered elements has to be strictly greater than 0—once the value of A is 0, there can be no successors with smaller values for A. Note that it suffices to consider order relations between concepts of neighboring elements, which are directly connected by some role to a degree greater than 0.

As in this example, we use the subscript $\uparrow$ to refer to values of the parent node in the tree-like model that we will construct. We additionally use a new element λ to represent the degree of the role connection from the parent node.

Definition 7 (order structure $\mathcal{U}$). We define the set $\mathsf{sub}_\uparrow(\mathcal{O}) := \{C_\uparrow \mid C \in \mathsf{sub}(\mathcal{O})\}$ and the order structure

$\mathcal{U} := \mathcal{V}_\mathcal{O} \cup \mathsf{sub}(\mathcal{O}) \cup \mathsf{sub}_\uparrow(\mathcal{O}) \cup \{\lambda, \neg\lambda\}$ with the involutive operation inv given by $\mathrm{inv}(\lambda) := \neg\lambda$, $\mathrm{inv}(C) := \neg C$, and $\mathrm{inv}(C_\uparrow) := (\neg C)_\uparrow$ for all $C \in \mathsf{sub}(\mathcal{O})$.

For convenience, we extend the notation of $\mathsf{sub}_\uparrow(\mathcal{O})$ to the elements of $\mathcal{V}_\mathcal{O}$ by setting $q_\uparrow := q$ for all $q \in \mathcal{V}_\mathcal{O}$.

Using total preorders from $\mathrm{order}(\mathcal{U})$, we can now describe the relationships between all the subconcepts from $\mathcal{O}$ and the truth degrees from $\mathcal{V}_\mathcal{O}$ at given domain elements. One can think of such a preorder as the *type* of a domain element, from which a tree-shaped interpretation can be built, represented by a *Hintikka tree*.

In the following, let n be the number of quantified concepts in $\mathsf{sub}(\mathcal{O})$ and ϕ an arbitrary but fixed bijection between the set of all quantified concepts in $\mathsf{sub}(\mathcal{O})$ and $\{1, \dots, n\}$. This bijection specifies which quantified concept is witnessed by which successor in the Hintikka tree. For a given role $r \in \mathsf{N_R}$, we denote by Φ_r the set of all indices $\phi(E)$ where $E \in \mathsf{sub}(\mathcal{O})$ is a quantified concept of the form $\exists r.C$ or $\forall r.C$. Our algorithm will try to decide the existence of an n-ary infinite tree whose nodes are labeled with preorders from $\mathrm{order}(\mathcal{U})$, such that the semantics of the constructors and all the axioms in $\mathcal{O}$ are preserved.

Definition 8 (Hintikka ordering). A *Hintikka ordering* is a total preorder $\lesssim_H \in \mathrm{order}(\mathcal{U})$ that satisfies the following conditions for every $C \in \mathsf{sub}(\mathcal{O})$:

- $C = \top$ implies $C \equiv_H 1$,
- if $C = D_1 \sqcap D_2$, then $C \equiv_H \min_H(D_1, D_2)$,
- if $C = D_1 \to D_2$, then $C \equiv_H \mathrm{res}_H(D_1, D_2)$.

This preorder is *compatible* with the TBox $\mathcal{T}$ if for every GCI $\langle C \sqsubseteq D \geq q\rangle \in \mathcal{T}$ we have $\mathrm{res}_H(C, D) \gtrsim_H q$. It is *compatible* with $\mathcal{A}$ if for every order assertion $\langle a\!:\!C \bowtie q\rangle$ or $\langle a\!:\!C \bowtie a\!:\!D\rangle$ in $\mathcal{A}$, we have $C \bowtie_H q$ or $C \bowtie_H D$, respectively.

The conditions imposed on Hintikka orderings ensure that they preserve the semantics of all the *propositional* constructors. For every *quantified* concept E, we still need to ensure the existence of a witness. This is achieved through ϕ and the following Hintikka condition.

Definition 9 (Hintikka condition). The *Hintikka condition* consists of the following requirements for an $(n{+}1)$-tuple $(\lesssim_0, \lesssim_1, \dots, \lesssim_n)$ of Hintikka orderings:

- for every $1 \leq i \leq n$ and all $\alpha, \beta \in \mathcal{V}_\mathcal{O} \cup \mathsf{sub}(\mathcal{O})$, we have $\alpha \lesssim_0 \beta$ iff $\alpha_\uparrow \lesssim_i \beta_\uparrow$, where $q_\uparrow := q$ for all $q \in \mathcal{V}_\mathcal{O}$;
- for every $\exists r.D \in \mathsf{sub}(\mathcal{O})$, we have
  - $(\exists r.D)_\uparrow \equiv_i \min_i(\lambda, D)$ for $i = \phi(\exists r.D)$, and
  - $(\exists r.D)_\uparrow \gtrsim_i \min_i(\lambda, D)$ for all $i \in \Phi_r$; and
- for every $\forall r.D \in \mathsf{sub}(\mathcal{O})$, we have
  - $(\forall r.D)_\uparrow \equiv_i \mathrm{res}_i(\lambda, D)$ for $i = \phi(\forall r.D)$, and
  - $(\forall r.D)_\uparrow \lesssim_i \mathrm{res}_i(\lambda, D)$ for all $i \in \Phi_r$.

A *Hintikka tree* for $\mathcal{O}$ is an infinite n-ary tree,[1] where every node u is associated with a Hintikka ordering $\lesssim_u$ compatible with $\mathcal{T}$, such that:

[1] We will use words from $\{1, \dots, n\}^*$ to denote the nodes in an infinite n-ary tree.

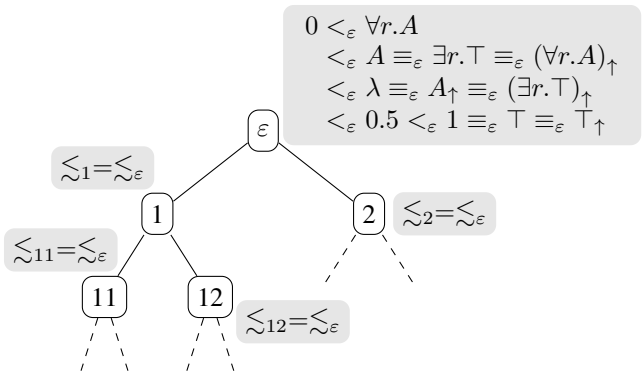

Figure 4: A Hintikka tree for Example 3

- every tuple $(\lesssim_u, \lesssim_{u1}, \dots, \lesssim_{un})$ satisfies the Hintikka condition, and
- $\lesssim_\varepsilon$ is compatible with $\mathcal{A}$.

For instance, Figure 4 shows a Hintikka tree for the TBox $\mathcal{T}_1$ from Example 3 and the ABox $\mathcal{A} = \{\langle a\!:\!A < 1\rangle\}$. Notice that every node is labeled with the same preorder and the tree is invariant w.r.t. the choice of ϕ. We now show that the existence of a Hintikka tree for an ontology $\mathcal{O}$ characterizes the consistency of $\mathcal{O}$.

Proposition 10. *If there is a Hintikka tree for $\mathcal{O}$, then $\mathcal{O}$ has a model.*

Proof. Given a Hintikka tree, we construct a model in two steps. In the first step, we recursively define a function $v\colon \mathcal{U} \times \{1, \dots, n\}^* \to [0, 1]$ satisfying the following conditions for all nodes u and all $\alpha, \beta \in \mathcal{U}$:

(P1) for all values $q \in \mathcal{V}_\mathcal{O}$ we have $v(q, u) = q$,
(P2) $v(\alpha, u) \leq v(\beta, u)$ iff $\alpha \lesssim_u \beta$,
(P3) $v(\mathrm{inv}(\alpha), u) = 1 - v(\alpha, u)$,
(P4) for all $C \in \mathsf{sub}(\mathcal{O})$ and all $i \in \{1, \dots, n\}$

$$v(C, u) = v(C_\uparrow, ui).$$

In the second step, we construct, with the help of this function v, an interpretation $\mathcal{I}_v = (\{1, \dots, n\}^*, \cdot^{\mathcal{I}_v})$ satisfying $C^{\mathcal{I}_v}(u) = v(C, u)$ for all concepts C and all nodes u, and show that $\mathcal{I}_v$ is indeed a model of $\mathcal{O}$.

Step 1 The function v is defined recursively, starting from the root node ε. Let $\mathcal{U}/{\equiv_\varepsilon}$ be the set of all equivalence classes of $\equiv_\varepsilon$. Then $\lesssim_\varepsilon$ yields a total order on $\mathcal{U}/{\equiv_\varepsilon}$. In particular, $[0]_\varepsilon <_\varepsilon [q_1]_\varepsilon <_\varepsilon [q_2]_\varepsilon <_\varepsilon \cdots <_\varepsilon [q_{k-1}]_\varepsilon <_\varepsilon [1]_\varepsilon$ holds if we extend $<_\varepsilon$ to $\mathcal{U}/{\equiv_\varepsilon}$ in the obvious way. For an equivalence class $[\alpha]_\varepsilon$, we set $\mathrm{inv}([\alpha]_\varepsilon) := [\mathrm{inv}(\alpha)]_\varepsilon$, which is well-defined since $\lesssim_\varepsilon$ is an element of $\mathrm{order}(\mathcal{U})$.

We first define an auxiliary function $\tilde{v}_\varepsilon\colon \mathcal{U}/{\equiv_\varepsilon} \to [0, 1]$. For all $q \in \mathcal{V}_\mathcal{O}$ we define $\tilde{v}_\varepsilon([q]_\varepsilon) := q$. It remains to define a value for all equivalence classes that do not contain a value from $\mathcal{V}_\mathcal{O}$. Notice that due to the minimality of $[0]_\varepsilon$ and maximality of $[1]_\varepsilon$ every such class must be strictly between $[q_i]_\varepsilon$ and $[q_{i+1}]_\varepsilon$ for two adjacent truth degrees q_i, q_{i+1}. For

every $i \in \{0, \dots, k-1\}$, let ν_i be the number of equivalence classes that are strictly between $[q_i]_\varepsilon$ and $[q_{i+1}]_\varepsilon$. We assume that these classes are denoted by E^i_j such that $[q_i]_\varepsilon <_\varepsilon E^i_1 <_\varepsilon E^i_2 <_\varepsilon \cdots <_\varepsilon E^i_{\nu_i} <_\varepsilon [q_{i+1}]_\varepsilon$. We then define values $q_i < s^i_1 < s^i_2 < \cdots < s^i_{\nu_i} < q_{i+1}$ as

$$s^i_j := q_i + \tfrac{j}{\nu_i+1}(q_{i+1} - q_i) \tag{3}$$

and set $\tilde{v}_\varepsilon(E^i_j) := s^i_j$ for every j, $1 \le j \le \nu_i$. Finally, we define $v(\alpha, \varepsilon) := \tilde{v}_\varepsilon([\alpha]_\varepsilon)$ for all $\alpha \in \mathcal{U}$. This construction ensures that (P1) and (P2) hold at the node ε. To see that (P3) is also satisfied, note that $1-q_{i+1}$ and $1-q_i$ are also adjacent in $\mathcal{V}_\mathcal{O}$ and have exactly the inverses $\mathrm{inv}(E^i_j)$ between them in reversed order.

For the recursion step, assume that we have already defined v for a node u, such that (P1)–(P3) are satisfied at u and let $i \in \{1, \dots, n\}$. We initialize the auxiliary function $\tilde{v}_{ui} \colon \mathcal{U}/{\equiv_{ui}} \to [0,1]$ by setting $\tilde{v}_{ui}([q]_{ui}) := q$ for all $q \in \mathcal{V}_\mathcal{O}$ and $\tilde{v}_{ui}([C_\uparrow]_{ui}) := v(C, u)$ for all $C \in \mathsf{sub}(\mathcal{O})$. To see that this is well-defined, consider $[C_\uparrow]_{ui} = [D_\uparrow]_{ui}$, i.e. $C_\uparrow \equiv_{ui} D_\uparrow$. From the Hintikka condition, it follows that $C \equiv_u D$, and from (P2) at u we obtain $v(C,u) = v(D,u)$. A similar argument can be used to show that $[q]_{ui} = [C_\uparrow]_{ui}$ implies $v(q,u) = v(C,u)$. For the remaining equivalence classes, we can use a construction analogous to the case for ε by considering the two unique neighboring equivalence classes that contain an element of $\mathcal{V}_\mathcal{O} \cup \mathsf{sub}_\uparrow(\mathcal{O})$. We now define $v(\alpha, ui) := \tilde{v}_{ui}([\alpha]_{ui})$. This construction ensures that (P1)–(P3) hold at ui, and that (P4) holds for u.

Step 2 We define the interpretation $\mathcal{I}_v$ over the domain $\{1, \dots, n\}^*$ as follows. For every concept name $A \in \mathsf{N_C}$ and all domain elements u, we set

$$A^{\mathcal{I}_v}(u) := \begin{cases} v(A,u) & \text{if } A \in \mathsf{sub}(\mathcal{O}), \\ 0 & \text{otherwise.} \end{cases}$$

For every role name $r \in \mathsf{N_R}$ and all domain elements u, we likewise define

$$r^{\mathcal{I}_v}(u,w) := \begin{cases} v(\lambda, ui) & \text{if } w = ui \text{ with } i \in \Phi_r, \\ 0 & \text{otherwise.} \end{cases}$$

Finally, we define $a^{\mathcal{I}_v} := \varepsilon$ for the individual name a. It can be shown by induction on the structure of C that

$$C^{\mathcal{I}_v}(u) = v(C,u) \text{ for all } C \in \mathsf{sub}(\mathcal{O}), u \in \{1, \dots, n\}^* \tag{4}$$

holds. In this proof by induction

- the base case follows trivially from the definition of $\mathcal{I}_v$,
- the cases $\top$, $C \sqcap D$, and $C \to D$ follow from (P1), (P2), and Definition 8,
- the case $\neg C$ follows from (P3), and
- Definition 9 and (P4) entail the cases $\exists r.C$ and $\forall r.C$.

For details, we refer the reader to the technical report (Borgwardt, Distel, and Peñaloza 2013).

It remains to show that $\mathcal{I}_v$ is indeed a model of $\mathcal{O}$. For every $\langle a\colon C \bowtie q\rangle \in \mathcal{A}$, the Hintikka tree satisfies $C \bowtie_\varepsilon q$, and thus we obtain from (4), (P1), and (P2):

$$C^{\mathcal{I}_v}(a^{\mathcal{I}_v}) = v(C, \varepsilon) \bowtie v(q, \varepsilon) = q,$$

and similarly for assertions of the form $\langle a\colon C \bowtie a\colon D\rangle$.

Now, let $u \in \{1, \dots, n\}^*$ be a domain element of $\mathcal{I}_v$ and $\langle C \sqsubseteq D \ge q\rangle \in \mathcal{T}$. Since $p \in \mathcal{V}_\mathcal{O}$ and $\lesssim_u$ is compatible with $\mathcal{T}$, it must hold that

$$q \lesssim_u \mathrm{res}_u(C,D) = \begin{cases} 1 & \text{if } C \lesssim_u D \\ D & \text{if } D <_u C \end{cases} \overset{\text{(P2)}}{=} \begin{cases} 1 & \text{if } v(C,u) \le v(D,u) \\ D & \text{if } v(D,u) < v(C,u). \end{cases}$$

Thus, (P1) and (P2) yield

$$\begin{aligned} q = v(q,u) &\le \begin{cases} v(1,u) & \text{if } v(C,u) \le v(D,u) \\ v(D,u) & \text{if } v(D,u) < v(C,u) \end{cases} \\ &= v(C,u) \Rightarrow v(D,u) \\ &= C^{\mathcal{I}_v}(u) \Rightarrow D^{\mathcal{I}_v}(u). \end{aligned}$$

□

Conversely, every model can be transformed into a Hintikka tree. The idea is to *unravel* the model into an infinite tree, and then abstract from the specific values by just considering the ordering between the elements of $\mathcal{U}$. This idea is formalized next.

Proposition 11. *If $\mathcal{O}$ has a model, then there is a Hintikka tree for $\mathcal{O}$.*

Proof. Let $\mathcal{I}$ be a model of $\mathcal{O}$. We use this model to guide the construction of a Hintikka tree for $\mathcal{O}$. During this construction, we will recursively generate a mapping $g\colon \{1, \dots, n\}^* \to \Delta^\mathcal{I}$ specifying which domain elements correspond to the nodes in the tree. This mapping will satisfy the following condition for all $\alpha, \beta \in \mathcal{V}_\mathcal{O} \cup \mathsf{sub}(\mathcal{O})$ and all $u \in \{1, \dots, n\}^*$:

(P5) $\alpha \lesssim_u \beta$ iff $\alpha^\mathcal{I}(g(u)) \le \beta^\mathcal{I}(g(u))$,

where we define $q^\mathcal{I}(x) := q$ for all $q \in \mathcal{V}_\mathcal{O}$ and $x \in \Delta^\mathcal{I}$.

We first consider the root node ε of the tree. Recall that the ontology contains a local ordered ABox, using only the individual name a. We define $g(\varepsilon) := a^\mathcal{I}$ and the Hintikka ordering $\lesssim_\varepsilon$ as follows for all $\alpha, \beta \in \mathcal{V}_\mathcal{O} \cup \mathsf{sub}(\mathcal{O})$:

$$\alpha \lesssim_\varepsilon \beta \text{ iff } \alpha^\mathcal{I}(a^\mathcal{I}) \le \beta^\mathcal{I}(a^\mathcal{I}).$$

We extend this order to the elements in $\mathsf{sub}_\uparrow(\mathcal{O}) \cup \{\lambda, \neg\lambda\}$ arbitrarily, in such a way that for all $\alpha, \beta \in \mathcal{U}$ we have $\alpha \lesssim_\varepsilon \beta$ iff $\mathrm{inv}(\beta) \lesssim_\varepsilon \mathrm{inv}(\alpha)$. It is straightforward to show that $\lesssim_\varepsilon$ is an element of $\mathrm{order}(\mathcal{U})$ satisfying (P5) at ε, and that furthermore $\lesssim_\varepsilon$ is a Hintikka ordering that is compatible with $\mathcal{T}$ (cf. (Borgwardt, Distel, and Peñaloza 2013)).

Assume now that we have already defined $g(u)$ and $\lesssim_u$ for a node $u \in \{1, \dots, n\}^*$ such that (P5) is satisfied. For all $i \in \{1, \dots, n\}$, we now construct $\lesssim_{ui}$ in such a way that the tuple $(\lesssim_u, \lesssim_{u1}, \dots, \lesssim_{un})$ satisfies the Hintikka condition. For brevity, we consider only the case that $i = \phi(\exists r.D)$;

value restrictions can be handled using similar arguments. Since $\mathcal{I}$ is witnessed, there must be a $y_i \in \Delta^{\mathcal{I}}$ such that $(\exists r.D)^{\mathcal{I}}(g(u)) = \min(r^{\mathcal{I}}(g(u), y_i), D^{\mathcal{I}}(y_i))$. We define $g(ui) := y_i$, and $\lesssim_{ui}$ for all $\alpha, \beta \in \mathcal{U}$ by

$$\alpha \lesssim_{ui} \beta \text{ iff } \alpha^{\mathcal{I}}(g(ui)) \leq \beta^{\mathcal{I}}(g(ui)), \tag{5}$$

where we abbreviate $\lambda^{\mathcal{I}}(g(ui)) := r^{\mathcal{I}}(g(u), g(ui))$ and $(C_\uparrow)^{\mathcal{I}}(g(ui)) := C^{\mathcal{I}}(g(u))$ for all concepts $C \in \mathsf{sub}(\mathcal{O})$. It is clear that $\lesssim_{ui}$ behaves on $\mathcal{V}_\mathcal{O} \cup \mathsf{sub}_\uparrow(\mathcal{O})$ exactly as $\lesssim_u$ does on $\mathcal{V}_\mathcal{O} \cup \mathsf{sub}(\mathcal{O})$. Following the same arguments used for the root node, it is easy to show that $\lesssim_{ui}$ is actually a Hintikka ordering compatible with $\mathcal{T}$.

We show the Hintikka condition for $(\lesssim_u, \lesssim_{u1}, \ldots, \lesssim_{un})$. For the case $i = \phi(\exists r.D)$, the construction of g yields that $(\exists r.D)^{\mathcal{I}}(g(u)) = \min\left(r^{\mathcal{I}}(g(u), g(ui)), D^{\mathcal{I}}(g(ui))\right)$, and thus

$$((\exists r.D)_\uparrow)^{\mathcal{I}}(g(ui)) = \min\left(\lambda^{\mathcal{I}}(g(ui)), D^{\mathcal{I}}(g(ui))\right).$$

Using (5), we obtain $(\exists r.D)_\uparrow \equiv_{ui} \min_{ui}(\lambda, D)$ as required. Furthermore, for all $i \in \Phi_r$, it holds that

$$\begin{aligned}(\exists r.D)^{\mathcal{I}}(g(u)) &= \sup_{y \in \Delta^{\mathcal{I}}} \min\left(r^{\mathcal{I}}(g(u), y), D^{\mathcal{I}}(y)\right) \\ &\geq \min\left(r^{\mathcal{I}}(g(u), g(ui)), D^{\mathcal{I}}(g(ui))\right),\end{aligned}$$

which similarly shows $(\exists r.D)_\uparrow \gtrsim_{ui} \min_{ui}(\lambda, D)$. Similar arguments apply to the value restrictions in $\mathsf{sub}(\mathcal{O})$.

Finally, for every $\langle a\!:\!C \bowtie q\rangle \in \mathcal{A}$, we have $C^{\mathcal{I}}(a^{\mathcal{I}}) \bowtie q$, and thus $C \bowtie_\varepsilon q$ by definition of $\lesssim_\varepsilon$, and similarly for assertions of the form $\langle a\!:\!C \bowtie a\!:\!D\rangle$. Hence, the tree defined by $\lesssim_u$, for $u \in \{1, \ldots, n\}^*$, is a Hintikka tree for $\mathcal{O}$. □

Propositions 10 and 11 show that Hintikka trees characterize consistency of an ontology with a local ordered ABox. In other words, deciding the existence of a Hintikka tree for $\mathcal{O}$ suffices for deciding consistency of $\mathcal{O}$. We now turn our attention to the former problem, and show that it can be solved in exponential time in the size of $\mathcal{O}$. For this, we construct a *looping tree automaton* whose runs correspond exactly to such Hintikka trees. Thus, the automaton accepts a non-empty language iff the ontology $\mathcal{O}$ is consistent.

A *looping automaton* over n-ary (infinite) trees is a tuple $\mathbf{A} = (Q, I, \Delta)$, consisting of a non-empty set Q of *states*, a subset $I \subseteq Q$ of *initial states*, and a *transition relation* $\Delta \subseteq Q^{n+1}$. A *run* of this automaton is a mapping $\rho\colon \{1, \ldots, n\}^* \to Q$ such that (i) $\rho(\varepsilon) \in I$, and (ii) for all $u \in \{1, \ldots, n\}^*$, we have $\left(\rho(u), \rho(u1), \ldots, \rho(un)\right) \in \Delta$. $\mathbf{A}$ is *non-empty* iff it has a run.

Definition 12. The *Hintikka automaton* for an ontology $\mathcal{O}$ is the looping tree automaton $\mathbf{A}_\mathcal{O} := (Q_\mathcal{O}, I_\mathcal{O}, \Delta_\mathcal{O})$, where

- $Q_\mathcal{O}$ is the set of all Hintikka orderings compatible with $\mathcal{T}$,
- $I_\mathcal{O} := \{\lesssim_H \in Q_\mathcal{O} \mid \lesssim_H \text{ is compatible with } \mathcal{A}\}$, and
- $\Delta_\mathcal{O}$ contains all tuples from $Q_\mathcal{O}^{n+1}$ that satisfy the Hintikka condition.

It is easy to see that the runs of $\mathbf{A}_\mathcal{O}$ are exactly the Hintikka trees for $\mathcal{O}$. Observe that the number of Hintikka orderings for $\mathcal{O}$ is bounded by $2^{|\mathcal{U}|^2}$ and the cardinality of $\mathcal{U} = \mathcal{V}_\mathcal{O} \cup \mathsf{sub}(\mathcal{O}) \cup \mathsf{sub}_\uparrow(\mathcal{O}) \cup \{\lambda, \neg\lambda\}$ is linear in the size of $\mathcal{O}$. Likewise, the arity n of the automaton is bounded by $|\mathsf{sub}(\mathcal{O})|$, which is linear in the size of $\mathcal{O}$. Thus, the size of the Hintikka automaton $\mathbf{A}_\mathcal{O}$ is exponential in the size of $\mathcal{O}$. Since (non-)emptiness of looping tree automata can be decided in polynomial time (Vardi and Wolper 1986), we obtain overall an ExpTime-decision procedure for consistency of ontologies with local ordered ABoxes in G-$\mathfrak{I}\mathcal{ALC}$. Note that concept satisfiability in classical $\mathcal{ALC}$ is already ExpTime-hard w.r.t. general TBoxes (Schild 1991), and hence our complexity bounds are tight.

Theorem 13. *Consistency in* G-$\mathfrak{I}\mathcal{ALC}$ *w.r.t. local ordered ABoxes and witnessed models is* ExpTime*-complete.*

In the following section, we remove the restriction to local ordered ABoxes and show that consistency remains ExpTime-complete in the general case.

5 Reducing Consistency to Local Consistency

To decide consistency of G-$\mathfrak{I}\mathcal{ALC}$-ontologies containing more that one individual name, we adapt a technique from classical DLs known as *pre-completion* (Hollunder 1996). Intuitively, we try to build a forest-shaped model that satisfies the ontology. This model is composed of a finite set of trees, one for each individual name appearing in the ABox, whose roots can be arbitrarily interconnected due to the presence of role assertions. As before, rather than explicitly building such models, we use total preorders to represent them in an abstract manner.

The idea of pre-completion is to extend the input ABox to a full specification of each individual, and then decide consistency w.r.t. the local ABoxes associated with each individual name. In our setting, this amounts to extending the input ABox to a total preorder $\lesssim_\mathcal{A}$. This preorder represents the nucleus of a model of the ontology. To extend this to a full model, we check an (ordered) local consistency condition for each of the individual names, and use $\lesssim_\mathcal{A}$ to combine the resulting tree-shaped interpretations.

More formally, let $\mathcal{O} = (\mathcal{A}, \mathcal{T})$ be an ontology, and let $\mathsf{Ind}(\mathcal{A})$ denote the set of individual names occurring in $\mathcal{A}$. We define the order structure

$$\begin{aligned}\mathcal{W} := \mathcal{V}_\mathcal{O} &\cup \{a\!:\!C \mid a \in \mathsf{Ind}(\mathcal{A}),\ C \in \mathsf{sub}(\mathcal{O})\} \\ &\cup \{(a,b)\!:\!r \mid a, b \in \mathsf{Ind}(\mathcal{A}),\ r \text{ occurs in } \mathcal{O}\} \\ &\cup \{(a,b)\!:\!\neg r \mid a, b \in \mathsf{Ind}(\mathcal{A}),\ r \text{ occurs in } \mathcal{O}\}\end{aligned}$$

with $\mathrm{inv}(a\!:\!C) := a\!:\!\neg C$ and $\mathrm{inv}((a,b)\!:\!r) := (a,b)\!:\!\neg r$.

Definition 14 (pre-completion). A *pre-completion* of $\mathcal{A}$ w.r.t. $\mathcal{T}$ is a total preorder $\lesssim_\mathcal{A} \in \mathrm{order}(\mathcal{W})$ such that:

a) for every $a \in \mathsf{Ind}(\mathcal{A})$ and all $C \in \mathsf{sub}(\mathcal{O})$,
   - if $C = \top$, then $a\!:\!C \equiv_\mathcal{A} 1$,
   - if $C = D_1 \sqcap D_2$, then $a\!:\!C \equiv_\mathcal{A} \min_\mathcal{A}(a\!:\!D_1, a\!:\!D_2)$,
   - if $C = D_1 \to D_2$, then $a\!:\!C \equiv_\mathcal{A} \mathrm{res}_\mathcal{A}(a\!:\!D_1, a\!:\!D_2)$;

b) for every $\exists r.C \in \mathsf{sub}(\mathcal{O})$ and $a, b \in \mathsf{Ind}(\mathcal{A})$, we have
$$a\!:\!\exists r.C \gtrsim_\mathcal{A} \min_\mathcal{A}((a,b)\!:\!r, b\!:\!C);$$

c) for every $\forall r.C \in \mathsf{sub}(\mathcal{O})$ and $a, b \in \mathsf{Ind}(\mathcal{A})$, we have
$$a\!:\!\forall r.C \lesssim_\mathcal{A} \mathrm{res}_\mathcal{A}((a,b)\!:\!r, b\!:\!C);$$

d) for all $a \in \mathsf{Ind}(\mathcal{A})$ and every GCI $\langle C \sqsubseteq D \geq q\rangle \in \mathcal{T}$, we have $\mathrm{res}_{\mathcal{A}}(a\!:\!C, a\!:\!D) \gtrsim_{\mathcal{A}} q$; and

e) for every assertion $\langle \alpha \bowtie \beta\rangle \in \mathcal{A}$, we have $\alpha \bowtie_{\mathcal{A}} \beta$.

This definition generalizes the local conditions of Definitions 8 and 9 to handle several named individuals simultaneously. One difference is that we do not create witnesses for the quantified concepts here. This will be taken care of by testing the following local ordered ABoxes for consistency. For a pre-completion $\lesssim_{\mathcal{A}}$ and $a \in \mathsf{Ind}(\mathcal{A})$, we define the local ordered ABox $\mathcal{A}_a$ as the set of all order assertions $\langle \alpha \bowtie \beta\rangle$ over a and $\mathsf{sub}(\mathcal{O})$ satisfying $\alpha \bowtie_{\mathcal{A}} \beta$.[2] That is,

$$\mathcal{A}_a := \{\langle a\!:\!C \bowtie q\rangle \mid C \in \mathsf{sub}(\mathcal{O}),\ q \in \mathcal{V}_{\mathcal{O}},\ a\!:\!C \bowtie_{\mathcal{A}} q\} \cup \{\langle a\!:\!C \bowtie a\!:\!D\rangle \mid C, D \in \mathsf{sub}(\mathcal{O}),\ a\!:\!C \bowtie_{\mathcal{A}} a\!:\!D\}.$$

Lemma 15. *An ontology $\mathcal{O} = (\mathcal{A}, \mathcal{T})$ is consistent iff there is a pre-completion $\lesssim_{\mathcal{A}}$ of $\mathcal{A}$ w.r.t. $\mathcal{T}$ such that, for every $a \in \mathsf{Ind}(\mathcal{A})$, the ontology $\mathcal{O}_a := (\mathcal{A}_a, \mathcal{T})$ is consistent.*

Proof. Let $\mathcal{I}$ be a model of $\mathcal{O}$. We define the total preorder $\lesssim_{\mathcal{A}}$ by setting $\alpha \lesssim_{\mathcal{A}} \beta$ if and only if $\alpha^{\mathcal{I}} \leq \beta^{\mathcal{I}}$, where we set $((a,b)\!:\!\neg r)^{\mathcal{I}} := 1 - r^{\mathcal{I}}(a^{\mathcal{I}}, b^{\mathcal{I}})$. A straightforward argument that $\lesssim_{\mathcal{A}}$ is a pre-completion of $\mathcal{A}$ w.r.t. $\mathcal{T}$ and that $\mathcal{I}$ is a model of $(\mathcal{A}_a, \mathcal{T})$ for each $a \in \mathsf{Ind}(\mathcal{A})$ can be found in (Borgwardt, Distel, and Peñaloza 2013).

Conversely, let $\lesssim_{\mathcal{A}}$ be a pre-completion of $\mathcal{A}$ w.r.t. $\mathcal{T}$ and each $(\mathcal{A}_a, \mathcal{T})$ be consistent. By Proposition 11, there are Hintikka trees for $(\mathcal{A}_a, \mathcal{T})$ that consist of Hintikka orderings $\lesssim^a_u$ for all $u \in \{1, \dots, n\}^*$, where n is the number of existential and value restrictions in $\mathsf{sub}(\mathcal{O})$. Similar to the proof of Proposition 10, we first construct a function $v\colon \mathcal{W} \cup (\mathsf{Ind}(\mathcal{A}) \times \mathcal{U} \times \{1, \dots, n\}^*) \to [0,1]$ such that

- for all values $q \in \mathcal{V}_{\mathcal{O}}$, we have $v(q) = q$,
- for all $\alpha, \beta \in \mathcal{W}$, we have $v(\alpha) \leq v(\beta)$ iff $\alpha \lesssim_{\mathcal{A}} \beta$,
- for all $\alpha \in \mathcal{W}$, we have $v(\mathrm{inv}(\alpha)) = 1 - v(\alpha)$,
- for every $C \in \mathsf{sub}(\mathcal{O})$ and all $a \in \mathsf{Ind}(\mathcal{A})$, we have $v(a\!:\!C) = v(a, C, \varepsilon)$,
- for all $u \in \{1, \dots, n\}^*$ and all $a \in \mathsf{Ind}(\mathcal{A})$,
  - for all values $q \in \mathcal{V}_{\mathcal{O}}$, we have $v(a, q, u) = q$,
  - for all $\alpha, \beta \in \mathcal{U}$, we have $v(a, \alpha, u) \leq v(a, \beta, u)$ iff $\alpha \lesssim^a_u \beta$,
  - for all $\alpha \in \mathcal{U}$, we have $v(a, \mathrm{inv}(\alpha), u) = 1 - v(a, \alpha, u)$, and
  - for all concepts $C \in \mathsf{sub}(\mathcal{O})$ and all $i \in \{1, \dots, n\}$, we have that $v(a, C, u) = v(a, C_\uparrow, ui)$.

We will then use this function to define a model of $\mathcal{O}$.

Using the technique from the proof of Proposition 10, we first define v on $\mathcal{W}$. On the set $\mathcal{W}/\!\equiv_{\mathcal{A}}$ of all equivalence classes of $\equiv_{\mathcal{A}}$, we define an auxiliary function $\tilde{v}_{\mathcal{A}}\colon \mathcal{W}/\!\equiv_{\mathcal{A}} \to [0,1]$, by setting $\tilde{v}_{\mathcal{A}}([q]_{\mathcal{A}}) := q$ for each $q \in \mathcal{V}_{\mathcal{O}}$ and treating the remaining equivalence classes as in (3). We then define $v(\alpha) := \tilde{v}_{\mathcal{A}}([\alpha]_{\mathcal{A}})$ for all $\alpha \in \mathcal{W}$.

For each $a \in \mathsf{Ind}(\mathcal{A})$, $C \in \mathsf{sub}(\mathcal{O})$, and $q \in \mathcal{V}_{\mathcal{O}}$, we now set $v(a, C, \varepsilon) := v(a\!:\!C)$ and $v(a, q, \varepsilon) := q$. The values of $v(a, \alpha, \varepsilon)$ for elements $\alpha \in \mathsf{sub}_\uparrow(\mathcal{O}) \cup \{\lambda, \neg\lambda\}$ are irrelevant for the desired properties and can be fixed arbitrarily, as long as we have $v(a, \alpha, \varepsilon) \leq v(a, \beta, \varepsilon)$ iff $\alpha \lesssim^a_\varepsilon \beta$ and $v(a, \mathrm{inv}(\alpha), \varepsilon) = 1 - v(a, \alpha, u)$ for all $\alpha, \beta \in \mathcal{U}$, e.g. using the technique in (3). The definition of $v(a, \alpha, u)$ can now proceed as in the proof of Proposition 10 based on the Hintikka trees for $(\mathcal{A}_a, \mathcal{T})$. This construction ensures that v has the desired properties.

We now define the interpretation $\mathcal{I}$ as follows:

- $\Delta^{\mathcal{I}} := \mathsf{Ind}(\mathcal{A}) \times \{1, \dots, n\}^*$,
- $a^{\mathcal{I}} := (a, \varepsilon)$ for each $a \in \mathsf{Ind}(\mathcal{A})$,
- $A^{\mathcal{I}}(a, u) := v(a, A, u)$ for all $a \in \mathsf{Ind}(\mathcal{A})$, concept names $A \in \mathsf{sub}(\mathcal{O})$, and $u \in \{1, \dots, n\}^*$, and
- $r^{\mathcal{I}}((a,u),(b,u')) :=$
$$\begin{cases} v(a, \lambda, ui) & \text{if } a = b \text{ and } u' = ui \text{ with } i \in \Phi_r, \\ v((a,b)\!:\!r) & \text{if } u = u' = \varepsilon \text{ and } r \text{ occurs in } \mathcal{O}, \\ 0 & \text{otherwise.} \end{cases}$$

The interpretation of the remaining individual and concept names is irrelevant and can be fixed arbitrarily. As in Proposition 10, we can show by induction on the structure of C that $C^{\mathcal{I}}(a, u) = v(a, C, u)$ holds for all $C \in \mathsf{sub}(\mathcal{O})$, $a \in \mathsf{Ind}(\mathcal{A})$, and $u \in \{1, \dots, n\}^*$ by induction on the structure of C. The claim for $\top$, $\neg C$, $C \sqcap D$, and $C \to D$ follows as before from Condition a) of Definition 14 and the fact that each $\lesssim^a_u$ is a Hintikka ordering.

Consider now an existential restriction $\exists r.C \in \mathsf{sub}(\mathcal{O})$ and the domain element (a, ε) for some $a \in \mathsf{Ind}(\mathcal{A})$. By the Hintikka condition and the induction hypothesis, we have $v(a, \exists r.C, u) = \min\big(r^{\mathcal{I}}((a,\varepsilon),(a,i_0)), C^{\mathcal{I}}(a, i_0)\big)$, where $i_0 = \phi(\exists r.C)$, as in the proof of Proposition 10. Likewise, $v(a, \exists r.C, u) \geq \min(r^{\mathcal{I}}((a,\varepsilon),(a,i)), C^{\mathcal{I}}(a,i))$ holds for all $i \in \Phi_r$. Finally, for each $b \in \mathsf{Ind}(\mathcal{A})$, we have $v(a, \exists r.C, u) \geq \min(r^{\mathcal{I}}((a,\varepsilon),(b,\varepsilon)), C^{\mathcal{I}}(b,\varepsilon))$ by Condition b) of Definition 14. Since (a, ε) does not have any other relevant r-successors, this shows the claim for $\exists r.C$ at (a, ε). At the other domain elements, it can be shown as for Proposition 10. Similar arguments apply to all $\forall r.C \in \mathsf{sub}(\mathcal{O})$.

Finally, the fact that $\mathcal{I}$ is actually a model of $\mathcal{O}$ is ensured by compatibility of all Hintikka orderings with $\mathcal{T}$ and Conditions e) and d) of Definition 14. □

Note that the cardinality of $\mathrm{order}(\mathcal{W})$ is exponential in the size of $\mathcal{O}$, and all elements of $\mathrm{order}(\mathcal{W})$ are of polynomial size. We can thus enumerate $\mathrm{order}(\mathcal{W})$, check for each element whether it satisfies Definition 14 in polynomial time, and then execute the polynomially many local consistency tests as described by Lemma 15. This yields the following complexity result.

Corollary 16. *Consistency in* G-$\mathcal{IALC}$ *w.r.t. witnessed models is* ExpTime*-complete.*

6 Satisfiability and Subsumption

We have described an exponential-time algorithm for deciding consistency of G-$\mathcal{IALC}$ ontologies. We now direct our attention at other standard reasoning problems in fuzzy

[2] It actually suffices to consider only $\bowtie \in \{>, =, <\}$.

DLs; namely, deciding concept satisfiability and subsumption, and computing the best truth degrees to which these hold. Recall from Section 2 that for these reasoning problems we can restrict our attention to ontologies with an empty ABox.

Let now $\mathcal{O} = (\emptyset, \mathcal{T})$ be an ontology. It is easy to see that p-subsumption and p-satisfiability w.r.t. $\mathcal{O}$ can be reduced in polynomial time to consistency w.r.t. local ordered ABoxes. More precisely, for any two concepts C, D and $p \in [0, 1]$,

- C is p-satisfiable w.r.t. $\mathcal{O}$ iff $(\{\langle a : C \geq p\rangle\}, \mathcal{T})$ is consistent, and
- C is p-subsumed by D w.r.t. $\mathcal{O}$ iff $(\{\langle a : C \rightarrow D < p\rangle\}, \mathcal{T})$ is inconsistent,

where a is an arbitrary individual name. We thus obtain the following result from Theorem 13.

Theorem 17. *Satisfiability and subsumption in* G-$\mathcal{IALC}$ *w.r.t. witnessed models are* EXPTIME*-complete.*

We now shift our attention to the problems of computing the *best* satisfiability and subsumption degrees. We first show that the local consistency checks required for deciding p-satisfiability and p-subsumption only depend on the position of p relative to the values occurring in $\mathcal{T}$, but not on the precise value of p. To prove this, we again use the preorders of the previous sections, and in particular Hintikka trees.

Lemma 18. *Let $p, p' \in (q_i, q_{i+1})$ for two adjacent values $q_i, q_{i+1} \in \mathcal{V}_\mathcal{O}$, and C be a concept. Then $(\{\langle a : C \bowtie p\rangle\}, \mathcal{T})$ is consistent iff $(\{\langle a : C \bowtie p'\rangle\}, \mathcal{T})$ is consistent.*

Proof. By Propositions 10 and 11, both consistency conditions are equivalent to the existence of Hintikka trees, albeit over different order structures. We denote by $\mathcal{U}_p$ the order structure from Definition 7 over $\mathcal{V}_p := \mathcal{V}_\mathcal{O} \cup \{p, 1 - p\}$, and by $\mathcal{U}_{p'}$ the one over $\mathcal{V}_{p'} := \mathcal{V}_\mathcal{O} \cup \{p', 1 - p'\}$. Observe that the bijection $\iota \colon \mathcal{V}_p \to \mathcal{V}_{p'}$ that simply maps p to p' and $1 - p$ to $1 - p'$ and leaves the other values as they are, can be extended to a bijection between $\mathcal{U}_p$ and $\mathcal{U}_{p'}$ by defining it as the identity on all elements outside of $\mathcal{V}_p$. Furthermore, it is compatible with the involutive operator inv, i.e. we have $\iota(\mathrm{inv}(\alpha)) = \mathrm{inv}(\iota(\alpha))$ for all $\alpha \in \mathcal{U}_p$.

It is straightforward to extend this bijection to Hintikka orderings and Hintikka tress (see (Borgwardt, Distel, and Peñaloza 2013) for details). Then there is a Hintikka tree for $(\{\langle a : C \bowtie p\rangle\}, \mathcal{T})$ iff there is one for $(\{\langle a : C \bowtie p'\rangle\}, \mathcal{T})$, which concludes the proof. □

This shows that subsumption between C and D or satisfiability of C either holds for all values in an interval (q_i, q_{i+1}), or for none of them.

Corollary 19. *For any two concepts C and D, the best subsumption degree of C and D w.r.t. $\mathcal{O}$ and the best satisfiability degree of C w.r.t. $\mathcal{O}$ are always in $\mathcal{V}_\mathcal{O}$.*

Since the best subsumption degree p of C and D is always a subsumption degree, i.e. C is p-subsumed by D, it suffices to check subsumption w.r.t. the values from $\mathcal{V}_\mathcal{O}$ in order to determine the best subsumption degree. Thus, we only have to execute linearly many (in-)consistency checks to compute the best subsumption degree.

However, it is possible that C is p-satisfiable for every $p \in (q_i, q_{i+1})$, but not q_{i+1}-satisfiable. Therefore, we check satisfiability for all values $\frac{q_i + q_{i+1}}{2}$. The best satisfiability degree is then the largest q_{i+1} for which this check succeeds (or 0 if it never succeeds). Again, this means that we have to execute linearly many consistency checks to compute the best satisfiability degree.

By combining these reductions with Theorem 13, we obtain the following results.

Corollary 20. *In* G-$\mathcal{IALC}$ *w.r.t. witnessed models, best subsumption and satisfiability degrees can be computed in exponential time.*

7 Conclusions

We have studied the standard reasoning problems for the fuzzy DL G-$\mathcal{IALC}$ w.r.t. witnessed model semantics. The contributions of the paper are twofold. First, we have shown that, contrary to popular belief, reasoning in this logic cannot be restricted to reasoning over finitely-valued models without affecting its consequences. In particular, this implies that the algorithms based on maintaining only a finite set of truth degrees (Bobillo et al. 2009; 2012) are incomplete for the general semantics. Moreover, this also implies that the logic does not have the finite model property, and hence standard tableau-based approaches cannot terminate (Bobillo and Straccia 2007; Straccia and Bobillo 2007; Bobillo, Bou, and Straccia 2011).

As the second contribution of the paper, we showed that all standard reasoning problems can be solved in exponential time. To achieve this, we developed an automaton that decides the existence of a Hintikka tree, which is an abstract representation of a model of a given ontology. The main insight needed for this approach is that we can abstract from the precise truth degrees assigned by an interpretation, and focus only on their ordering.

As an added benefit, in our formalism we can express order assertions like $\langle \mathsf{ana} : \mathsf{Tall} > \mathsf{bob} : \mathsf{Tall}\rangle$, intuitively stating that Ana is taller than Bob, without needing to specify the precise degrees to which ana and bob belong to the concept Tall. This is similar to concrete domains (Lutz 2003), which can even compare values at unnamed domain elements. But concrete domains allow only for atomic attributes, whereas order assertions can also contain complex concepts.

As we have developed an automata-based algorithm, it is natural to ask whether previous automata-based approaches (Baader, Hladik, and Peñaloza 2008; Borgwardt and Peñaloza 2013a) can be adapted to this setting in order to handle the expressivity up to G-$\mathcal{ISCHI}$, or provide better upper-bounds for reasoning w.r.t. *acyclic* TBoxes. We will study this problem in future work. We also plan to adapt these ideas into a tableau-based algorithm which is more suitable for implementation.

Recall that we have restricted our framework to reasoning w.r.t. *witnessed* models only. Indeed, this restriction is fundamental for our proof of Proposition 11. One open question is whether consistency of G-$\mathcal{IALC}$ ontologies w.r.t. *general* models is still decidable. We conjecture that it is, and in fact remains in EXPTIME.

Abstract

We investigate conjunctive query inseparability of description logic (DL) knowledge bases (KBs) with respect to a given signature, a fundamental problem for KB versioning, module extraction, forgetting and knowledge exchange. We study the data and combined complexity of deciding KB query inseparability for fragments of *Horn-$\mathcal{ALCHI}$*, including the DLs underpinning *OWL 2 QL* and *OWL 2 EL*. While all of these DLs are P-complete for data complexity, the combined complexity ranges from P to ExpTime and 2ExpTime. We also resolve two major open problems for *OWL 2 QL* by showing that TBox query inseparability and the membership problem for universal UCQ-solutions in knowledge exchange are both ExpTime-complete for combined complexity.

Introduction

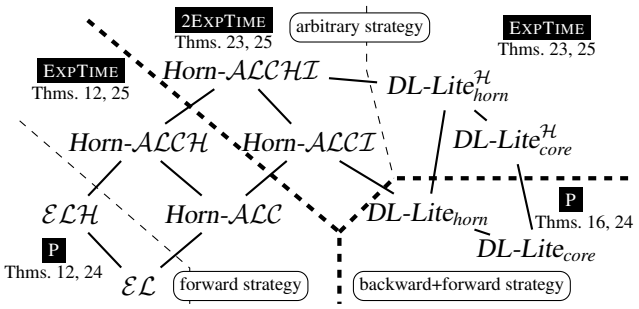
A description logic (DL) knowledge base (KB) consists of a terminological box (TBox), storing conceptual knowledge, and an assertion box (ABox), storing data. Typical applications of KBs involve answering queries over incomplete data sources (ABoxes) augmented by ontologies (TBoxes) that provide additional information about the domain of interest as well as a convenient vocabulary for user queries. The standard query language in such applications, which balances expressiveness and computational complexity, is the language of conjunctive queries (CQs).

With typically large data, often tangled ontologies, and the hard problem of answering CQs over ontologies, various transformation and comparison tasks are becoming indispensable for KB engineering and maintenance. For example, to make answering certain CQs more efficient, one may want to extract from a given KB a smaller module returning the same answers to those CQs as the original KB; to provide the user with a more convenient query vocabulary, one may want to reformulate the KB in a new language. These tasks are known as module extraction (Stuckenschmidt, Parent, and Spaccapietra 2009) and knowledge exchange (Arenas et al. 2012); other relevant tasks include versioning, revision and forgetting (Jiménez-Ruiz et al. 2011; Wang, Wang, and Topor 2010; Lin and Reiter 1994).

In this paper, we investigate the following relationship between KBs that is fundamental for all such tasks. Let Σ be a signature consisting of concept and role names. We call KBs $\mathcal{K}_1$ and $\mathcal{K}_2$ Σ-*query inseparable* and write $\mathcal{K}_1 \equiv_\Sigma \mathcal{K}_2$ if any CQ formulated in Σ has the same answers over $\mathcal{K}_1$ and $\mathcal{K}_2$. Note that even for Σ containing all concept and role names, Σ-query inseparability does not necessarily imply logical equivalence. The relativisation to (smaller) signatures is crucial to support the tasks mentioned above:

(versioning) When comparing two *versions* $\mathcal{K}_1$ and $\mathcal{K}_2$ of a KB with respect to their answers to CQs in a relevant signature Σ, the basic task is to check whether $\mathcal{K}_1 \equiv_\Sigma \mathcal{K}_2$.

(modularisation) A Σ-*module of* a KB $\mathcal{K}$ is a KB $\mathcal{K}' \subseteq \mathcal{K}$ such that $\mathcal{K}' \equiv_\Sigma \mathcal{K}$. If we are only interested in answering CQs in Σ over $\mathcal{K}$, then we can achieve our aim by querying any Σ-module of $\mathcal{K}$ instead of $\mathcal{K}$ itself.



(knowledge exchange) In knowledge exchange, we want to transform a KB $\mathcal{K}_1$ in a signature Σ_1 to a new KB $\mathcal{K}_2$ in a disjoint signature Σ_2 connected to Σ_1 via a declarative mapping specification given by a TBox $\mathcal{T}_{12}$. Thus, the target KB $\mathcal{K}_2$ should satisfy the condition $\mathcal{K}_1 \cup \mathcal{T}_{12} \equiv_{\Sigma_2} \mathcal{K}_2$, in which case it is called a *universal UCQ-solution* (CQ and UCQ inseparabilities coincide for Horn DLs).

(forgetting) A KB $\mathcal{K}'$ results from *forgetting* a signature Σ in a KB $\mathcal{K}$ if $\mathcal{K}' \equiv_{\mathsf{sig}(\mathcal{K}) \setminus \Sigma} \mathcal{K}$ and $\mathsf{sig}(\mathcal{K}') \subseteq \mathsf{sig}(\mathcal{K}) \setminus \Sigma$. Thus, the result of forgetting Σ does not use Σ and gives the same answers to CQs without symbols in Σ as $\mathcal{K}$.

We investigate the data and combined complexity of deciding Σ-query inseparability for KBs given in various fragments of the DL *Horn-$\mathcal{ALCHI}$* (Krötzsch, Rudolph, and Hitzler 2013), which include *DL-Lite*$^{\mathcal{H}}_{core}$ (Calvanese et al. 2007) and $\mathcal{EL}$ (Baader, Brandt, and Lutz 2005) underlying the W3C profiles *OWL 2 QL* and *OWL 2 EL*. For all of these DLs, Σ-query inseparability turns out to be P-complete for data complexity, which matches the data complexity of CQ evaluation for all of our DLs lying outside the *DL-Lite* family. For combined complexity, the obtained tight complexity results are summarised in the diagram below. Most interesting are ExpTime-completeness of *DL-Lite*$^{\mathcal{H}}_{core}$ and 2ExpTime-completeness of *Horn-$\mathcal{ALCI}$*, which contrast with NP-completeness and ExpTime-completeness of CQ evaluation for those logics. For *DL-Lite* without role inclusions and $\mathcal{ELH}$, Σ-query inseparability is P-complete, while CQ evaluation is NP-complete. In general, it is the combined presence of inverse roles and qualified existential

restrictions (or role inclusions) that makes Σ-query inseparability hard. To establish the upper complexity bounds, we develop a uniform game-theoretic technique for checking finite Σ-homomorphic embeddability between (possibly infinite) materialisations of KBs.

Σ-query inseparability for KBs has not been investigated systematically before. The polynomial upper bound for $\mathcal{EL}$ was established as a preliminary step to study TBox inseparability (Lutz and Wolter 2010), and this notion was also used to study forgetting for *DL-Lite*$^{\mathcal{N}}_{bool}$ (Wang et al. 2010).

We apply our results to resolve two important open problems. First, we show that the membership problem for universal UCQ-solutions in knowledge exchange for KBs in *DL-Lite*$^{\mathcal{H}}_{core}$ is ExpTime-complete for combined complexity, which settles an open question of (Arenas et al. 2013), where only PSpace-hardness was established. We also show that Σ-query inseparability of *DL-Lite*$^{\mathcal{H}}_{core}$ TBoxes is ExpTime-complete, which closes the PSpace–ExpTime gap that was left open by Konev et al. (2011).

Recall that TBoxes $\mathcal{T}_1$ and $\mathcal{T}_2$ are Σ-query inseparable if, for *all* Σ-ABoxes $\mathcal{A}$ (which only use concept and role names from Σ), the KBs $(\mathcal{T}_1, \mathcal{A})$ and $(\mathcal{T}_2, \mathcal{A})$ are Σ-query inseparable. TBox and KB inseparabilities have different applications. The former supports ontology engineering when data is not known or changes frequently: one can equivalently replace one TBox with another only if they return the same answers to queries for *every* Σ-ABox. In contrast, KB inseparability is useful in applications where data is stable—such as knowledge exchange or variants of module extraction and forgetting with fixed data—in order to use the KB in a new application or as a compilation step to make CQ answering more efficient. As we show below, TBox and KB Σ-query inseparabilities also have different computational properties.

TBox Σ-query inseparability has been extensively studied (Kontchakov, Wolter, and Zakharyaschev 2010; Lutz and Wolter 2010; Konev et al. 2012). For work on different notions of TBox inseparability and the corresponding notions of modules and forgetting, we refer the reader to (Cuenca Grau et al. 2008; Konev, Walther, and Wolter 2009; Del Vescovo et al. 2011; Nikitina and Rudolph 2012; Nikitina and Glimm 2012; Lutz, Seylan, and Wolter 2012).

Omitted proofs can be found in the full version available at www.dcs.bbk.ac.uk/~roman/KR2014.pdf.

Horn-$\mathcal{ALCHI}$ and its Fragments

All the DLs for which we investigate KB Σ-query inseparability are Horn fragments of $\mathcal{ALCHI}$. To define these DLs, we fix sequences of *individual names* a_i, *concept names* A_i, and *role names* P_i, where $i < \omega$. A *role* is either a role name P_i or an *inverse role* P_i^-; we assume that $(P_i^-)^- = P_i$. $\mathcal{ALCI}$*-concepts*, C, are defined by the grammar

$$C ::= A_i \mid \top \mid \bot \mid \neg C \mid C_1 \sqcap C_2 \mid C_1 \sqcup C_2 \mid \exists R.C \mid \forall R.C,$$

where R is a role. $\mathcal{ALC}$*-concepts* are $\mathcal{ALCI}$-concepts without inverse roles; $\mathcal{EL}$*-concepts* are $\mathcal{ALC}$-concepts without the constructs $\bot$, $\sqcup$, $\neg$ and $\forall R.C$. *DL-Lite*$_{horn}$*-concepts* are $\mathcal{ALCI}$-concepts without $\sqcup$, $\neg$ and $\forall R.C$, in which $C = \top$ in every occurrence of $\exists R.C$. Finally, *DL-Lite*$_{core}$*-concepts* are *DL-Lite*$_{horn}$-concepts without $\sqcap$; in other words, they are *basic concepts* of the form $\bot$, $\top$, A_i or $\exists R.\top$.

For a DL $\mathcal{L}$, an $\mathcal{L}$*-concept inclusion* (CI) takes the form $C \sqsubseteq D$, where C and D are $\mathcal{L}$-concepts. An $\mathcal{L}$*-TBox*, $\mathcal{T}$, contains a finite set of $\mathcal{L}$-CIs. An $\mathcal{ALCHI}$, *DL-Lite*$^{\mathcal{H}}_{horn}$ and *DL-Lite*$^{\mathcal{H}}_{core}$ TBox can also contain a finite set of *role inclusions* (RIs) $R_1 \sqsubseteq R_2$, where the R_i are roles. In $\mathcal{ELH}$ TBoxes, RIs do not have inverse roles. *DL-Lite* TBoxes may also contain *disjointness constraints* $B_1 \sqcap B_2 \sqsubseteq \bot$ and $R_1 \sqcap R_2 \sqsubseteq \bot$, for basic concepts B_i and roles R_i.

To introduce the Horn fragments of these DLs, we require the following (standard) recursive definition (Hustadt, Motik, and Sattler 2005; Kazakov 2009): a concept C occurs positively in C; if C occurs positively (respectively, negatively) in C' then C occurs positively (negatively) in $C' \sqcup D$, $C' \sqcap D$, $\exists R.C'$, $\forall R.C'$, $D \sqsubseteq C'$, and it occurs negatively (positively) in $\neg C'$ and $C' \sqsubseteq D$. Now, we call a TBox $\mathcal{T}$ *Horn* if no concept of the form $C \sqcup D$ occurs positively in $\mathcal{T}$, and no concept of the form $\neg C$ or $\forall R.C$ occurs negatively in $\mathcal{T}$. In the DL *Horn-*$\mathcal{L}$, where $\mathcal{L}$ is one of our DLs, only *Horn-*$\mathcal{L}$-TBoxes are allowed. Clearly, the $\mathcal{EL}$- and *DL-Lite*-TBoxes are Horn by definition.

An *ABox*, $\mathcal{A}$, is a finite set of *assertions* of the form $A_k(a_i)$ or $P_k(a_i, a_j)$. An $\mathcal{L}$-TBox $\mathcal{T}$ and an ABox $\mathcal{A}$ together form an $\mathcal{L}$ *knowledge base* (KB) $\mathcal{K} = (\mathcal{T}, \mathcal{A})$. The set of individual names in $\mathcal{K}$ is denoted by $\mathsf{ind}(\mathcal{K})$.

The semantics for the DLs is defined in the usual way based on interpretations $\mathcal{I} = (\Delta^{\mathcal{I}}, \cdot^{\mathcal{I}})$ that comply with the *unique name assumption*: $a_i^{\mathcal{I}} \neq a_j^{\mathcal{I}}$ for $i \neq j$ (Baader et al. 2003). We write $\mathcal{I} \models \alpha$ in case an inclusion or assertion α is true in $\mathcal{I}$. If $\mathcal{I} \models \alpha$, for all $\alpha \in \mathcal{T} \cup \mathcal{A}$, then $\mathcal{I}$ is a *model* of a KB $\mathcal{K} = (\mathcal{T}, \mathcal{A})$; in symbols: $\mathcal{I} \models \mathcal{K}$. $\mathcal{K}$ is *consistent* if it has a model. $\mathcal{K} \models \alpha$ means that $\mathcal{I} \models \alpha$ for all $\mathcal{I} \models \mathcal{K}$.

A *conjunctive query* (CQ) $\boldsymbol{q}(\vec{x})$ is a formula $\exists \vec{y}\, \varphi(\vec{x}, \vec{y})$, where φ is a conjunction of atoms of the form $A_k(z_1)$ or $P_k(z_1, z_2)$ with $z_i \in \vec{x} \cup \vec{y}$. A tuple $\vec{a} \subseteq \mathsf{ind}(\mathcal{K})$ (of the same length as $\vec{x}$) is a *certain answer* to $\boldsymbol{q}(\vec{x})$ over $\mathcal{K} = (\mathcal{T}, \mathcal{A})$ if $\mathcal{I} \models \boldsymbol{q}(\vec{a})$ for all $\mathcal{I} \models \mathcal{K}$; in this case we write $\mathcal{K} \models \boldsymbol{q}(\vec{a})$. If $\vec{x} = \emptyset$, the answer to $\boldsymbol{q}$ is 'yes' if $\mathcal{K} \models \boldsymbol{q}$ and 'no' otherwise.

For combined complexity, the problem '$\mathcal{K} \models \boldsymbol{q}(\vec{a})$?' is NP-complete for the *DL-Lite* logics (Calvanese et al. 2007), $\mathcal{EL}$ and $\mathcal{ELH}$ (Rosati 2007), and ExpTime-complete for the remaining Horn DLs above (Eiter et al. 2008). For data complexity (with fixed $\mathcal{T}$ and $\boldsymbol{q}$), this problem is in AC^0 for the *DL-Lite* logics (Calvanese et al. 2007) and P-complete for the remaining DLs (Rosati 2007; Eiter et al. 2008).

A *signature*, Σ, is a set of concept and role names. By a Σ-concept, Σ-role, Σ-CQ, etc. we understand any concept, role, CQ, etc. constructed using the names from Σ.

Σ-Query Entailment and Inseparability

We define the central notions of this paper.

Definition 1 Let $\mathcal{K}_1$ and $\mathcal{K}_2$ be KBs and Σ a signature.

- $\mathcal{K}_1$ Σ-*query entails* $\mathcal{K}_2$ if $\mathcal{K}_2 \models \boldsymbol{q}(\vec{a})$ implies $\mathcal{K}_1 \models \boldsymbol{q}(\vec{a})$ for *all* Σ-CQs $\boldsymbol{q}(\vec{x})$ and all $\vec{a} \subseteq \mathsf{ind}(\mathcal{K}_2)$.
- $\mathcal{K}_1$ and $\mathcal{K}_2$ are Σ-*query inseparable* if they Σ-query entail each other. In this case we write $\mathcal{K}_1 \equiv_\Sigma \mathcal{K}_2$.

Observe that Σ-query inseparability is weaker than logical equivalence even if $\Sigma = \mathsf{sig}(\mathcal{K}_1) \cup \mathsf{sig}(\mathcal{K}_2)$, where $\mathsf{sig}(\mathcal{K}_i)$ is the signature of $\mathcal{K}_i$. For example, $(\emptyset, \{A(a)\})$ is $\{A, B\}$-query inseparable from $(\{B \sqsubseteq A\}, \{A(a)\})$ but the two KBs are clearly not logically equivalent. Since checking Σ-query inseparability can be reduced to two Σ-query entailment checks, we can prove complexity upper bounds for entailment. Conversely, for most languages we have a semantically transparent reduction of Σ-query entailment to Σ-query inseparability:

Theorem 2 *Let $\mathcal{L}$ be any of our DLs containing $\mathcal{EL}$ or having role inclusions. Then Σ-query entailment for $\mathcal{L}$-KBs is* LogSpace*-reducible to Σ-query inseparability for $\mathcal{L}$-KBs.*

Proof sketch. Let $\mathcal{K}_i = (\mathcal{T}_i, \mathcal{A}_i)$, $i = 1, 2$, and Σ be given. We may assume that $\Sigma = \mathsf{sig}(\mathcal{K}_1) \cap \mathsf{sig}(\mathcal{K}_2)$. We also assume that $\mathcal{L}$ has role inclusions, $\mathcal{K}_1$ and $\mathcal{K}_2$ are consistent and the *trivial interpretation* $\mathcal{I}_\emptyset$ (with $|\Delta^{\mathcal{I}_\emptyset}| = 1$ and $S^{\mathcal{I}_\emptyset} = \emptyset$, for any S) is a model of the $\mathcal{T}_i$ (a proof without those assumptions is given in the full version). Let $\mathcal{K}_i'$ be a copy of $\mathcal{K}_i$ in which all symbols S are replaced by fresh S_i, and let $\mathcal{K}_i^\Sigma$ extend $\mathcal{K}_i'$ with $S_i \sqsubseteq S$, for $S \in \Sigma$. One can show that $\mathcal{K}_1$ Σ-query entails $\mathcal{K}_2$ iff $\mathcal{K}_1 \equiv_\Sigma \mathcal{K}_1^\Sigma \cup \mathcal{K}_2^\Sigma$. ❑

That $\mathcal{I}_\emptyset \models \mathcal{K}_i$ is essential in the reduction above. Take $\mathcal{T}_1 = \{A \sqsubseteq B, A \sqsubseteq \exists R.C\}$, $\mathcal{T}_2 = \{\top \sqsubseteq B, C \sqcap B \sqsubseteq \bot\}$ and $\Sigma = \{A, B, R, C\}$. Then $\mathcal{K}_1 = (\mathcal{T}_1, \{A(a)\})$ Σ-query entails $\mathcal{K}_2 = (\mathcal{T}_2, \{A(a)\})$ but $\mathcal{K}_1 \not\equiv_\Sigma \mathcal{K}_1^\Sigma \cup \mathcal{K}_2^\Sigma$.

We now consider the relationship between inseparability and universal UCQ-solutions in knowledge exchange. Suppose $\mathcal{K}_1$ and $\mathcal{K}_2$ are KBs in disjoint signatures Σ_1 and Σ_2. Let $\mathcal{T}_{12}$ be a mapping consisting of inclusions of the form $S_1 \sqsubseteq S_2$, where the S_i are concept (or role) names in Σ_i. Then $\mathcal{K}_2$ is a universal UCQ-solution for $(\mathcal{K}_1, \mathcal{T}_{12}, \Sigma_2)$ if $\mathcal{K}_1 \cup \mathcal{T}_{12} \equiv_{\Sigma_2} \mathcal{K}_2$. Deciding the latter is called the *membership problem for universal UCQ-solutions*. For DLs $\mathcal{L}$ with role inclusions, the problem whether $\mathcal{K}_1 \cup \mathcal{T}_{12} \equiv_{\Sigma_2} \mathcal{K}_2$ is a Σ_2-query inseparability problem in $\mathcal{L}$. Conversely, we have:

Theorem 3 *Σ-query entailment for any of our DLs $\mathcal{L}$ is* LogSpace*-reducible to the membership problem for universal UCQ-solutions in $\mathcal{L}$.*

Proof sketch. We want to decide whether $\mathcal{K}_1$ Σ-query entails $\mathcal{K}_2$. We again assume that $\mathcal{I}_\emptyset \models \mathcal{T}_i$ and use the proof of Theorem 2 (for the general case, see the full version). We may assume that $\Sigma = \mathsf{sig}(\mathcal{K}_1) \cap \mathsf{sig}(\mathcal{K}_2)$. Let $\Sigma_1 = \mathsf{sig}(\mathcal{K}_1)$. Then $\mathcal{K}_1$ Σ-query entails $\mathcal{K}_2$ iff $\mathcal{K}_1$ Σ_1-query entails $\mathcal{K}_2$. By the proof of Theorem 2, the latter is the case iff $\mathcal{K}_1$ Σ_1-query entails $\mathcal{K}_1^{\Sigma_1} \cup \mathcal{K}_2^{\Sigma_1}$. Clearly, $\mathcal{K}_1^{\Sigma_1} \cup \mathcal{K}_2^{\Sigma_1}$ Σ_1-query entails $\mathcal{K}_1$, and so the two KBs are Σ_1-query inseparable. Then $\mathcal{K}_1$ Σ-query entails $\mathcal{K}_2$ iff $\mathcal{K}_1$ is a universal UCQ-solution for $(\mathcal{K}_1' \cup \mathcal{K}_2', \mathcal{T}_{12}, \Sigma_1)$, where $\mathcal{T}_{12} = \{S_1 \sqsubseteq S, S_2 \sqsubseteq S \mid S \in \Sigma_1\}$. ❑

Semantic Characterisation

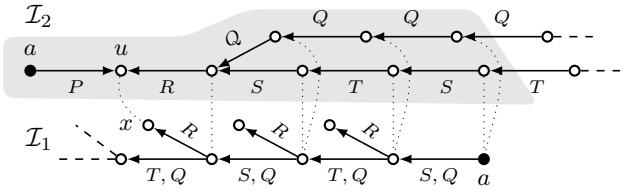
In this section, we give a semantic characterisation of KB Σ-query entailment based on an abstract notion of materialisation and finite homomorphisms between such structures.

Let $\mathcal{K}$ be a KB. An interpretation $\mathcal{I}$ is called a *materialisation* of $\mathcal{K}$ if, for all CQs $\boldsymbol{q}(\vec{x})$ and tuples $\vec{a} \subseteq \mathsf{ind}(\mathcal{K})$,

$$\mathcal{K} \models \boldsymbol{q}(\vec{a}) \quad \text{iff} \quad \mathcal{I} \models \boldsymbol{q}(\vec{a}).$$

We say that $\mathcal{K}$ is *materialisable* if it has a materialisation.

Materialisations can be used to characterise KB Σ-query entailment by means of Σ-homomorphisms. For an interpretation $\mathcal{I}$ and a signature Σ, the Σ-*types* $\boldsymbol{t}_\Sigma^\mathcal{I}(x)$ and $\boldsymbol{r}_\Sigma^\mathcal{I}(x, y)$ of $x, y \in \Delta^\mathcal{I}$ are defined by taking:



$$\boldsymbol{t}_\Sigma^\mathcal{I}(x) = \{\, \Sigma\text{-concept name } A \mid x \in A^\mathcal{I} \,\},$$
$$\boldsymbol{r}_\Sigma^\mathcal{I}(x, y) = \{\, \Sigma\text{-role } R \mid (x, y) \in R^\mathcal{I} \,\}.$$

Suppose $\mathcal{I}_i$ is a materialisation of $\mathcal{K}_i$, $i = 1, 2$. A function $h\colon \Delta^{\mathcal{I}_2} \to \Delta^{\mathcal{I}_1}$ is a Σ-*homomorphism* from $\mathcal{I}_2$ to $\mathcal{I}_1$ if, for any $a \in \mathsf{ind}(\mathcal{K}_2)$ and any $x, y \in \Delta^{\mathcal{I}_2}$,

- $h(a^{\mathcal{I}_2}) = a^{\mathcal{I}_1}$ whenever $\boldsymbol{t}_\Sigma^{\mathcal{I}_2}(a) \neq \emptyset$ or $\boldsymbol{r}_\Sigma^{\mathcal{I}_2}(a, y) \neq \emptyset$ for some $y \in \Delta^{\mathcal{I}_2}$, and
- $\boldsymbol{t}_\Sigma^{\mathcal{I}_2}(x) \subseteq \boldsymbol{t}_\Sigma^{\mathcal{I}_1}(h(x))$, $\boldsymbol{r}_\Sigma^{\mathcal{I}_2}(x, y) \subseteq \boldsymbol{r}_\Sigma^{\mathcal{I}_1}(h(x), h(y))$.

As answers to Σ-CQs are preserved under Σ-homomorphisms, $\mathcal{K}_1$ Σ-query entails $\mathcal{K}_2$ if there is a Σ-homomorphism from $\mathcal{I}_2$ to $\mathcal{I}_1$. However, the converse does not hold:

Example 4 Suppose $\mathcal{I}_2$ and $\mathcal{I}_1$ below are materialisations of KBs $\mathcal{K}_2$ and $\mathcal{K}_1$, where a is the only ABox individual:

Let $\Sigma = \{Q, R, S, T\}$. Then there is no Σ-homomorphism from $\mathcal{I}_2$ to $\mathcal{I}_1$ (as $\boldsymbol{r}_\Sigma^{\mathcal{I}_2}(a, u) = \emptyset$, we can map u to, say, x but then only the shaded part of $\mathcal{I}_2$ can be mapped Σ-homomorphically to $\mathcal{I}_1$). However, for any Σ-query $\boldsymbol{q}(\vec{x})$, $\mathcal{I}_2 \models \boldsymbol{q}(\vec{a})$ implies $\mathcal{I}_1 \models \boldsymbol{q}(\vec{a})$ as any finite subinterpretation of $\mathcal{I}_2$ can be Σ-homomorphically mapped to $\mathcal{I}_1$.

We say that $\mathcal{I}_2$ is *finitely Σ-homomorphically embeddable into* $\mathcal{I}_1$ if, for every *finite* subinterpretation $\mathcal{I}_2'$ of $\mathcal{I}_2$, there exists a Σ-homomorphism from $\mathcal{I}_2'$ to $\mathcal{I}_1$.

To prove the following theorem, one can regard any finite subinterpretation of $\mathcal{I}_2$ as a CQ whose variables are elements of $\Delta^{\mathcal{I}_2}$, with the answer variables being in $\mathsf{ind}(\mathcal{K}_2)$.

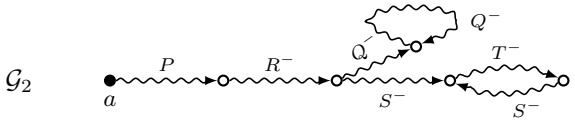
Theorem 5 *Suppose $\mathcal{K}_i$ is a consistent KB with a materialisation $\mathcal{I}_i$, $i = 1, 2$. Then $\mathcal{K}_1$ Σ-query entails $\mathcal{K}_2$ iff $\mathcal{I}_2$ is finitely Σ-homomorphically embeddable into $\mathcal{I}_1$.*

One problem with applying Theorem 5 is that materialisations are in general infinite for any of the DLs considered in this paper. We address this problem by introducing finite representations of materialisations. Let $\mathcal{K} = (\mathcal{T}, \mathcal{A})$ be a KB and let $\mathcal{G} = (\Delta^\mathcal{G}, \cdot^\mathcal{G}, \rightsquigarrow)$ be a finite structure such that $\Delta^\mathcal{G} = \mathsf{ind}(\mathcal{K}) \cup \Omega$, for $\mathsf{ind}(\mathcal{K}) \cap \Omega = \emptyset$, $\cdot^\mathcal{G}$ is an interpretation

function on $\Delta^{\mathcal{G}}$ with $A_i^{\mathcal{G}} \subseteq \Delta^{\mathcal{G}}$, $P_i^{\mathcal{G}} \subseteq \mathsf{ind}(\mathcal{K}) \times \mathsf{ind}(\mathcal{K})$, and $(\Delta^{\mathcal{G}}, \rightsquigarrow)$ is a directed graph (containing loops) with nodes $\Delta^{\mathcal{G}}$ and edges $\rightsquigarrow \subseteq \Delta^{\mathcal{G}} \times \Omega$, in which every edge $u \rightsquigarrow v$ is labelled with a set $(u,v)^{\mathcal{G}} \neq \emptyset$ of roles satisfying the condition: if $u_1 \rightsquigarrow v$ and $u_2 \rightsquigarrow v$, then $(u_1,v)^{\mathcal{G}} = (u_2,v)^{\mathcal{G}}$. We call $\mathcal{G}$ a *generating structure for* $\mathcal{K}$ if the interpretation $\mathcal{M}$ defined below is a materialisation of $\mathcal{K}$.

A *path* in $\mathcal{G}$ is a sequence $\sigma = u_0 \dots u_n$ with $u_0 \in \mathsf{ind}(\mathcal{K})$ and $u_i \rightsquigarrow u_{i+1}$ for $i < n$. Let $\mathsf{tail}(\sigma) = u_n$ and let $\mathsf{path}(\mathcal{G})$ be the set of paths in $\mathcal{G}$. The materialisation $\mathcal{M}$ is given by:

$$\Delta^{\mathcal{M}} = \mathsf{path}(\mathcal{G}), \quad a^{\mathcal{M}} = a, \ \text{ for } a \in \mathsf{ind}(\mathcal{K}),$$
$$A^{\mathcal{M}} = \{\sigma \mid \mathsf{tail}(\sigma) \in A^{\mathcal{G}}\},$$
$$P^{\mathcal{M}} = P^{\mathcal{G}} \cup \{(\sigma, \sigma u) \mid \mathsf{tail}(\sigma) \rightsquigarrow u,\ P \in (\mathsf{tail}(\sigma), u)^{\mathcal{G}}\}$$
$$\cup \{(\sigma u, \sigma) \mid \mathsf{tail}(\sigma) \rightsquigarrow u,\ P^- \in (\mathsf{tail}(\sigma), u)^{\mathcal{G}}\}.$$



We say that a DL $\mathcal{L}$ has *finitely generated materialisations* if every $\mathcal{L}$-KB has a generating structure.

Theorem 6 *Horn-$\mathcal{ALCHI}$ and all of its fragments defined above have finitely generated materialisations. Moreover,*

- *for any $\mathcal{L} \in \{\mathcal{ALCHI}, \mathcal{ALCI}, \mathcal{ALCH}, \mathcal{ALC}\}$ and any Horn-$\mathcal{L}$ KB $(\mathcal{T}, \mathcal{A})$, a generating structure can be constructed in time $|\mathcal{A}| \cdot 2^{p(|\mathcal{T}|)}$, p a polynomial*;
- *for any $\mathcal{L}$ in the $\mathcal{EL}$ and DL-Lite families introduced above and any $\mathcal{L}$-KB $(\mathcal{T}, \mathcal{A})$, a generating structure can be constructed in time $|\mathcal{A}| \cdot p(|\mathcal{T}|)$, p a polynomial.*

Finite generating structures have been defined for $\mathcal{EL}$ (Lutz, Toman, and Wolter 2009), *DL-Lite* (Kontchakov et al. 2010) and more expressive Horn DLs (Eiter et al. 2008). With the exception of *DL-Lite*, however, the relation $\rightsquigarrow$ guiding the construction of materialisations was implicit. We show how the existing constructions can be converted to generating structures in the full version.

Example 7 The materialisation $\mathcal{I}_2$ from Example 4 can be generated by the structure $\mathcal{G}_2$ shown below:

For a generating structure $\mathcal{G}$ for $\mathcal{K}$ and a signature Σ, the Σ-*types* $\boldsymbol{t}_\Sigma^{\mathcal{G}}(u)$ and $\boldsymbol{r}_\Sigma^{\mathcal{G}}(u,v)$ of $u, v \in \Delta^{\mathcal{G}}$ are defined by:

$$\boldsymbol{t}_\Sigma^{\mathcal{G}}(u) = \{\, \Sigma\text{-concept name } A \mid u \in A^{\mathcal{G}} \,\},$$
$$\boldsymbol{r}_\Sigma^{\mathcal{G}}(u,v) = \begin{cases} \{\, \Sigma\text{-role } R \mid (u,v) \in R^{\mathcal{G}} \,\}, & \text{if } u, v \in \mathsf{ind}(\mathcal{K}), \\ \{\, \Sigma\text{-role } R \mid R \in (u,v)^{\mathcal{G}} \,\}, & \text{if } u \rightsquigarrow v, \\ \emptyset, & \text{otherwise,} \end{cases}$$

where $(P^-)^{\mathcal{G}}$ is the converse of $P^{\mathcal{G}}$. We also define $\bar{\boldsymbol{r}}_\Sigma^{\mathcal{G}}(u,v)$ to contain the inverses of the roles in $\boldsymbol{r}_\Sigma^{\mathcal{G}}(u,v)$; note that $\bar{\boldsymbol{r}}_\Sigma^{\mathcal{G}}(u,v)$ is not the same as $\boldsymbol{r}_\Sigma^{\mathcal{G}}(v,u)$; cf. the T^-, S^--cycle in Example 7. We write $u \rightsquigarrow^\Sigma v$ if $u \rightsquigarrow v$ and $\boldsymbol{r}_\Sigma^{\mathcal{G}}(u,v) \neq \emptyset$.

In the next section, we show that, for a DL $\mathcal{L}$ having finitely generated materialisations, the problem of checking Σ-query entailment between $\mathcal{L}$-KBs can be reduced to the problem of finding a winning strategy in a game played on the generating structures for these KBs.

Σ-Query Entailment by Games

Suppose a DL $\mathcal{L}$ has finitely generated materialisations, $\mathcal{K}_i$ is a consistent $\mathcal{L}$-KB, for $i = 1, 2$, and Σ a signature. Let $\mathcal{G}_i = (\Delta^{\mathcal{G}_i}, \cdot^{\mathcal{G}_i}, \rightsquigarrow_i)$ be a generating structure for $\mathcal{K}_i$ and let $\mathcal{M}_i$ be its materialisation; $\mathcal{G}_i^\Sigma$ and $\mathcal{M}_i^\Sigma$ denote the restrictions of $\mathcal{G}_i$ and $\mathcal{M}_i$ to Σ.

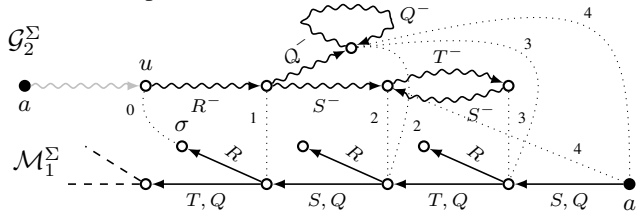
We begin with a very simple game on the finite generating structure $\mathcal{G}_2^\Sigma$ and the possibly infinite materialisation $\mathcal{M}_1^\Sigma$.

Infinite game $G_\Sigma(\mathcal{G}_2, \mathcal{M}_1)$**.** This game is played by two players: player 2 and player 1. The *states* of the game are of the form $\mathfrak{s}_i = (u_i \mapsto \sigma_i)$, for $i \geq 0$, where $u_i \in \Delta^{\mathcal{G}_2}$ and $\sigma_i \in \Delta^{\mathcal{M}_1}$ satisfy the following condition:

(s$_1$) $\boldsymbol{t}_\Sigma^{\mathcal{G}_2}(u_i) \subseteq \boldsymbol{t}_\Sigma^{\mathcal{M}_1}(\sigma_i)$.

The game starts in a state $\mathfrak{s}_0 = (u_0 \mapsto \sigma_0)$ with $\sigma_0 = u_0$ in case $u_0 \in \mathsf{ind}(\mathcal{K}_2)$. In each round $i > 0$, player 2 challenges player 1 with some $u_i \in \Delta^{\mathcal{G}_2}$ such that $u_{i-1} \rightsquigarrow_2^\Sigma u_i$. Player 1 has to respond with a $\sigma_i \in \Delta^{\mathcal{M}_1}$ satisfying **(s$_1$)** and

(s$_2$) $\boldsymbol{r}_\Sigma^{\mathcal{G}_2}(u_{i-1}, u_i) \subseteq \boldsymbol{r}_\Sigma^{\mathcal{M}_1}(\sigma_{i-1}, \sigma_i)$.



This gives the next state $\mathfrak{s}_i = (u_i \mapsto \sigma_i)$. Note that of all the u_i only u_0 may be an ABox individual; however, there is no such a restriction on the σ_i. A *play of length* $n \geq 0$ *starting from* $\mathfrak{s}_0$ is any sequence $\mathfrak{s}_0, \dots, \mathfrak{s}_n$ of states obtained as described above. For an ordinal $\lambda \leq \omega$, we say that player 1 has a λ-*winning strategy in the game* $G_\Sigma(\mathcal{G}_2, \mathcal{M}_1)$ *starting from a state* $\mathfrak{s}_0$ if, for any play of length $i < \lambda$, which starts from $\mathfrak{s}_0$ and conforms with this strategy, and any challenge of player 2 in round $i+1$, player 1 has a response.

The following theorem gives a game-theoretic flavour to the criterion of Theorem 5 (see the full paper for a proof).

Theorem 8 *$\mathcal{M}_2$ is finitely Σ-homomorphically embeddable into $\mathcal{M}_1$ iff the following conditions hold*:

(abox) $\boldsymbol{r}_\Sigma^{\mathcal{M}_2}(a,b) \subseteq \boldsymbol{r}_\Sigma^{\mathcal{M}_1}(a,b)$*, for any* $a, b \in \mathsf{ind}(\mathcal{K}_2)$;
(win) *for any $u_0 \in \Delta^{\mathcal{G}_2}$ and $n < \omega$, there exists $\sigma_0 \in \Delta^{\mathcal{M}_1}$ such that player 1 has an n-winning strategy in the game $G_\Sigma(\mathcal{G}_2, \mathcal{M}_1)$ starting from $(u_0 \mapsto \sigma_0)$.*

Example 9 Let $\Sigma = \{Q, R, S, T\}$. Consider $\mathcal{G}_2^\Sigma$ and $\mathcal{M}_1^\Sigma$ shown in the picture below:

For any $n < \omega$ and $u \in \Delta^{\mathcal{G}_2}$, player 1 has an n-winning strategy in $G_\Sigma(\mathcal{G}_2, \mathcal{M}_1)$. A 4-winning strategy starting from $(u \mapsto \sigma)$ is shown by dotted lines (in round 2, player 2 has two possible challenges). For a larger n, a suitable σ can be chosen further away from the root a of $\mathcal{M}_1$.

The criterion of Theorem 8 does not seem to be a big improvement on Theorem 5 as we still have to deal with an infinite materialisation. Our aim now is to show that condition **(win)** in the infinite game $G_\Sigma(\mathcal{G}_2, \mathcal{M}_1)$ can be checked

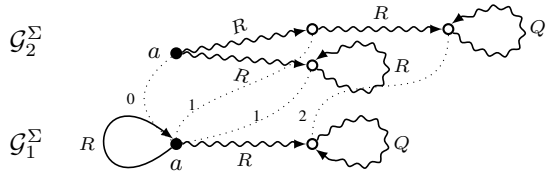
by analysing a more complex game on the *finite* generating structures $\mathcal{G}_2$ and $\mathcal{G}_1$. We consider four types of strategies in $G_\Sigma(\mathcal{G}_2, \mathcal{M}_1)$. For each type, τ, we define a game $G^\tau_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$ such that, for any $u_0 \in \Delta^{\mathcal{G}_2}$, the following conditions are equivalent:

($< \omega$) for every $n < \omega$, player 1 has an n-winning strategy of type τ in $G_\Sigma(\mathcal{G}_2, \mathcal{M}_1)$ starting from some $(u_0 \mapsto \sigma^n_0)$;

(ω) player 1 has an ω-winning strategy in $G^\tau_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$ starting from some state depending on u_0 and τ.

We start by considering 'forward' winning strategies that are sufficient for the DLs without inverse roles.

Forward strategy and game $G^f_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$. We say that a λ-strategy ($\lambda \leq \omega$) for player 1 in the game $G_\Sigma(\mathcal{G}_2, \mathcal{M}_1)$ is *forward* if, for any play of length $i - 1 < \lambda$, which conforms with this strategy, and any challenge $u_{i-1} \rightsquigarrow^\Sigma_2 u_i$ by player 2, the response σ_i of player 1 is such that either $\sigma_{i-1}, \sigma_i \in \mathsf{ind}(\mathcal{K}_1)$ or $\sigma_i = \sigma_{i-1}v$, for some $v \in \Delta^{\mathcal{G}_1}$.



For example, if the $\mathcal{G}_i$, $i = 1, 2$, satisfy the condition

(f) the Σ-labels on $\rightsquigarrow_i$-edges contain no inverse roles,

then *every* strategy in $G_\Sigma(\mathcal{G}_2, \mathcal{M}_1)$ is forward. This is clearly the case for *Horn-$\mathcal{ALCH}$*, *Horn-$\mathcal{ALC}$*, $\mathcal{ELH}$ and $\mathcal{EL}$, which by definition do not have inverse roles.

The existence of a forward λ-winning strategy for player 1 in $G_\Sigma(\mathcal{G}_2, \mathcal{M}_1)$ is equivalent to the existence of such a strategy in the game $G^f_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$, which is defined similarly to $G_\Sigma(\mathcal{G}_2, \mathcal{M}_1)$ but with two modifications: (1) it is played on $\mathcal{G}_2$ and $\mathcal{G}_1$; and (2) the response $x_i \in \Delta^{\mathcal{G}_1}$ of player 1 to a challenge $u_{i-1} \rightsquigarrow^\Sigma_2 u_i$ must be such that either $x_{i-1}, x_i \in \mathsf{ind}(\mathcal{K}_1)$ or $x_{i-1} \rightsquigarrow_1 x_i$, and **($\mathbf{s}_1$)–($\mathbf{s}_2$)** hold (with $\mathcal{G}_1$ and x_i in place of $\mathcal{M}_1$ and σ_i).

Example 10 Let $\mathcal{G}_2$ and $\mathcal{G}_1$ be as shown below. Then, for any $u \in \Delta^{\mathcal{G}_2}$, there is $x \in \Delta^{\mathcal{G}_1}$ such that player 1 has an ω-winning strategy in $G^f_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$ starting from $(u \mapsto x)$.

The next theorem follows from König's Lemma:

Lemma 11 *For $u_0 \in \Delta^{\mathcal{G}_2}$, condition ($< \omega$) holds for forward strategies in $G_\Sigma(\mathcal{G}_2, \mathcal{M}_1)$ iff (ω) holds in $G^f_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$ for some state $(u_0 \mapsto x_0)$.*

$G^f_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$ is a standard simulation or reachability game on finite graphs, where the existence of ω-winning strategies for player 1 follows from the existence of n-winning strategies for $n = O(|\mathcal{G}_2| \times |\mathcal{G}_1|)$, which can be checked in polynomial time (Mazala 2001; Baier and Katoen 2007). By Theorem 6 and **(f)**, we obtain:

Theorem 12 *For combined complexity, checking Σ-query entailment is in* P *for $\mathcal{EL}$ and $\mathcal{ELH}$ KBs, and in* EXPTIME *for Horn-$\mathcal{ALC}$ and Horn-$\mathcal{ALCH}$ KBs. For data complexity, it is in* P *for all these DLs.*

In comparison to forward strategies, the winning strategies used in Example 9 can be described as 'backward.'

Backward strategy and game $G^b_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$. A λ-strategy for player 1 in $G_\Sigma(\mathcal{G}_2, \mathcal{M}_1)$ is *backward* if, for any play of length $i - 1 < \lambda$, which conforms with this strategy, and any challenge $u_{i-1} \rightsquigarrow^\Sigma_2 u_i$ by player 2, the response σ_i of player 1 is the *immediate predecessor* of σ_{i-1} in $\mathcal{M}_1$ in the sense that $\sigma_{i-1} = \sigma_i w$, for some $w \in \Delta^{\mathcal{G}_1}$ (player 1 loses in case $\sigma_{i-1} \in \mathsf{ind}(\mathcal{K}_1)$). Note that, since $\mathcal{M}_1$ is tree-shaped, the response of player 1 to any different challenge $u_{i-1} \rightsquigarrow^\Sigma_2 u'_i$ must be the same σ_i; cf. Example 9.

That is why the states of the game $G^b_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$ are of the form $\mathfrak{s}_i = (\Xi_i \mapsto x_i)$, where $\Xi_i \subseteq \Delta^{\mathcal{G}_2}$, $\Xi_i \neq \emptyset$, and $x_i \in \Delta^{\mathcal{G}_1}$ satisfy the following condition:

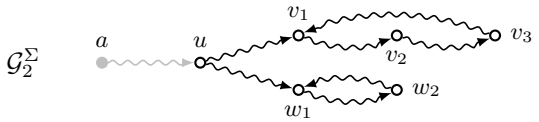
($\mathbf{s}'_1$) $\boldsymbol{t}^{\mathcal{G}_2}_\Sigma(u) \subseteq \boldsymbol{t}^{\mathcal{G}_1}_\Sigma(x_i)$, for all $u \in \Xi_i$.

The game starts in a state $\mathfrak{s}_0 = (\Xi_0 \mapsto x_0)$ such that

($\mathbf{s}'_0$) if $u \in \Xi_0 \cap \mathsf{ind}(\mathcal{K}_2)$, then $x_0 = u \in \mathsf{ind}(\mathcal{K}_1)$.

For each $i > 0$, player 2 always challenges player 1 with the set $\Xi_i = \Xi^{\rightsquigarrow}_{i-1}$, where

$$\Xi^{\rightsquigarrow} = \{v \in \Delta^{\mathcal{G}_2} \mid u \rightsquigarrow^\Sigma_2 v, \text{ for some } u \in \Xi\},$$



provided that it is not empty (otherwise, player 2 loses). Player 1 responds with $x_i \in \Delta^{\mathcal{G}_1}$ such that $x_i \rightsquigarrow_1 x_{i-1}$ and **($\mathbf{s}'_1$)** and the following condition hold:

($\mathbf{s}'_2$) $\boldsymbol{r}^{\mathcal{G}_2}_\Sigma(u, v) \subseteq \bar{\boldsymbol{r}}^{\mathcal{G}_1}_\Sigma(x_{i-1}, x_i)$, for all $u \in \Xi_{i-1}$, $v \in \Xi_i$.

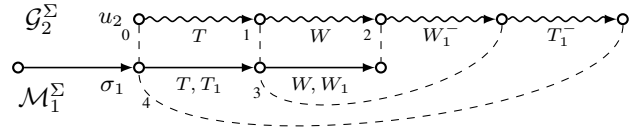
Lemma 13 *For $u_0 \in \Delta^{\mathcal{G}_2}$, condition ($< \omega$) holds for backward strategies in $G_\Sigma(\mathcal{G}_2, \mathcal{M}_1)$ iff (ω) holds in $G^b_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$ for some state $(\{u_0\} \mapsto x_0)$.*

Although Lemmas 11 and 13 look similar, the game $G^b_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$ turns out to be more complex than $G^f_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$.

Example 14 To illustrate, consider $\mathcal{G}^\Sigma_2$ shown below (with concepts and roles omitted) and an arbitrary $\mathcal{G}_1$:

A play in $G^b_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$ may proceed as: $(\{u\} \mapsto x_0)$, $(\{v_1, w_1\} \mapsto x_1)$, $(\{v_2, w_2\} \mapsto x_2)$, $(\{v_3, w_1\} \mapsto x_3)$, etc. This gives at least 6 different sets Ξ_i. But if $\mathcal{G}_2$ contained k cycles of lengths $p_1, \dots, p_k$, where p_i is the ith prime number, then the number of states in $G^b_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$ could be exponential ($p_1 \times \dots \times p_k$). In fact, we have the following:

Lemma 15 *Checking (ω) in Lemma 13 is* CONP*-hard.*



Observe that in the case of *DL-Lite$_{core}$* and *DL-Lite$_{horn}$* (which have inverse roles but no RIs), generating structures $\mathcal{G} = (\Delta^{\mathcal{G}}, \cdot^{\mathcal{G}}, \rightsquigarrow)$ can be defined so that, for any $u \in \Delta^{\mathcal{G}}$ and R, there is *at most one* v with $u \rightsquigarrow v$ and $R \in \boldsymbol{r}^{\mathcal{G}}(u, v)$ (Kontchakov et al. 2010). As a result, any n-winning strategy starting from $(u_0 \mapsto \sigma_0)$ in $G_\Sigma(\mathcal{G}_2, \mathcal{M}_1)$ consists of a (possibly empty) backward part followed by a (possibly empty) forward part. Moreover, in the backward games for these DLs, the sets Ξ_i are always *singletons*. Thus, the number of states in the combined backward/forward games on the $\mathcal{G}_i$ is polynomial, and the existence of winning strategies can be checked in polynomial time.

Theorem 16 *Checking Σ-query entailment for DL-Lite$_{core}$ and DL-Lite$_{horn}$ KBs is in* P *for both combined and data complexity.*

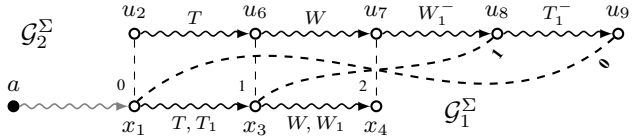
An arbitrary strategy for player 1 in $G_\Sigma(\mathcal{G}_2, \mathcal{M}_1)$ is a combination of a backward strategy and a number of start-bounded strategies to be defined next.

Start-bounded strategy and game $G^s_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$. A strategy for player 1 in the game $G_\Sigma(\mathcal{G}_2, \mathcal{M}_1)$ starting from a state $(u_0 \mapsto \sigma_0)$ is *start-bounded* if it never leads to $(u_i \mapsto \sigma_i)$ such that $\sigma_0 = \sigma_i v$, for some v and $i > 0$. In other words, player 1 cannot use those elements of $\mathcal{M}_1$ that are located closer to the ABox than σ_0; the ABox individuals in $\mathcal{M}_1$ can only be used if $\sigma_0 \in \mathsf{ind}(\mathcal{K}_1)$.

Example 17 The strategy starting from $(u_2 \mapsto \sigma_1)$ and shown below is start-bounded:

In the game $G^s_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$, player 1 will have to guess *all* the points of $\mathcal{G}_2$ that are mapped to the same point of $\mathcal{M}_1$.

The *states* of $G^s_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$ are of the form $(\Gamma_i, \Xi_i \mapsto x_i)$, $i \geq 0$, where $\Gamma_i, \Xi_i \subseteq \Delta^{\mathcal{G}_2}$, $\Xi_i \neq \emptyset$, $x_i \in \Delta^{\mathcal{G}_1}$ and **($\mathbf{s}'_1$)** holds. The initial state is of the form $(\emptyset, \Xi_0 \mapsto x_0)$ such that **($\mathbf{s}'_0$)** holds. In each round $i > 0$, player 2 challenges player 1 with some $u \rightsquigarrow^\Sigma_2 v$ such that $u \in \Xi_{i-1}$ and



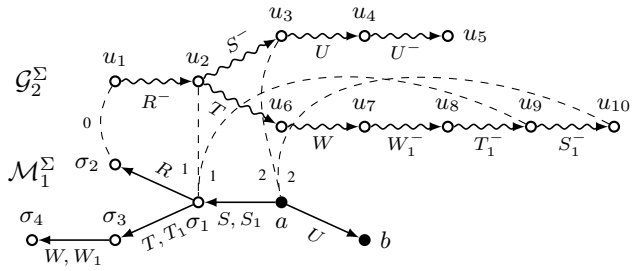
(nbk) if $v \in \Gamma_{i-1}$ then $\boldsymbol{r}^{\mathcal{G}_2}_\Sigma(u, v) \not\subseteq \bar{\boldsymbol{r}}^{\mathcal{G}_1}_\Sigma(x_{i-2}, x_{i-1})$.

Player 1 responds with either a state $(\Xi_{i-1}, \Xi_i \mapsto x_i)$ such that $x_{i-1} \rightsquigarrow_1 x_i$ (and so $x_i \notin \mathsf{ind}(\mathcal{K}_1)$) and **($\mathbf{s}''_2$)** holds, or a state $(\emptyset, \Xi_i \mapsto x_i)$ such that $x_{i-1}, x_i \in \mathsf{ind}(\mathcal{K}_1)$ and

($\mathbf{s}''_2$) $\boldsymbol{r}^{\mathcal{G}_2}_\Sigma(u, v) \subseteq \boldsymbol{r}^{\mathcal{G}_1}_\Sigma(x_{i-1}, x_i)$.

We make challenges $u \rightsquigarrow^\Sigma_2 v$, for which $u \in \Xi_{i-1}$ and **(nbk)** does not hold, 'illegitimate' because x_{i-2} can always be used as a response. Because of this, player 1 always moves 'forward' in $\mathcal{G}_1$, but has to guess appropriate sets Ξ_i in advance. Note that Γ_i is always uniquely determined by x_{i-1}, x_i and Ξ_{i-1} (and it is either Ξ_{i-1} or empty).

Example 18 Let $\mathcal{G}^\Sigma_2$ and $\mathcal{G}^\Sigma_1$ be as follows (cf. Example 17):

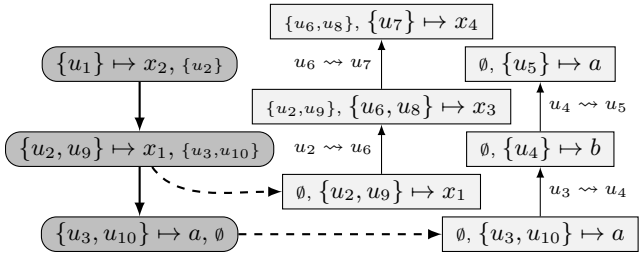


We show that player 1 has an ω-winning strategy in $G^s_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$ starting from $(\emptyset, \{u_2, u_9\} \mapsto x_1)$. Player 2 challenges with $u_2 \rightsquigarrow^\Sigma_2 u_6$, and player 1 responds with $(\{u_2, u_9\}, \{u_6, u_8\} \mapsto x_3)$. Then player 2 picks $u_6 \rightsquigarrow^\Sigma_2 u_7$ and player 1 responds with $(\{u_6, u_8\}, \{u_7\} \mapsto x_4)$, where the game ends. Note the crucial guesses $\{u_2, u_9\} \mapsto x_1$ and $\{u_6, u_8\} \mapsto x_3$ made by player 1. If player 1 responded with $(\{u_2, u_9\}, \{u_6\} \mapsto x_3)$ (and failed to guess that u_8 must also be mapped to x_3), then after the challenge $u_6 \rightsquigarrow^\Sigma_2 u_7$ and response $(\{u_6\}, \{u_7\} \mapsto x_4)$), player 2 would pick $u_7 \rightsquigarrow^\Sigma_2 u_8$, to which player 1 could not respond.

Lemma 19 *For any $u_0 \in \Delta^{\mathcal{G}_2}$, condition $(< \omega)$ holds for start-bounded strategies in $G_\Sigma(\mathcal{G}_2, \mathcal{M}_1)$ iff (ω) holds in $G^s_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$ for some state $(\emptyset, \Xi_0 \mapsto x_0)$ with $u_0 \in \Xi_0$.*

As we shall see in the next section, the problem of checking the conditions of this lemma is ExpTime-hard.

Arbitrary strategies and game $G^a_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$. An arbitrary winning strategy in the game $G_\Sigma(\mathcal{G}_2, \mathcal{M}_1)$ can be composed of one backward and a number of start-bounded strategies.



Example 20 Consider $\mathcal{G}^\Sigma_2$ and $\mathcal{M}^\Sigma_1$ shown below:

Starting from $(u_1 \mapsto \sigma_2)$, player 1 can respond to the challenges $u_1 \rightsquigarrow^\Sigma_2 u_2 \rightsquigarrow^\Sigma_2 u_3$ according to the backward strategy; the challenges $u_2 \rightsquigarrow^\Sigma_2 u_6 \rightsquigarrow^\Sigma_2 u_7 \rightsquigarrow^\Sigma_2 u_8 \rightsquigarrow^\Sigma_2 u_9$ according to the start-bounded strategy as in Example 17; the challenges $u_3 \rightsquigarrow^\Sigma_2 u_4 \rightsquigarrow^\Sigma_2 u_5$ also according to the obvious start-bounded strategy; finally, the challenge $u_9 \rightsquigarrow^\Sigma_2 u_{10}$ needs a response according to the backward strategy. We will combine the two backward strategies into a single one, but keep the start-bounded ones separate.

The game $G^a_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$ begins as $G^b_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$, but with states of the form $(\Xi_i \mapsto x_i, \Psi_i)$, $i \geq 0$, where $\Xi_i \subseteq \Delta^{\mathcal{G}_2}$ and $x_i \in \Delta^{\mathcal{G}_1}$ satisfy **($\mathbf{s}'_1$)** and Ψ_i is a (possibly empty) subset of $\Xi_i^{\rightsquigarrow}$, which indicates initial challenges in start-bounded games. The initial state satisfies **($\mathbf{s}'_0$)**. In each round $i > 0$, if $x_{i-1} \in \mathsf{ind}(\mathcal{K}_1)$ then player 2 launches the start-bounded game $G^s_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$ with the initial state $(\emptyset, \Xi_{i-1} \mapsto x_{i-1})$. Otherwise, if $x_{i-1} \notin \mathsf{ind}(\mathcal{K}_1)$, player 2 has two options. First, he can challenge player 1 with the set Ψ_{i-1} (that is, similar to the backward game but with a possibly smaller Ψ_{i-1} in place of $\Xi_{i-1}^{\rightsquigarrow}$); player 1 responds to this challenge with a state $(\Xi_i \mapsto x_i, \Psi_i)$ such that $\Psi_{i-1} \subseteq \Xi_i$, $x_i \rightsquigarrow_1 x_{i-1}$ and **($\mathbf{s}'_2$)** holds. Second, player 2 can launch the start-bounded game $G^s_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$ with the initial state $(\emptyset, \Xi_{i-1} \mapsto x_{i-1})$, where the first challenge of player 2 must be picked from $\Phi_{i-1} = \Xi_{i-1}^{\rightsquigarrow} \setminus \Psi_{i-1}$.

Example 21 We illustrate the ω-winning strategy for player 1 in $G^a_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$ starting from $(\{u_1\} \mapsto x_2, \{u_2\})$, where $\mathcal{G}^\Sigma_2$ is from Example 20 and $\mathcal{G}^\Sigma_1$ looks like $\mathcal{M}^\Sigma_1$ from Example 20 (but with x_i in place of σ_i):

Lemma 22 *For any $u_0 \in \Delta^{\mathcal{G}_2}$, condition $(<\omega)$ holds for arbitrary strategies in $G_\Sigma(\mathcal{G}_2, \mathcal{M}_1)$ iff (ω) holds in $G^a_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$ for some state $(\Xi_0 \mapsto x_0, \Psi_0)$ with $u_0 \in \Xi_0$.*

Condition (ω) in the lemma above is checked in time $O(|\mathsf{ind}(\mathcal{K}_2)| \times 2^{|\Delta^{\mathcal{G}_2} \setminus \mathsf{ind}(\mathcal{K}_2)|} \times |\Delta^{\mathcal{G}_1}|)$, which can be readily seen by analysing the full game graph for $G^a_\Sigma(\mathcal{G}_2, \mathcal{G}_1)$ (similar to that in Example 21). By Theorem 6, we then obtain:

Theorem 23 *For combined complexity, Σ-query entailment is in* 2ExpTime *for Horn-$\mathcal{ALCHI}$ and Horn-$\mathcal{ALCI}$ KBs, and in* ExpTime *for DL-Lite$^{\mathcal{H}}_{horn}$ and DL-Lite$^{\mathcal{H}}_{core}$ KBs. For data complexity, these problems are all in* P.

Lower Bounds

We have shown that, for all of our DLs, Σ-query entailment and inseparability are in P for data complexity. The next theorem establishes a matching lower bound:

Theorem 24 *For data complexity, Σ-query entailment and inseparability are* P*-hard for DL-Lite$_{core}$ and $\mathcal{EL}$ KBs.*

Proof. The proof is by reduction of the P-complete entailment problem for *acyclic* Horn ternary clauses: given a conjunction φ of clauses of the form a_i and $a_i \wedge a_{i'} \to a_j$, $i, i' < j$, decide whether a_n is true in every model of φ. Consider the $\mathcal{EL}$ TBox $\mathcal{T} = \{V \sqsubseteq \exists P.(\exists R_1.V \sqcap \exists R_2.V)\}$ and an ABox $\mathcal{A}$ comprised of $F(a_n)$ and

$$P(a_i, a_i),\ R_1(a_i, a_i),\ R_2(a_i, a_i), \text{ for each clause } a_i \text{ in } \varphi,$$
$$P(a_j, c), R_1(c, a_i), R_2(c, a_{i'}), \text{ for } c = a_i \wedge a_{i'} \to a_j \text{ in } \varphi.$$

Set $\Sigma = \{F, P, R_1, R_2\}$, $\mathcal{K}_2 = (\mathcal{T}, \mathcal{A} \cup \{V(a_n)\})$ and $\mathcal{K}_1 = (\emptyset, \mathcal{A})$. Obviously, $\mathcal{K}_2$ Σ-query entails $\mathcal{K}_1$. On the other hand, the materialisation of $\mathcal{K}_2$ is (finitely) Σ-homomorphically embeddable in the materialisation of $\mathcal{K}_1$ iff φ derives a_n (see the full version for details). For *DL-Lite$_{core}$*, we take $\mathcal{T}$ to contain $V \sqsubseteq \exists P$, $\exists P^- \sqsubseteq \exists R_i$ and $\exists R_i^- \sqsubseteq V$, for $i = 1, 2$. ❑

For combined complexity, ExpTime-hardness of Σ-query inseparability for *Horn-$\mathcal{ALC}$* can be proved by reduction of the subsumption problem: we have $\mathcal{T} \models A \sqsubseteq B$ iff $(\mathcal{T}, \{A(a)\})$ and $(\mathcal{T} \cup \{A \sqsubseteq B\}, \{A(a)\})$ are $\{B\}$-query inseparable. We now establish matching lower bounds in the technically challenging cases.

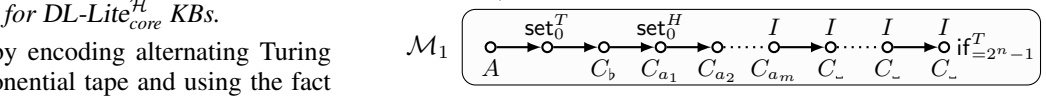
Theorem 25 *For combined complexity, Σ-query entailment and inseparability are (i) 2*ExpTime*-hard for Horn-$\mathcal{ALCI}$ KBs and (ii)* ExpTime*-hard for DL-Lite$^{\mathcal{H}}_{core}$ KBs.*

Proof. The proof of (*i*) is by encoding alternating Turing machines (ATMs) with exponential tape and using the fact that AExpSpace = 2ExpTime; see, e.g. (Kozen 2006).

Let $M = (\Gamma, Q, q_0, q_1, \delta)$ be an ATM with a tape alphabet Γ, a set of states Q partitioned into existential $Q_\exists$ and universal $Q_\forall$ states, an initial state $q_0 \in Q_\exists$, an accepting state $q_1 \in Q$, and a transition function

$$\delta \colon (Q \setminus \{q_1\}) \times \Gamma \times \{1, 2\} \to Q \times \Gamma \times \{-1, 0, +1\},$$

which, for a state q and symbol a, gives two instructions, $\delta(q, a, 1)$ and $\delta(q, a, 2)$. We assume that existential and universal states strictly alternate: any transition from an existential state results in a universal state, and vice versa. We extend δ with the instructions $\delta(q_1, a, k) = (q_1, a, 0)$, for $a \in \Gamma$ and $k = 1, 2$, which go into an infinite loop if M reaches the accepting state q_1. Thus, assuming that M terminates on every input, it accepts $\vec{w}$ iff the modified ATM M' has a run on $\vec{w}$, all branches of which are infinite.



Our aim is to construct, given M and $\vec{w}$, TBoxes $\mathcal{T}_1$ and $\mathcal{T}_2$ and a signature Σ such that M' has a run with only infinite branches iff the materialisation $\mathcal{M}_2$ of $(\mathcal{T}_2, \{A(c)\})$ is finitely Σ-homomorphically embeddable into the materialisation $\mathcal{M}_1$ of $(\mathcal{T}_1, \{A(c)\})$. Let f be a polynomial such that, on any input of length m, M uses at most $2^n - 2$ tape cells, with $n = f(m)$, which are numbered from 1 to $2^n - 2$, and the head stays to the right of cell 0, which contains the marker $\flat \in \Gamma$. The construction proceeds in five steps.

Step 0. We use tuples of $2n$ concepts to represent distances of up to 2^n between the cells on the tape in consecutive configurations. We refer to a tuple $Y_{n-1}, \overline{Y}_{n-1}, \dots, Y_0, \overline{Y}_0$ of concept names as Y and assume that the TBox contains the following CIs to encode an n-bit *R-counter on Y*:

$$\overline{Y}_k \sqcap Y_{k-1} \sqcap \dots \sqcap Y_0 \sqsubseteq \forall R.(Y_k \sqcap \overline{Y}_{k-1} \sqcap \dots \sqcap \overline{Y}_0), \quad n > k \geq 0,$$
$$\overline{Y}_i \sqcap \overline{Y}_k \sqsubseteq \forall R.\overline{Y}_i \text{ and } Y_i \sqcap \overline{Y}_k \sqsubseteq \forall R.Y_i, \quad n > i > k.$$

We use the expression $\mathsf{if}^Y_{=2^n-1}$ on the left-hand side of CIs to say that the Y-value is $2^n - 1$ (which is a shortcut for $Y_{n-1} \sqcap \dots \sqcap Y_0$); we also use $\mathsf{if}^Y_{<2^n-1}$ on the left-hand side of CIs for the complementary statement (which is a shortcut for n CIs with $\mathsf{if}^Y_{<2^n-1}$ replaced by each of $\overline{Y}_{n-1}, \dots, \overline{Y}_0$). Finally, we use set^Y_0 on the right-hand side of CIs for the reset command (which is equivalent to $\overline{Y}_{n-1} \sqcap \dots \sqcap \overline{Y}_0$). Note that the counter stops at $2^n - 1$: the R-successors of a domain element in $\mathsf{if}^Y_{=2^n-1}$ do not have to encode any value.

Step 1. First we encode configurations and transitions of M' using $\mathcal{T}_1$. We represent a configuration by a *block*, which is a sequence of $2^n + 1$ domain elements connected by a role P. The first element distinguishes the blocks for the two alternative transitions; using a P-counter on a tuple T, we assign indices from 0 to $2^n - 1$ to all other elements in each block. The element with index 0 is needed for padding. Each of the remaining $2^n - 1$ elements belongs to a concept C_a, for some $a \in \Gamma$: if the element with index $i + 1$ is in C_a, then the cell i is assumed to contain a in the configuration represented by the block (in particular, the element with index 1 contains $\flat$ for cell 0) as shown below:

The first block represents the initial configuration: the input $\vec{w} = a_1 \dots a_m$ is followed by $2^n - m - 2$ blank symbols $\sqcup$ and the head is positioned over cell 1, which is indicated by the 0 value of the P-counter on a tuple H. This is achieved by the following CIs in the TBox $\mathcal{T}_1$:

$$A \sqsubseteq \exists P.(\mathsf{set}^T_0 \sqcap \exists P.(C_\flat \sqcap \exists P.(C_{a_1} \sqcap \mathsf{set}^H_0 \sqcap \exists P.(C_{a_2} \sqcap \exists P.(\dots \exists P.(C_{a_m} \sqcap I) \dots))))), \quad (\mathcal{T}_1\text{-1})$$
$$\mathsf{if}^T_{<2^n-1} \sqcap I \sqsubseteq \exists P.(I \sqcap C_\sqcup), \quad (\mathcal{T}_1\text{-2})$$
$$\mathsf{if}^T_{=2^n-1} \sqcap I \sqsubseteq Z^0_{q_0 a_1}. \quad (\mathcal{T}_1\text{-3})$$

Step 2. The contents of the tape and the head position in each configuration is encoded in a block of length $2^n + 1$; the current state $q \in Q$ is recorded in the concept Z^0_{qa} that contains the last element of the block ($a \in \Gamma$ specifies the contents of the active cell scanned by the head). At the end of the block, when the T-value reaches $2^n - 1$, we branch out one block for each of the two transitions, reset the P-counter on T, and propagate via Z^1_{qa} and Z^2_{qa} the current state and symbol in the active cell: for $q \in Q$ and $a \in \Gamma$, we add to $\mathcal{T}_1$ the CI

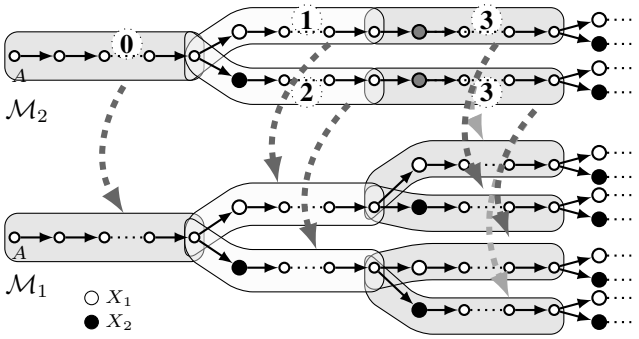
$$\mathsf{if}^T_{=2^n-1} \sqcap Z^0_{qa} \sqsubseteq \prod_{k=1,2} \exists P.(X_k \sqcap \exists P.(\mathsf{set}^T_0 \sqcap Z^k_{qa})), \quad (\mathcal{T}_1\text{-4})$$

where X_1 and X_2 are two fresh concept names.

The acceptance condition for M' is enforced by means of $\mathcal{T}_2$, which uses a P-counter on a tuple T^0 for a block representing the initial configuration (a T^0-block):

$$A \sqsubseteq \exists P.\mathsf{set}^{T^0}_0, \quad (\mathcal{T}_2\text{-1})$$

$$\mathsf{if}^{T^0}_{<2^n-1} \sqsubseteq \exists P. \quad (\mathcal{T}_2\text{-2})$$



Two P-counters, on T^1 and T^2, are used for blocks representing configurations with universal states (T^1- and T^2-blocks respectively) and one P-counter, on a tuple T^3, suffices for blocks representing configurations with existential states (T^3-blocks). These blocks are arranged into an infinite tree-like structure: the T^0-block is the root, from which a T^1- and a T^2-blocks branch out (successors of the initial state q_0 are universal). Each of them is followed by a T^3-block, which branches out a T^1- and a T^2-block, and so on. This is achieved by adding to $\mathcal{T}_2$ the following CIs:

$$\mathsf{if}^{T^k}_{=2^n-1} \sqsubseteq \prod_{j=1,2} \exists P.(X_j \sqcap \exists P.\mathsf{set}^{T^j}_0), \text{ for } k = 0, 3, \quad (\mathcal{T}_2\text{-3})$$

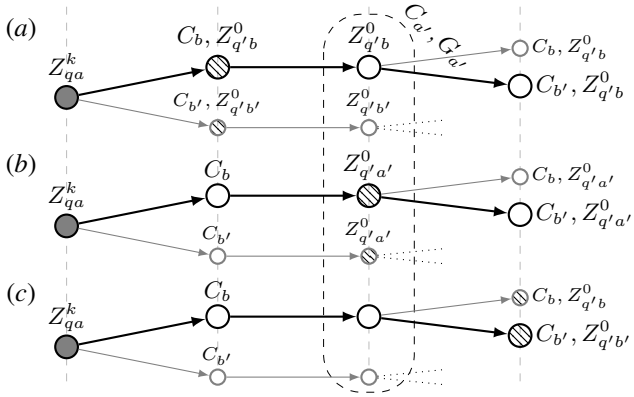
$$\mathsf{if}^{T^k}_{<2^n-1} \sqsubseteq \exists P.G, \quad \text{for } k = 1, 2, 3, \quad (\mathcal{T}_2\text{-4})$$

$$\mathsf{if}^{T^k}_{=2^n-1} \sqsubseteq \exists P.\exists P.\mathsf{set}^{T^3}_0, \quad \text{for } k = 1, 2, \quad (\mathcal{T}_2\text{-5})$$

where G is a concept name. If $\Sigma = \{A, X_1, X_2, P\}$ then there is a unique Σ-homomorphism from the T^0-block in $\mathcal{M}_2$ to the block of the initial configuration in $\mathcal{M}_1$. Next, concepts X_1 and X_2 ensure that the T^1- and T^2-blocks are Σ-homomorphically mapped (in a unique way) into the respective blocks in $\mathcal{M}_1$, which reflects the acceptance condition of universal states. The following T^3-block, however, contains neither X_1 nor X_2 and can be mapped to either of the blocks in $\mathcal{M}_1$, which reflects the choice in existential states; see the picture below, where possible Σ-homomorphisms are shown by thick dashed arrows:

Step 3. Recall that the P-counter on H measures the distance from the head: if the active cell in the current configuration is k, then its H-value is 0 and the H-value of the cell $k-2$ in a *successor* configuration is $2^n - 1$. So, until the H-counter reaches $2^n - 1$, the following CIs in $\mathcal{T}_1$ propagate the state and symbol in the active cell along the blocks: for $q \in Q$, $a \in \Gamma$ and $k = 0, 1, 2$,

$$\mathsf{if}^T_{<2^n-1} \sqcap \mathsf{if}^H_{<2^n-1} \sqcap Z^k_{qa} \sqsubseteq \prod_{b\in\Gamma} \exists P.(C_b \sqcap Z^k_{qa}) \quad (\mathcal{T}_1\text{-5})$$



(for each $b \in \Gamma$, these CIs generate a branch in $\mathcal{M}_1$ to represent the same cell but with a different symbol, b, tentatively assigned to the cell—Step 4 will ensure that the correct branch and symbol are selected to match the cell contents in the preceding configuration). When the distance from the last head position is 2^n, the contents of the cell and the current state are changed according to δ:

$$\mathsf{if}^T_{<2^n-1} \sqcap \mathsf{if}^H_{=2^n-1} \sqcap Z^k_{qa} \sqsubseteq \prod_{b\in\Gamma} \exists P.(C_b \sqcap \Delta^k_{qa,b}), \quad (\mathcal{T}_1\text{-6})$$

where $\delta(q, a, k) = (q', a', \sigma)$ and $\Delta^k_{qa,b}$ is the concept

$$\begin{aligned}
&\mathsf{set}^H_0 \sqcap Z^0_{q'b} \sqcap \exists P.(C_{a'} \sqcap G_{a'}), \quad \text{if } \sigma = -1,\\
&\exists P.(C_{a'} \sqcap G_{a'} \sqcap \mathsf{set}^H_0 \sqcap Z^0_{q'a'}), \quad \text{if } \sigma = 0,\\
&\exists P.(C_{a'} \sqcap G_{a'} \sqcap \prod_{b'\in\Gamma} \exists P.(C_{b'} \sqcap \mathsf{set}^H_0 \sqcap Z^0_{q'b'})), \text{ if } \sigma = +1
\end{aligned}$$

(the symbol in the active cell is changed according to the instruction, and the current state and symbol in the next active cell are then recorded in Z^0_{qa}). Since the head never visits cell 0, this happens over cells 0 to $2^n - 1$, that is, at least one element after the P-counter on T is reset to 0. These three situations are shown below, where grey and hatched nodes denote domain elements with H-values $2^n - 1$ and 0, respectively, and the domain elements in the dashed oval represent the active cell of the preceding configuration:

(Note that there is only one branch for the modified cell, which corresponds to the new symbol, a', in that cell; see explanations below.) Then, the current state and the symbol in the active cell are propagated along the tape using ($\mathcal{T}_1$-5).

Step 4. The CIs ($\mathcal{T}_1$-5)–($\mathcal{T}_1$-6) generate a separate P-successor for each $b \in \Gamma$. The correct one is chosen by a

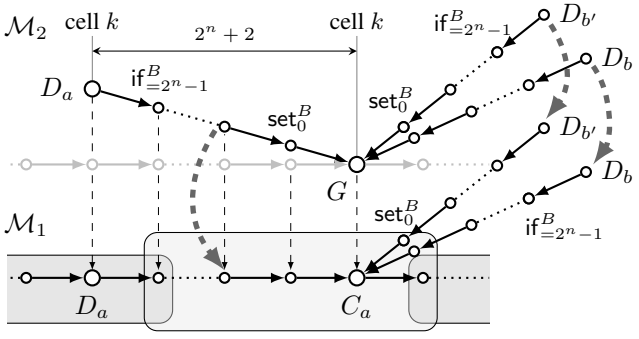
finite Σ-homomorphism, h, from $\mathcal{M}_2$ to $\mathcal{M}_1$. To exclude wrong choices, we take

$$\Sigma \;=\; \{A, P, X_1, X_2\} \;\cup\; \{D_a \mid a \in \Gamma\}.$$

Recall that if $d_1 \in C_a^{\mathcal{M}_1}$, for some $a \in \Gamma$, then it represents a cell containing a. The following CIs in $\mathcal{T}_1$ ensure that, for each $b \in \Gamma$ different from a, there is a block of $(2^n + 1)$-many P^--connected elements that ends in the concept D_b (called a D_b-*block* in the sequel):

$$C_a \sqsubseteq D_a \sqcap \textstyle\prod_{b \in \Gamma \setminus \{a\}} G_b, \qquad (\mathcal{T}_1\text{-}7)$$

$$G_b \sqsubseteq \exists P^-.(S_b \sqcap \mathsf{set}_0^B), \qquad (\mathcal{T}\text{-}1)$$



$$\mathsf{if}^B_{<2^n-1} \sqcap S_b \sqsubseteq \exists P^-.S_b, \qquad (\mathcal{T}\text{-}2)$$

$$\mathsf{if}^B_{=2^n-1} \sqcap S_b \sqsubseteq \exists P^-.D_b, \qquad (\mathcal{T}\text{-}3)$$

where we use a P^--counter on a tuple B (unlike P-counters in all other cases) and a concept S_b to propagate b along the whole block. Suppose $h(d_2) = d_1$ and d_2 belongs to G in $\mathcal{M}_2$ (it represents a cell in a non-initial configuration). Then the following CI and ($\mathcal{T}$-1)–($\mathcal{T}$-3), added to $\mathcal{T}_2$, generate a D_b-block, for *each* $b \in \Gamma$ (including a):

$$G \sqsubseteq \textstyle\prod_{b \in \Gamma} G_b. \qquad (\mathcal{T}_2\text{-}6)$$

Each of the D_b-blocks in $\mathcal{M}_2$, for $b \in \Gamma$ with $b \neq a$, can be mapped by h to the respective D_b-block in $\mathcal{M}_1$. By the choice of Σ, the only remaining D_a-block, in case a is tentatively contained in this cell, could be mapped (in the reverse order) along the branch in $\mathcal{M}_1$ *but only* if the cell contains a in the preceding configuration (that is, the element which is $2^n + 1$ steps closer to the root of $\mathcal{M}_1$ belongs to D_a):

Note (see $\Delta^k_{qa,b}$) that the cell whose content is changed generates the additional D_a-block in $\mathcal{M}_1$ to allow the respective D_a-block from $\mathcal{M}_2$ to be mapped there.

One can show that M' has a run with only infinite branches iff $(\mathcal{T}_1, \{A(c)\})$ Σ-query entails $(\mathcal{T}_2, \{A(c)\})$. It follows, by Theorem 2, that deciding Σ-query inseparability is 2ExpTime-hard.

(*ii*) A proof of ExpTime-hardness of Σ-query inseparability for *DL-Lite*$^{\mathcal{H}}_{core}$ KBs is given in the full paper. It uses the same idea of encoding computations of ATMs. One essential difference is that the expressive power of *DL-Lite*$^{\mathcal{H}}_{core}$ is not enough to represent n-bit counters in Step 0, and so we can only encode computations on polynomial tape. ❑

As a consequence of Theorems 3, 23 and 25 we obtain:

Theorem 26 *For combined complexity, the membership problem for universal UCQ-solutions is* 2ExpTime*-complete for Horn-$\mathcal{ALCHI}$ and Horn-$\mathcal{ALCI}$;* ExpTime*-complete for Horn-$\mathcal{ALCH}$, Horn-$\mathcal{ALC}$, DL-Lite*$^{\mathcal{H}}_{horn}$ *and DL-Lite*$^{\mathcal{H}}_{core}$*; and* P*-complete for $\mathcal{EL}$ and $\mathcal{ELH}$. For data complexity, all these problems are* P*-complete.*

In the case of *DL-Lite*$^{\mathcal{H}}_{core}$, we also obtain an ExpTime algorithm for checking the existence and computing universal UCQ-solutions. Indeed, given a KB $\mathcal{K}_1$, a target signature Σ_2 and a mapping $\mathcal{T}_{12}$, we first compute the Σ_2-ABox over $\mathsf{ind}(\mathcal{K}_1)$ that is implied by $\mathcal{K}_1$ and $\mathcal{T}_{12}$, and then check whether at least one KB $\mathcal{K}_2$ in Σ_2 with this ABox is a universal UCQ-solution (there are $\leq O(2^{|\Sigma_2|})$ such KBs). This gives an ExpTime upper bound for the non-emptiness problem for universal UCQ-solutions in *DL-Lite*$^{\mathcal{H}}_{core}$ (Arenas et al. 2013). Similarly, we can check in ExpTime whether the result of forgetting a signature in a *DL-Lite*$^{\mathcal{H}}_{core}$ KB exists.

Σ-query inseparability of *DL-Lite*$^{\mathcal{H}}_{core}$ TBoxes was known to sit between PSpace and ExpTime (Konev et al. 2011). Using the fact that witness ABoxes for *DL-Lite*$^{\mathcal{H}}_{core}$ TBox separability can always be chosen among the singleton ABoxes (Konev et al. 2011, Theorem 8), we can modify the proof of Theorem 25 to improve the PSpace lower bound:

Theorem 27 *Σ-query inseparability of DL-Lite*$^{\mathcal{H}}_{core}$ *TBoxes is* ExpTime*-complete.*

For more expressive DLs, TBox Σ-query inseparability is often harder than KB inseparability: for *DL-Lite*$_{horn}$, the space of relevant witness ABoxes for TBox separability is of exponential size and, in fact, TBox inseparability is NP-hard, while KB inseparability is in P. Similarly, Σ-query inseparability of $\mathcal{EL}$ KBs is tractable, while Σ-query inseparability of TBoxes is ExpTime-complete (Lutz and Wolter 2010). The complexity of TBox inseparability for Horn-DLs extending *Horn-$\mathcal{ALC}$* is not known.

Future Work

From a theoretical point of view, it would be of interest to investigate the complexity of Σ-query inseparability for KBs in more expressive Horn DLs (e.g., *Horn-$\mathcal{SHIQ}$*) and non-Horn DLs extending $\mathcal{ALC}$. We conjecture that the game technique developed in this paper can be extended to those DLs as well. Our games can also be used to define *efficient approximations* of Σ-query entailment and inseparability for KBs. The existence of a forward strategy, for example, provides a sufficient condition for Σ-query entailment for all of our DLs. Thus, one can extract a Σ-query module of a given KB $\mathcal{K}$ by exhaustively removing from $\mathcal{K}$ those inclusions and assertions α for which player 1 has a winning strategy in the game $G^f_\Sigma(\mathcal{G}_1, \mathcal{G}_2)$, where $\mathcal{G}_1$ is a generating structure for $\mathcal{K}\setminus\{\alpha\}$ and $\mathcal{G}_2$ for $\mathcal{K}$. The resulting modules are minimal for our DLs without inverse roles, and we conjecture that in practice they are often minimal for DLs with inverse roles as well; see (Konev et al. 2011) for experiments testing similar ideas for module extraction from TBoxes.

Finally, we plan to use the developed technique to investigate the complexity of the non-emptiness problem for universal UCQ-solutions in data exchange as well as algorithms for computing universal UCQ-solutions in various DLs.

Abstract

In Description Logic (DL) knowledge bases (KBs) information is typically captured by crisp concepts. For many applications, querying the KB by crisp query concepts is too restrictive. A controlled way of gradually relaxing a query concept can be achieved by the use of concept similarity measures. In this paper we formalize the task of instance query answering for crisp DL KBs using concepts relaxed by concept similarity measures. We investigate computation algorithms for this task in the DL $\mathcal{EL}$, their complexity and properties for the employed similarity measure regarding whether unfoldable or general TBoxes are used.

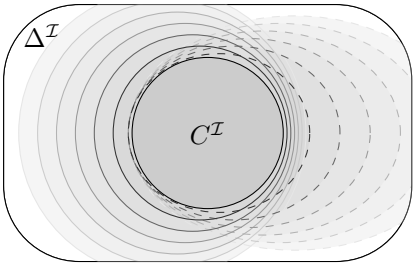

Figure 1: Relaxed instances w.r.t. two different similarity measures. Darker colors represent the relaxed instances of C w.r.t. higher degrees t.

1 Introduction

Description Logic (DL) knowledge bases are formal vocabularies that describe categories or specific subjects from application domains—such as for service matching, the biomedical or geo-spatial field. The concepts in the knowledge base are characterized by relationships to other concepts using constructors available in the DL in which the knowledge base is formulated.

The use of DLs became increasingly popular in recent years, due to the W3C standard OWL 2 for ontology languages which are based on DLs, and the development of powerful DL reasoner systems for those languages. These systems support various reasoning services, such as subsumption and instance queries. *Subsumption* determines for a pair of concepts whether elements belonging to the first concept necessarily also belong to the second one. Given a concept, *instance queries* retrieve from a knowledge base all those individuals that belong to the concept. For some applications exact matches to an instance query are sometimes too restrictive. In service matching, OWL TBoxes are employed to describe types of services and a user request for a service specifies several conditions for the desired service by a concept. For such a query concept instance query answering is performed over the OWL knowledge base that contains the individual services. If an exact match with the provided requirements is not available, a 'feasible' alternative needs to be retrieved. More precisely, the system should retrieve those individuals from the knowledge base that satisfy the main conditions, while all other conditions can be relaxed. A natural idea on how to relax the notion of instance query answering is to simply employ fuzzy DLs and perform query answering on a fuzzy variant of the initial query concept. However, on the one hand reasoning in fuzzy DLs easily becomes undecidable (Borgwardt and Peñaloza 2012) and on the other hand depending on the user and on the request, different ways of relaxing the query concept may be appropriate.

In this paper we investigate a form of answering relaxed instance queries, where the query concept can be relaxed by using concept similarity measures. A *concept similarity measure* (CSM) is a function from pairs of concepts to the unit interval, where the value 1 indicates total similarity and the value 0 total dissimilarity of the concepts. Answering *relaxed instance queries* is to compute, given concept C, a concept similarity measure $\sim$, and a degree $t \in [0,1]$, the set of individuals that instances of concepts similar to C by a degree of at least t, if measured by $\sim$. This approach, recently proposed in (Ecke, Peñaloza, and Turhan 2013), does not need to extend the DL in which the knowledge base is written, thus the complexity for standard reasoning tasks remain the same. The choice of a CSM allows to encode the application-specific notion of similarity. Furthermore the choice of t allows for a flexible degree of similarity, as depicted in Figure 1.

For DLs there is whole range of CSMs defined (see for example (Borgida, Walsh, and Hirsh 2005; d'Amato, Fanizzi, and Esposito 2005; Janowicz and Wilkes 2009;

Copyright © 2014, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

Lehmann and Turhan 2012)), which could be employed for this task. Computing concept similarity is an ontology service that is investigated in its own right. For instance, for the Gene Ontology (Gene Ontology Consortium 2000), which is written in the DL $\mathcal{EL}$ and is used, among others, to solve the task of finding genes that realize similar functionality (Lord et al. 2003), a proliferation of different similarity measures has been defined (Lord et al. 2003; Schlicker et al. 2006; Mistry and Pavlidis 2008; Alvarez and Yan 2011).

Since concept similarity is not a formalized notion, CSMs are often defined in an ad-hoc manner or simply tuned to test data. This makes their behavior hard to predict when applied to new ontologies. In (Lehmann and Turhan 2012) a set of properties for CSMs was described and the framework given there allows users to generate CSMs for $\mathcal{EL}$-concepts with those properties. Furthermore, users can specify which parts of the vocabulary used in their knowledge base are important in regard of assessing similarity of concepts. These measures naturally allow to select which aspect of a query concept to relax.

We devise a computation algorithm for answering relaxed instance queries for concepts defined w.r.t. unfoldable $\mathcal{EL}$ TBoxes and any CSM that meets certain requirements. The core reasoning problem in our algorithm is to compute, for an individual a and the query concept C, a concept C' that *mimics* C, i.e. a concept that is 'sufficiently similar' to C w.r.t. the used similarity measure $\sim$ and the degree t, while preserving a as an instance.

To the best of our knowledge there is no CSM defined in the literature that takes *all* of the information from *general* $\mathcal{EL}$-TBoxes into account. Existing CSMs for general TBoxes consider only the concept hierarchy (e.g. (d'Amato, Staab, and Fanizzi 2008; Alvarez and Yan 2011)). In this paper we devise a family of CSMs that handle all the knowledge encoded in general $\mathcal{EL}$-TBoxes. We derive such CSMs by employing the canonical models of TBoxes and applying a similarity measure for interpretations. We show that this interpretation similarity measure (ISM) has properties analogous to those from (Lehmann and Turhan 2012). We define corresponding CSMs, which also preserve these properties. These CSMs for general TBoxes are the foundation to lift the computation algorithm for answering relaxed instance queries to the case of general $\mathcal{EL}$-TBoxes. It shows that the stronger CMSs obtained for this case allow for computation of relaxed instances in polynomial time, if applied to unfoldable TBoxes.

This paper is structured as follows. The next section recalls some basic notions for DLs, in particular $\mathcal{EL}$, and CSMs. Section 3 introduces relaxed instance query answering and our approach to compute it by the auxiliary task of computing a mimic. Section 4 presents a computation algorithm for relaxed instances w.r.t. unfoldable $\mathcal{EL}$-TBoxes and gives an upper bound on the complexity. Afterwards, we introduce a family of similarity measures on pointed canonical interpretations $\sim_i$ which have well-defined formal properties. From this measure we derive a CSM $\sim_c$ with the same set of properties which can be used to compute relaxed instances w.r.t. general $\mathcal{EL}$-TBoxes. We give a computation algorithm in that section and end the paper with directions for future work. Due to space constraints the proofs can be found in the technical report (Ecke and Turhan 2013).

Table 1: Concept constructors, TBox axioms and ABox assertions for $\mathcal{EL}$.

	Syntax	Semantics
top concept	$\top$	$\top^{\mathcal{I}} = \Delta^{\mathcal{I}}$
concept name	A	$A^{\mathcal{I}} \subseteq \Delta^{\mathcal{I}}$
conjunction	$C \sqcap D$	$(C \sqcap D)^{\mathcal{I}} = C^{\mathcal{I}} \cap D^{\mathcal{I}}$
existential restriction	$\exists r.C$	$(\exists r.C)^{\mathcal{I}} = \{d \in \Delta^{\mathcal{I}} \mid \exists e.(d,e) \in r^{\mathcal{I}} \wedge e \in C^{\mathcal{I}}\}$
concept definition	$A \equiv C$	$A^{\mathcal{I}} = C^{\mathcal{I}}$
GCI	$C \sqsubseteq D$	$C^{\mathcal{I}} \subseteq D^{\mathcal{I}}$
concept assertion	$C(a)$	$a^{\mathcal{I}} \in C^{\mathcal{I}}$
role assertion	$r(a,b)$	$(a^{\mathcal{I}}, b^{\mathcal{I}}) \in r^{\mathcal{I}}$

2 Preliminaries

As we want to investigate the notion of similarity in the context of the DL $\mathcal{EL}$, we briefly introduce this logic and CSMs.

The Description Logic $\mathcal{EL}$

Starting from the fixed, countably infinite, disjoint sets of concept names N_C and role names N_R, $\mathcal{EL}$*-concepts* can be constructed by the following syntactic rule

$$C, D ::= \top \mid A \mid C \sqcap D \mid \exists r.D,$$

where A is a concept name and r is a role name. The set of all $\mathcal{EL}$-concepts is denoted by $\mathfrak{C}(\mathcal{EL})$.

The semantics of concepts is defined by means of *interpretations* $\mathcal{I} = (\Delta^{\mathcal{I}}, \cdot^{\mathcal{I}})$ consisting of a non-empty *domain* $\Delta^{\mathcal{I}}$ and an *interpretation function* $\cdot^{\mathcal{I}}$ that assigns binary relations on $\Delta^{\mathcal{I}}$ to role names and subsets of $\Delta^{\mathcal{I}}$ to concept names. The interpretation function is recursively extended to $\mathcal{EL}$-concepts as shown in the upper part of Table 1. We denote the class of all interpretations as $\mathfrak{I}$. A *pointed interpretation* $p = (\mathcal{I}, d)$ consists of an interpretation $\mathcal{I}$, and an element $d \in \Delta^{\mathcal{I}}$. $\mathfrak{P}$ is the class of all pointed interpretations, i.e., $\mathfrak{P} = \{(\mathcal{I}, d) \mid \mathcal{I} \in \mathfrak{I}, d \in \Delta^{\mathcal{I}}\}$. Given a pointed interpretation $p = (\mathcal{I}, d)$, the set of all $\mathcal{EL}$-concepts that have d as an instance in $\mathcal{I}$ is $\mathfrak{C}(p) = \{C \in \mathfrak{C}(\mathcal{EL}) \mid d \in C^{\mathcal{I}}\}$.

The middle part of Table 1 displays two kinds of concept axioms. An *$\mathcal{EL}$-TBox* or *terminology* $\mathcal{T}$ is a set of such concept axioms. An *unfoldable TBox*, is a set of concept definitions such that each concept name occurs at most once on the left-hand side of a concept definition and there are no cyclic dependencies between defined concepts. Concept names occurring on the left-hand side of a concept definition are called *defined concepts*, the other concept names are *atomic concepts*.

Consider an additional set N_I of *individual names*, which is disjoint with N_C and N_R. An interpretation $\mathcal{I} = (\Delta^{\mathcal{I}}, \cdot^{\mathcal{I}})$ additionally maps each individual name to an element of

$\Delta^{\mathcal{I}}$. An ABox $\mathcal{A}$ is a set of concept or role assertions, as displayed in the lower part of Table 1. An *$\mathcal{EL}$-knowledge base* (KB) is a pair $\mathcal{K} = (\mathcal{T}, \mathcal{A})$ where $\mathcal{T}$ is an *$\mathcal{EL}$-TBox* and $\mathcal{A}$ an *$\mathcal{EL}$-ABox*.

The semantics of interpretations is extended to TBox axioms and ABox assertions as shown in Table 1. An interpretation $\mathcal{I}$ is a model of a TBox $\mathcal{T}$ (ABox $\mathcal{A}$), if it satisfies all axioms in $\mathcal{T}$ (assertions in $\mathcal{A}$). $\mathcal{I}$ is a model of a knowledge base $\mathcal{K} = (\mathcal{T}, \mathcal{A})$ if it is a model for both $\mathcal{T}$ and $\mathcal{A}$.

The following commonly used reasoning tasks are implemented in most DL reasoning systems. *Concept subsumption* asks, given a TBox $\mathcal{T}$ and two concepts C and D, whether C is subsumed by D w.r.t. $\mathcal{T}$ (denoted $C \sqsubseteq_{\mathcal{T}} D$), i.e. $C^{\mathcal{I}} \subseteq D^{\mathcal{I}}$ for all models $\mathcal{I}$ of $\mathcal{T}$. *Concept equivalence* holds for two concepts C and D w.r.t. $\mathcal{T}$ (denoted $C \equiv_{\mathcal{T}} D$), iff $C \sqsubseteq_{\mathcal{T}} D$ and $D \sqsubseteq_{\mathcal{T}} C$. Given an individual a, a concept C, and a KB $\mathcal{K}$, a is called an *instance of* C w.r.t. $\mathcal{K}$, denoted $\mathcal{K} \models C(a)$, iff $a^{\mathcal{I}} \in C^{\mathcal{I}}$ for all models $\mathcal{I}$ of $\mathcal{K}$. Given a KB $\mathcal{K} = (\mathcal{T}, \mathcal{A})$ and a concept C, *instance retrieval* returns all individuals from $\mathcal{A}$ that are instances of C. These reasoning tasks can all be characterized by means of simulations between interpretations.

Definition 1 (simulation). Let $\mathcal{I}$ and $\mathcal{J}$ be interpretations. A relation $S \subseteq \Delta^{\mathcal{I}} \times \Delta^{\mathcal{J}}$ is a *simulation* between $\mathcal{I}$ and $\mathcal{J}$, if the following two conditions hold:

1. For all $(d, e) \in S$ and $A \in N_C$, if $d \in A^{\mathcal{I}}$ then $e \in A^{\mathcal{J}}$.
2. For all $(d, e) \in S$, $r \in N_R$ and $(d, d') \in r^{\mathcal{I}}$, there is an $(e, e') \in r^{\mathcal{J}}$ with $(d', e') \in S$.

The pointed interpretation $p = (\mathcal{I}, d)$ *simulates* the pointed interpretation $q = (\mathcal{J}, e)$ ($p \lesssim q$), if there exists a simulation $S \subseteq \Delta^{\mathcal{I}} \times \Delta^{\mathcal{J}}$ between $\mathcal{I}$ and $\mathcal{J}$ with $(d, e) \in S$. If $p \lesssim q$ and $q \lesssim p$, then p and q are *equisimilar* ($p \simeq q$). There is a strong connection between simulations between pointed interpretations and their concept sets.

Theorem 2 ((Lutz and Wolter 2010)). *Let $p, q \in \mathfrak{P}$. Then:*
1. $p \lesssim q$ iff $\mathfrak{C}(p) \subseteq \mathfrak{C}(q)$, and 2. $p \simeq q$ iff $\mathfrak{C}(p) = \mathfrak{C}(q)$.

For $\mathcal{EL}$ most reasoning procedures rely on the fact that canonical models can be built, from which entailments can be read-off directly. By $\mathrm{Sig}(X)$ we denote the set of names and by $\mathsf{sub}(X)$ the sub-concepts appearing in X.

Definition 3. Let $C \in \mathfrak{C}(\mathcal{EL})$ and $\mathcal{K} = (\mathcal{T}, \mathcal{A})$ be an $\mathcal{EL}$-KB. The *canonical model $\mathcal{I}_{C,\mathcal{T}} = (\Delta^{\mathcal{I}_{C,\mathcal{T}}}, \cdot^{\mathcal{I}_{C,\mathcal{T}}})$ of C* w.r.t. the TBox $\mathcal{T}$ is defined as follows:

- $\Delta^{\mathcal{I}_{C,\mathcal{T}}} = \{d_C\} \cup \{d_D \mid \exists r.D \in \mathsf{sub}(C) \cup \mathsf{sub}(\mathcal{T})\}$
- $A^{\mathcal{I}_{C,\mathcal{T}}} = \{d_D \mid D \sqsubseteq_{\mathcal{T}} A\}$, and
- $r^{\mathcal{I}_{C,\mathcal{T}}} = \{(d_D, d_E) \mid D \sqsubseteq_{\mathcal{T}} \exists r.E\}$.

The *canonical model $\mathcal{I}_{\mathcal{K}} = (\Delta^{\mathcal{I}_{\mathcal{K}}}, \cdot^{\mathcal{I}_{\mathcal{K}}})$ of the KB $\mathcal{K}$* is defined as follows:

- $\Delta^{\mathcal{I}_{\mathcal{K}}} = \{d_a \mid a \in \mathrm{Sig}(\mathcal{A}) \cap N_I\} \cup \{d_C \mid \exists r.C \in \mathsf{sub}(\mathcal{A}) \cup \mathsf{sub}(\mathcal{T})\}$,
- $A^{\mathcal{I}_{\mathcal{K}}} = \{d_D \mid D \sqsubseteq_{\mathcal{T}} A\} \cup \{d_a \mid \mathcal{K} \models A(a)$,
- $r^{\mathcal{I}_{\mathcal{K}}} = \{(d_D, d_E) \mid D \sqsubseteq_{\mathcal{T}} \exists r.E\} \cup \{(d_a, d_D) \mid \mathcal{K} \models \exists r.D(a)\} \cup \{(d_a, d_b) \mid r(a, b) \in \mathcal{A}\}$.

Note that canonical models for $\mathcal{EL}$ are always finite. The canonical model $\mathcal{I}_{C,\mathcal{T}}$ can be seen as the most general model for C and $\mathcal{T}$, as any other model $\mathcal{J}$ of $\mathcal{T}$ with a $d \in C^{\mathcal{J}}$ can be simulated by $(\mathcal{I}_{C,\mathcal{T}}, d_C)$. Similarly, for any other model $\mathcal{J}$ of $\mathcal{K}$ with $d = a^{\mathcal{J}}$ for an individual a, $(\mathcal{J}, d)$ is simulated by $(\mathcal{I}_{\mathcal{K}}, d_a)$.

Theorem 4 ((Lutz and Wolter 2010)). *Let $\mathcal{T}$ be an $\mathcal{EL}$-TBox, C and D be $\mathcal{EL}$-concepts. Then:*

1. *for all models $\mathcal{I}$ of $\mathcal{T}$ and all elements $d \in \Delta^{\mathcal{I}}$ it is the case that $d \in C^{\mathcal{I}}$ iff $(\mathcal{I}_{C,\mathcal{T}}, d_C) \lesssim (\mathcal{I}, d)$; and*
2. *$C \sqsubseteq_{\mathcal{T}} D$ iff $d_C \in D^{\mathcal{I}_{C,\mathcal{T}}}$ (i.e., $D \in \mathfrak{C}((\mathcal{I}_{C,\mathcal{T}}, d_C))$) iff $(\mathcal{I}_{D,\mathcal{T}}, d_D) \lesssim (\mathcal{I}_{C,\mathcal{T}}, d_C)$.*

When testing whether an individual is a relaxed instance of some concept C, we will see the need to compute 'the best-fitting $\mathcal{EL}$-concept description' that has the individual as an instance. This can be realized by the task of computing the most specific concept.

Definition 5 (most specific concept). Let $\mathcal{K} = (\mathcal{T}, \mathcal{A})$ be a KB and a an individual from $\mathcal{A}$. A concept C is the *most specific concept (msc) of a w.r.t. $\mathcal{K}$* (denoted $\mathrm{msc}_{\mathcal{K}}(a)$) if it satisfies:

1. $\mathcal{K} \models C(a)$, and
2. $\mathcal{K} \models D(a)$ implies $C \sqsubseteq_{\mathcal{T}} D$ for all concepts D.

Since the msc may not exists due to an infinite nesting of existential restrictions, one can compute an approximation by bounding the depth of the quantifiers. Formally, given a concept C, we define the role-depth $\mathrm{rd}(C)$ of C by

$$\mathrm{rd}(C) := \begin{cases} 0 & \text{if } C \in N_C \cup \{\top\} \\ 1 + \mathrm{rd}(D) & \text{if } C = \exists r.D \\ max\{\mathrm{rd}(C_1), \mathrm{rd}(C_2)\} & \text{if } C = C_1 \sqcap C_2 \end{cases}$$

If in Definition 5 C and D have a role-depth limited to $k \in \mathbb{N}$, then C is the *role-depth bounded msc* of a w.r.t. $\mathcal{K}$ (k-$\mathrm{msc}_{\mathcal{K}}(a)$). The msc and the k-msc are unique up to equivalence in $\mathcal{EL}$, if they exist (Peñaloza and Turhan 2011).

Concept Similarity Measures

Given a DL $\mathcal{L}$ and a TBox $\mathcal{T}$, a concept similarity measure (CSM) is a function $\sim_{\mathcal{T}} : \mathfrak{C}(\mathcal{L}) \times \mathfrak{C}(\mathcal{L}) \to [0, 1]$ such that $C \sim_{\mathcal{T}} C = 1$ for all concepts C. Intuitively, $\sim_{\mathcal{T}}$ expresses how close two concepts are. A value $C \sim_{\mathcal{T}} D = 0$ means that the concepts C and D are totally dissimilar w.r.t. $\mathcal{T}$, while a value of 1 indicates total similarity. We often simply write $\sim$ instead of $\sim_{\mathcal{T}}$ if the TBox $\mathcal{T}$ is clear from the context.

In (Lehmann and Turhan 2012) a set of properties for CSMs is defined and a framework is devised that allows to construct CSMs for $\mathcal{EL}$-concepts, w.r.t. unfoldable TBoxes, that have these formal properties. In this paper we investigate CSMs for $\mathcal{EL}$-concepts defined w.r.t. general TBoxes. We extend the definition of the properties of CSMs from (Lehmann and Turhan 2012) to the case of general TBoxes.

Definition 6. A CSM $\sim : \mathfrak{C}(\mathcal{EL}) \times \mathfrak{C}(\mathcal{EL}) \to [0, 1]$ is:

symmetric iff $C \sim_{\mathcal{T}} D = D \sim_{\mathcal{T}} C$;

equivalence invariant iff for all $C \equiv_\mathcal{T} D$ it holds that $C \sim_\mathcal{T} E = D \sim_\mathcal{T} E$;

equivalence closed iff $C \equiv_\mathcal{T} D \iff C \sim_\mathcal{T} D = 1$;

bounded iff the existence of $E \neq \top$ with $C \sqsubseteq_\mathcal{T} E$ and $D \sqsubseteq_\mathcal{T} E$ implies $C \sim_\mathcal{T} D > 0$;

dissimilar closed iff $C, D \neq \top$ and there is no $E \neq \top$ with $C \sqsubseteq_\mathcal{T} E$ and $D \sqsubseteq_\mathcal{T} E$ implies $C \sim_\mathcal{T} D = 0$;

subsumption preserving iff $C \sqsubseteq_\mathcal{T} D \sqsubseteq_\mathcal{T} E$ implies $C \sim_\mathcal{T} D \geq C \sim_\mathcal{T} E$;

reverse subsumption preserving iff $C \sqsubseteq_\mathcal{T} D \sqsubseteq_\mathcal{T} E$ implies $D \sim_\mathcal{T} E \geq C \sim_\mathcal{T} E$, and

These formally defined properties make CSMs more predictable for users. The measures in (Suntisrivaraporn 2013; Lehmann and Turhan 2012) fulfill most of these properties, in particular, they are symmetric and equivalence invariant, two properties that we will require later to compute relaxed instances. The parameterizable similarity measures from (Lehmann and Turhan 2012) additionally allow users to calibrate the measure to fit their expectations. In our setting these parametrizable CSMs enable users to specify which features of query concepts should be relaxed.

3 Relaxed Instances

As discussed before, our goal is to generalize query answering to allow for relaxing the solution set. This means, when a query concept Q is given, we are not only interested in the instances of Q, but also those individuals that are close enough to being instances; those individuals are called *relaxed instances*.

There are many ways to formalized the notion of relaxed instances, but in this paper we make use of CSMs for this relaxation. We say that relaxed instances of the query concept are those individuals that are instance of a (possibly different) concept that is sufficiently similar to the original query concept. The condition of 'sufficiently similar' is expressed via a threshold, or minimal similarity, t. One can then control how inclusive the relaxed instance solutions should be, by adjusting t, and guide the direction, in which solutions are relaxed by choosing an appropriate CSM.

Definition 7 (relaxed instance). Let $\mathcal{L}$ be some DL, $\sim$ be a CSM, and $t \in [0, 1)$. The individual $a \in N_I$ is a *relaxed instance* of the query concept Q w.r.t. the $\mathcal{L}$-knowledge base $\mathcal{K}$, $\sim$ and the threshold t iff there exists a $\mathcal{L}$-concept description $X \in \mathfrak{C}(\mathcal{L})$ such that $Q \sim X > t$ and $\mathcal{K} \models X(a)$. $\text{Relax}_t^\sim(Q)$ denotes the set of all individuals occurring in $\mathcal{K}$ that are relaxed instances of Q w.r.t. $\mathcal{K}$, $\sim$ and t.

The task we are mostly interested in is not *relaxed instance checking*, i.e. testing whether a given individual a is a relaxed instance of the query concept Q, but to compute all relaxed instances of Q, i.e. the set $\text{Relax}_t^\sim(Q)$.

One naive idea to compute this set would be to first computing all concepts X that are similar to C with degree greater than t, and then obtaining all the instances of these concepts X; in symbols,

$$\text{Relax}_t^\sim(C) = \bigcup_{C \sim X > t} \{a \mid a \text{ is an instance of } X\}.$$

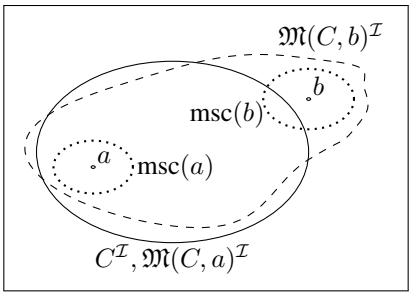

Figure 2: Two individuals, their most specific concepts (dotted), and the mimics of a concept C w.r.t. the individuals (dashed).

However, this approach is not feasible, since there might be an infinite number of concepts X sufficiently similar to C. Furthermore, given an CSM, it is not apparent how to even obtain all concepts that are similar to C with degree $> t$, since in general CSMs only allow to evaluate the similarity of two given concepts.

To avoid these issues, we consider a different reasoning problem, that considers the computation of a concept that has a given individual a as an instance and resembles C best w.r.t. the given CSM. We call this the *mimic* of C w.r.t. a.

Definition 8 (mimic). Let $\mathcal{L}$ be a DL, $\mathcal{K}$ be an $\mathcal{L}$-knowledge base, $a \in N_I$ be an individual name, C be an $\mathcal{L}$-concept description, and $\sim$ be a CSM. An $\mathcal{L}$-concept D is called a *mimic* of C w.r.t. a, denoted $D \in \mathfrak{M}(C, a)$, iff the following two conditions hold:

- a is an instance of D, i.e., $a^\mathcal{I} \in D^\mathcal{I}$ for all models $\mathcal{I}$ of $\mathcal{K}$, and
- for all $\mathcal{L}$-concept descriptions E holds, if a is an instance of E, then $C \sim D \geq C \sim E$.

Intuitively, a mimic of C w.r.t. a is the most similar concept to C that has a as an instance. In general, the mimic of C w.r.t. an individual a may not be unique, even modulo concept equivalence, however, for our purposes it suffices to compute only one of them.

Figure 2 depicts the idea of mimics. In the figure, a and b are two different individuals. Since a is an instance of C, C is also a mimic of C w.r.t. a because $C \sim C = 1$. The dashed line depicts a mimic of C w.r.t. b. Notice that this mimic must contain b and thus subsume $\text{msc}(b)$, but need not be a subsumer of C, it just tries to resemble C in a way that results in maximal similarity.

There is an easy reduction from the computation of relaxed instances to the computation of mimics. The idea is that, for each individual a appearing in the knowledge base $\mathcal{K}$, the mimic of Q w.r.t. a must have a similarity greater than t to the query concept Q for a to be a relaxed instance of Q; if not, a cannot be a relaxed instance, as no concept can have a greater similarity to Q while containing a. This is formalized in the following proposition.

Proposition 9. *Let $\mathcal{K}$ be a knowledge base, a be an individual occurring in $\mathcal{K}$, Q be a concept description, $\sim$ be a*

CSM and $t \in [0,1]$. Then $a \in \text{Relax}_t^{\sim}(Q)$ iff there is a mimic $D \in \mathfrak{M}(Q,a)$ of Q w.r.t. individual a such that $Q \sim D > t$.

This connection allows to study the problem of computing mimics in order to find relaxed instances. In the next section, we will show how this can be solved for CSMs on unfoldable terminologies.

4 Computing Relaxed Instances w.r.t. Unfoldable $\mathcal{EL}$-Terminologies

Structural concept similarity measures with nice properties are often only defined for unfoldable TBoxes, as in (Lehmann and Turhan 2012) and (Suntisrivaraporn 2013). The reason is that in those terminologies, any concept can be expanded by exhaustively replacing all defined concept names by their definitions, until only atomic concept names remain; the concept is then called *fully expanded*. After expanding all concepts, the TBox can be completely disregarded for computing similarities or other inferences like subsumption. In this section, we show how to compute mimics, and therefore relaxed instances w.r.t. unfoldable $\mathcal{EL}$-terminologies.

In general there may exist infinitely many concept descriptions which have the individual a as an instance, and thus enumerating them and finding the maximal similarity to the query concept Q to compute the mimic is not a feasible option. However, under some circumstances we can limit the number of concepts that need to be tested.

Recall that any mimic $D \in \mathfrak{M}(Q,a)$ must have a as an instance, and thus, by definition of the msc, $\text{msc}(a) \sqsubseteq_{\mathcal{T}} D$ holds. For equivalence invariant similarity measures one can use the $\text{msc}(a)$ as a lower bound for the mimic, and only consider concept descriptions that can be obtained from syntactic manipulations of $\text{msc}(a)$ that result in a generalized concept, i.e., by removing some concept names or existential restrictions.

Definition 10 (generalized concept). Let C be a concept description of the form

$$C = \textstyle\bigsqcap_{i\in I} A_i \sqcap \bigsqcap_{j\in J} \exists r_j.E_j,$$

with $A_i \in N_C$ for all $i \in I$, and $r_j \in N_R$, E_j is a concept description for all $j \in J$. Then a concept description D is a *generalized concept* of C iff it has the form

$$D = \textstyle\bigsqcap_{i\in I'} A_i \sqcap \bigsqcap_{j\in J'} \exists r_j.E'_j$$

with $I' \subseteq I$, $J' \subseteq J$ and E'_j is a generalized concept of E_j for $j \in J'$.

Clearly, if D is a generalized concept of C, then we always have $C \sqsubseteq D$, since generalizing only removes parts of C, but never adds new features. Indeed, in our setting the other direction holds as well for unfoldable TBoxes $\mathcal{T}$: If $\text{msc}(a)$ is fully expanded w.r.t. $\mathcal{T}$, then any concept description D with $\text{msc}(a) \sqsubseteq D$ is equivalent to a generalized concept of $\text{msc}(a)$. If we now restrict to equivalence invariant CSMs, we get the following result for the mimic.

Lemma 11. *Let $\mathcal{K} = (\mathcal{T},\mathcal{A})$ be an unfoldable $\mathcal{EL}$-KB, a be an individual from $\mathcal{A}$, C be an $\mathcal{EL}$-concept, and $\sim$ be an equivalence invariant similarity measure. If $E = \text{msc}(a)$ is the fully expanded most specific concept of a, then there is a mimic $D \in \mathfrak{M}(C,a)$ of C w.r.t. a and $\mathcal{K}$ that is a generalized concept of E.*

Proof sketch. We show that any concept having a as an instance is equivalent to a generalized concept of $\text{msc}(a)$. Let F be a concept description with $\mathcal{K} \models F(a)$. Since $\sim$ is equivalence invariant, we can assume F to be fully expanded as well. $E \sqsubseteq_{\mathcal{K}} F$ holds by definition of the msc. As both E and F are fully expanded and thus do not contain defined concept names from the TBox, any subconcept of F must also be a subconcept E, but F may contain redundancies that can simply be removed to get an equivalent concept. Thus F is equivalent to a generalized concept of E. □

However, in general the msc may result in infinitely nested existential restrictions, and thus could only be described by concept descriptions of infinite size. In this case there are infinitely many generalized concepts of finite size that would need to be checked to find a mimic. Lemma 11 therefore does not always provide a solution to the problem. However, the query concept Q has always a finite role-depth, even if fully expanded. Since most structural similarity measures used in practice, like those presented in (Suntisrivaraporn 2013; Lehmann and Turhan 2012), compute the similarity recursively between sub-concepts at the same role-depth, it is possible to also limit the role-depth of the most specific concept and still get the same result:

Lemma 12. *Let $\mathcal{K} = (\mathcal{T},\mathcal{A})$ be an unfoldable $\mathcal{EL}$-KB, a be an individual from $\mathcal{A}$, Q be a fully expanded $\mathcal{EL}$-concept, and $\sim$ be a equivalence invariant similarity measure, which is additionally structural and depth-bounded, i.e.:*

$$C \sim D \geq C \sim E \Rightarrow \exists r.C \sim \exists r.D \geq \exists r.C \sim \exists r.E, \quad (1)$$

$$C \sim \textstyle\bigsqcap_{i\in I} A_i \;\geq\; C \sqcap \exists r.D \sim \bigsqcap_{i\in I} A_i, \quad (2)$$

for all fully expanded concepts C, D, and E, and atomic concept names A_i. If $k = \text{rd}(Q)$ and $E = k\text{-msc}(a)$ is the fully expanded most specific concept of a bounded to the role-depth k, then there is a mimic $D = \mathfrak{M}(Q,a)$ of Q w.r.t. a that is a generalized concept of E.

Proof sketch. Using the properties (1) and (2) above, we can show the following: Trimming the role-depth of two concepts C and D to the minimal role-depth $\min(\text{rd}(C),\text{rd}(D))$ never reduces the similarity value, i.e., the similarity value between the trimmed concepts must be greater than or equal to the similarity value of C and D.

Using this, we can prove the lemma as follows: Let M be any mimic of Q w.r.t. a. Since the mimic is always equivalent to a generalized concept M' of the (possibly infinite) $\text{msc}(a)$, and since $\sim$ is equivalence invariant, M' is also a mimic. Using the previous property, we know that M' trimmed to role-depth k must still have (at least) the same similarity to Q, and hence also be a mimic. But M' trimmed to role-depth k is also a generalized concept of the $k\text{-msc}(a)$. □

This shows that we can always find the mimic of Q w.r.t. a from a finite set of concept descriptions: the generalized

Procedure: relaxed-instance? $(a, Q, \mathcal{K}, \sim, t)$
Input: a: individual in $\mathcal{K}$; Q: $\mathcal{EL}$-concept; $\mathcal{K}$: unfoldable $\mathcal{EL}$-KB; $\sim$: CSM; $t \in (0, 1]$: threshold
Output: whether $a \in \text{Relax}_t^{\sim}(Q)$ w.r.t. $\mathcal{K}$

1: $k := \text{rd}(Q)$
2: $E := k\text{-msc}(a)$ w.r.t. $\mathcal{K}$
3: guess a generalized concept F of E
4: **return** $F \sim Q > t$

Figure 3: Non-deterministic algorithm for relaxed instances checking w.r.t. unfoldable $\mathcal{EL}$ terminologies.

concepts of the fully expanded k-msc(a). However, instead of computing the mimic $D \in \mathfrak{M}(Q, a)$ and testing whether the similarity between the Q and D is greater than t, it is enough to find *any* concept D' with a as an instance and $Q \sim D' > t$ to show that a is a relaxed instance of Q; this gives rise to the non-deterministic algorithm in Figure 3, that checks whether a is a relaxed instance of Q.

Corollary 13. *Let $\mathcal{K} = (\mathcal{T}, \mathcal{A})$ be an unfoldable $\mathcal{EL}$-KB, Q be a fully expanded $\mathcal{EL}$-concept, a be an individual in $\mathcal{K}$, $\sim$ be an equivalence invariant similarity measure fulfilling properties 1 and 2 from Lemma 12 and $t \in [0, 1]$. Then* relaxed-instance?$(a, Q, \mathcal{K}, \sim, t)$ *computes whether $a \in \text{Relax}_t^{\sim}(Q)$ w.r.t. $\mathcal{K}$.*

Guessing a generalized concept F of a concept description E can be done in time linear on the size $\|E\|$ of E by recursively guessing for each concept name and each existential restriction in E whether they should occur in F or not. However, the size of $E = k$-msc(a) can be exponential in k and polynomial in $\|\mathcal{K}\|$ (Peñaloza and Turhan 2011). Since $k = \text{rd}(C)$ is bounded linearly by $\|C\|$, the algorithm runs in NEXP-time (provided that $\sim$ can be computed in NEXP-time). However, the algorithm runs in NP-time in $\|\mathcal{K}\|$ (provided that $\sim$ can be computed in NP), and since C is an input concept, its role-depth can be assumed to be rather low. Hence, we conjecture that the exponential blow-up of the msc usually plays only a minor role in practical applications.

5 Relaxed Instances w.r.t. General $\mathcal{EL}$-TBoxes

The approach presented in the previous section does not work for general $\mathcal{EL}$-TBoxes since those structural similarity measures first fully expand the concepts w.r.t. the background knowledge. As soon as the background knowledge contains cyclic concept inclusions, this expansion is no longer possible. In fact, to the best of our knowledge no equivalence invariant, structural concept similarity measure that can handle general $\mathcal{EL}$-TBoxes has been introduced in the literature so far. In this section, we therefore define such a concept similarity measure $\sim_c$; this measure can then be used to find all relaxed instances for such TBoxes.

The approach to compute the similarity $C \sim_c D$ w.r.t. $\mathcal{T}$ is to translate the concepts C and D into their canonical models $\mathcal{I}_{C,\mathcal{T}}$ and $\mathcal{I}_{D,\mathcal{T}}$ and then structurally compute the similarities for the elements d_C and d_D in these interpretations. As observed before, $\mathcal{I}_{C,\mathcal{T}}$ and $\mathcal{I}_{D,\mathcal{T}}$ are always finite. The TBox $\mathcal{T}$ itself can be disregarded when computing the interpretation similarity from the canonical models, since all its axioms are already used to construct the models.

We need to define similarity measures on interpretations and their properties, which are derived from the properties of concept similarity measures. All proofs for this section can be found in the technical report (Ecke and Turhan 2013).

Interpretation Similarity Measures

An *interpretation similarity measure* (ISM) is defined as a similarity measure on pointed interpretations, i.e., a function $\sim_{\mathfrak{P}}: \mathfrak{P} \times \mathfrak{P} \to [0, 1]$ such that $p \sim_{\mathfrak{P}} p = 1$ for all $p \in \mathfrak{P}$. It maps any pair of pointed interpretations to a similarity value between 0 and 1.

There are various desirable properties that ISMs can have. We concentrate here on those that directly transfer from analogous properties of CSMs introduced by (Lehmann and Turhan 2012). Given suitable simulation relations $\lesssim$ and $\simeq$ (like e.g., those defined in Definition 1 for $\mathcal{EL}$), we call an interpretation similarity measure:

- *symmetric* iff $p \sim_{\mathfrak{P}} q = q \sim_{\mathfrak{P}} p$ for all $p, q \in \mathfrak{P}$;
- *bounded* iff $\mathfrak{C}(p) \cap \mathfrak{C}(q) \supsetneq \{\top\}$ implies $p \sim_{\mathfrak{P}} q > 0$ for all $p, q \in \mathfrak{P}$;
- *dissimilar closed* iff $\mathfrak{C}(p) \cap \mathfrak{C}(q) = \{\top\}$ implies $p \sim_{\mathfrak{P}} q = 0$ for all $p, q \in \mathfrak{P}$ with $\mathfrak{C}(p) \supsetneq \{\top\}$ and $\mathfrak{C}(q) \supsetneq \{\top\}$;
- *equisimulation invariant* iff for all $p, q, u \in \mathfrak{P}$, $p \simeq q$ implies $p \sim_{\mathfrak{P}} u = q \sim_{\mathfrak{P}} u$;
- *equisimulation closed* iff $p \simeq q \iff p \sim_{\mathfrak{P}} q = 1$ for all $p, q \in \mathfrak{P}$;
- *simulation preserving* iff for all $p, q, r \in \mathfrak{P}$, $r \lesssim q \lesssim p$ implies $p \sim_{\mathfrak{P}} q \geq p \sim_{\mathfrak{P}} r$;
- *reverse simulation preserving* iff $r \lesssim q \lesssim p$ implies $q \sim_{\mathfrak{P}} r \geq p \sim_{\mathfrak{P}} r$ for all $p, q, r \in \mathfrak{P}$.

We now define a parameterizable ISM $\sim_i$, using the simulation relations defined in Definition 1, which correspond to subsumption and equivalence in $\mathcal{EL}$. This is important when lifting those properties to the CSMs $\sim_c$. Given a pointed interpretation $p = (\mathcal{I}, d)$, we denote with

- $\text{CN}(p) = \{A \in N_C \mid d \in A^{\mathcal{I}}\}$ the set of concept names that have d as instance in $\mathcal{I}$, and
- $\text{SC}(p) = \{(r, (\mathcal{I}, e)) \in N_R \times \mathfrak{P} \mid (d, e) \in r^{\mathcal{I}}\}$ the set of direct successors of d in $\mathcal{I}$.

For two pointed interpretations to be perfectly similar, they need to have the same set of concept names and edges labeled with the same roles going to perfectly similar successor elements. Otherwise, the most similar concept names and the most similar direct successors are compared and a similarity value is computed from this pair. For both cases, we need the notion of pairings:

A *pairing* $P \subseteq X \times Y$ is a total binary relation, where totality means that all elements of X and all elements of Y appear in some tuple of P as the first component or second

component, respectively. For two pointed interpretations p and q, we are interested in two types of pairings:

- $P_C(p,q) \subseteq \mathcal{P}(\text{CN}(p) \times \text{CN}(q))$ is the set of all *concept name pairing* on the concept names that p and q are instances of; and
- $P_S(p,q) \subseteq \mathcal{P}(\text{SC}(p) \times \text{SC}(q))$ is the set of all *successor pairings* on the direct successors of p and q.

Note that when one of $\text{CN}(p)$ or $\text{CN}(q)$ is empty, the pairings can not be total. In this case, we use $\{\top\}$ instead of the empty concept name set. Similarly, when one of $\text{SC}(p)$ or $\text{SC}(q)$ is empty, we instead use the set $\{(r_\top, p)\}$ or $\{(r_\top, q)\}$, respectively, where $r_\top \in N_R$ is a new role name. This way, the pairings are always well-defined.

The ISM $\sim_i$ will extend a primitive measure. A *primitive measure* $\sim_{\text{prim}} : N_C \cup \{\top\} \times N_C \cup \{\top\} \cup N_R \times N_R \to [0,1]$ assigns similarity values to each pair of basic concepts (i.e., concept names or $\top$) and each pair of role names. Any primitive measure has to satisfy the following properties: $x \sim_{\text{prim}} x = 1$ for any role name or basic concept x, $\top \sim_{\text{prim}} A = A \sim_{\text{prim}} \top = 0$ for all $A \in N_C$, and similarly $r_\top \sim_{\text{prim}} s = s \sim_{\text{prim}} r_\top = 0$ for all $s \in N_R \setminus \{r_\top\}$. Additionally, for the similarity measure $\sim_i$ to be symmetric, $\sim_{\text{prim}}$ needs to be symmetric as well.

We give a default primitive measure, that simply assigns similarity 0 to pairs of different basic concepts or role names:

$$x \sim_{\text{default}} y = \begin{cases} 1 & \text{if } x = y \\ 0 & \text{otherwise} \end{cases}$$

However, other primitive measures are imaginable and useful. For example, one might want to express that two colours Red and Orange are similar to *some* degree even if they have different concept names. Additionally, one can assign weights to different concept and role names through a weighting function $g : N_C \cup N_R \to \mathbb{R}_{>0}$ that prioritizes different features of the similarity measure. This function g can be extended to pairs of concept names as $g(A,B) = \max(g(A), g(B))$ and pairs of role names as $g(r,s) = \max(g(r), g(s))$.

Any primitive measure $\sim_{\text{prim}}$ and weighting function g can then be extended to a similarity measure on pointed interpretations by recursively traversing the interpretation graphs, computing the primitive measure for each pair of concepts in the best concept name pairing and combining it with the discounted similarity between all pairs of successors in the best successor pairing at each element.

Definition 14. Given a primitive measure $\sim_{\text{prim}}$, a weighting function g, and a discounting factor $w \in (0,1)$, the ISM $\sim_i$: $\mathfrak{P} \times \mathfrak{P} \to [0,1]$ is defined as follows:

$$p \sim_i q = \max_{\substack{P_C \in P_C(p,q) \\ P_S \in P_S(p,q)}} \left(\frac{\text{sim}(P_C) + \text{sim}(P_S)}{\sum_{(A,B)\in P_C} g(A,B) + \sum_{((r,p'),(s,q'))\in P_S} g(r,s)} \right)$$

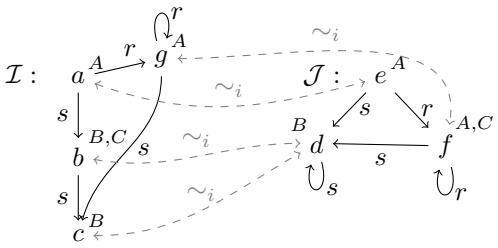

Figure 4: Computation of $(\mathcal{I}, a) \sim_i (\mathcal{J}, e)$ by pairing their successors and recursively computing $\sim_i$ between those.

where

$$\text{sim}(P_C) = \sum_{(A,B)\in P_C} g(A,B)(A \sim_{\text{prim}} B), \text{ and}$$

$$\text{sim}(P_S) = \sum_{\substack{((r,p'),(s,q'))\\ \in P_S}} g(r,s)(r \sim_{\text{prim}} s)((1-w) + w(p' \sim_i q')).$$

The constant w allows for discounting of successors, and should have a value $0 < w < 1$.

Example 15. Consider the pointed interpretations $(\mathcal{I}, a)$ and $(\mathcal{J}, e)$ depicted in Figure 4, the default primitive measure, a weighting function g that assigns 1 to all concept and role names, and a discounting factor $w = 0.8$. To compute the similarity $(\mathcal{I}, a) \sim_i (\mathcal{J}, e)$, we proceed as follows.

1. To compute the similarity between c and d, we find the only concept name pairing is $\{(B,B)\}$ and the only successor pairing is $\{((r_\top, c), (s,d))\}$. Thus we have that $(\mathcal{I}, a) \sim_i (\mathcal{J}, b)$ is $\frac{B \sim_{\text{default}} B + (r_\top \sim_{\text{default}} s) \cdot \dots}{2} = 0.5$.
2. The similarity between b and d, for the best concept name pairing $\{(B,B),(C,B)\}$ and the best successor pairing $\{((s,c),(s,d))\}$, is $\frac{1+0+(0.2+0.8\cdot 0.5)}{3} = 0.533$.
3. The similarity between g and f, for the best concept name pairing $\{(A,A),(A,C)\}$ and the best successor pairing $\{((s,c),(s,d)),((r,g),(r,f))\}$, is the solution to the equation $x = \frac{1+0+(0.2+0.8\cdot 0.5)+(0.2+0.8\cdot x)}{4}$, which is $x = 0.563$.
4. Finally, the similarity between a and e, for the best concept name pairing $\{(A,A)\}$ and the best successor pairing $\{((s,b),(s,d)),((r,g),(r,f))\}$, is $\frac{1+(0.2+0.8\cdot 0.533)+(0.2+0.8\cdot 0.563)}{3} = 0.759$.

If role s is very important for the similarity, one can adapt the similarity measure by increase the weight $g(s)$. Similarly, if concept name A is less important than the other concept names, since it only describes a broad category, one can decrease its weight. One can also change the primitive measure to evaluate $r \sim_{\text{prim}} s = 0.5$ if roles r and s actually denote similar relations, even though they use different role names. In general, this might imply that different best pairings will be found. Finally, if one wants to put more emphasize on the similarity of the role names itself and less on the similarity of the actual elements of the successors, one can do so by reducing the discounting factor. These three degrees of freedom allow for the adaptation of $\sim_i$ to many different use cases.

Note that by defining the ISM $\sim_i$ this way, it is not equisimulation closed. The reason is that the successor pairing always connects successors symmetrically, which gives rise to problems for the case where one successor of an element simulates a second successor. To regain equivalence invariance, one can first normalize the interpretations $\mathcal{I}$ and $\mathcal{J}$ before applying the similarity measure.

Definition 16 (normal form for interpretations). An interpretation $\mathcal{I} = (\Delta^{\mathcal{I}}, \cdot^{\mathcal{I}})$ is in *normal form* if there are no elements $a, b, c \in \Delta^{\mathcal{I}}$ with $\{(a,b),(a,c)\} \in r^{\mathcal{I}}$ and $(\mathcal{I}, b) \lesssim (\mathcal{I}, c)$, i.e., no node has two successor nodes for the same role name that are in a simulation relation.

Any interpretation $\mathcal{I}$ can be transformed into normal form as follows:

1. remove all edges $(a,b) \in r^{\mathcal{I}}$ in the interpretation graph, for which there exists an edge $(a,c) \in r^{\mathcal{I}}$ such that $(\mathcal{I}, b) \lesssim (\mathcal{I}, c)$ but not $(\mathcal{I}, b) \simeq (\mathcal{I}, c)$
2. for all edges $(a, b_0) \in r^{\mathcal{I}}$, check if there are other edges $(a, b_i) \in r^{\mathcal{I}}$, $i > 0$, with $(\mathcal{I}, b_0) \simeq (\mathcal{I}, b_i)$ and choose one representative b_j; then remove all other edges (a, b_i), $i \neq j$, from $r^{\mathcal{I}}$.

Note that this normalization is well-defined, since the pointed interpretations are always finite, and simulations can be computed in polynomial time in the size of the interpretation. In the following, whenever we write $(\mathcal{I}, a) \sim_i (\mathcal{J}, b)$, we implicitly assume that $\mathcal{I}$ and $\mathcal{J}$ have been normalized first. Using this, we can finally show that $\sim_i$ is a well-defined ISM with formal properties:

Theorem 17. *The similarity measure $\sim_i$ is well-defined, i.e., $p \sim_i q$ has a unique solution for all pointed interpretations $p, q \in \mathfrak{P}$. Furthermore $\sim_i$ is symmetric, bounded, dissimilar closed, equisimulation invariant, and equisimulation closed for the simulation relations defined in Definition 1 and normalized pointed interpretations.*

Although $\sim_i$ as given in Definition 14 is well-defined, it cannot be used directly to compute the similarity value, since cycles in the interpretation would lead to infinite recursion. Instead, one can view the defining equation as an iterative algorithm: When starting with a similarity value of 0 between all elements of two interpretations $\mathcal{I}$ and $\mathcal{J}$, and iteratively applying the equation to update those similarity values, they will converge to the solution in the limit. This follows from the Banach fixed-point theorem (Banach 1922), as $\sim_i$ can be seen as a contraction mapping on the similarity values between all elements of $\mathcal{I}$ and $\mathcal{J}$.

Using this canonical model, we define a concept similarity measure $\sim_c$ on $\mathcal{EL}$-concept descriptions w.r.t. a general $\mathcal{EL}$-TBox $\mathcal{T}$ as follows:

$$C \sim_c D = (\mathcal{I}'_{C,\mathcal{T}}, d_C) \sim_i (\mathcal{I}'_{D,\mathcal{T}}, d_D),$$

where $\mathcal{I}'_{C,T}$ and $\mathcal{I}'_{D,\mathcal{T}}$ are the normalized canonical models of C and D w.r.t. $\mathcal{T}$.

The concept similarity measure $\sim_c$ inherits the useful properties of $\sim_i$, since the properties for interpretation similarity measures were defined to correspond exactly to the concept similarity properties given in the preliminaries.

Theorem 18 (Properties of $\sim_c$). *The concept similarity measure $\sim_c$ is symmetric, bounded, dissimilar closed, equivalence invariant, and equivalence closed.*

The proof for this theorem is given in (Ecke and Turhan 2013).

Computing Relaxed Instances w.r.t. $\sim_c$

First we define the notion of *fully expanded concepts* also for the general $\mathcal{EL}$ case:

Definition 19 (fully expanded concept). Let $\mathcal{T}$ be a general $\mathcal{EL}$-TBox. A concept description C is *fully expanded* w.r.t. $\mathcal{T}$ iff for all GCIs $D \sqsubseteq E \in \mathcal{T}$ with $C \sqsubseteq_{\mathcal{T}} \exists r_1 \ldots \exists r_n.D$ we have that $\exists r_1 \ldots \exists r_n.E$ is a generalized concept of C.

For the computation of relaxed instances for $\sim_c$, recall that $a \in Relax_t^{\sim}(Q)$ can be computed for unfoldable terminologies by checking all generalized concepts of the k-msc(a) for $k = \text{rd}(Q)$. Of course, as soon as we have a general TBox, expanding Q may result in an infinite role-depth by expanding cyclic definitions, so this approach does not work directly here. However, given a KB $\mathcal{K} = (\mathcal{T}, \mathcal{A})$, one can express the fully expanded msc(a) in $\mathcal{EL}$ by unraveling the canonical model $\mathcal{I}_{\mathcal{K}}$ starting from d_a, and thus for any concept C we have

$$C \sim_c \text{msc}(a) = (\mathcal{I}_{C,\mathcal{T}}{}', d_C) \sim_i (\mathcal{I}_{\mathcal{K}}{}', d_a),$$

where $\mathcal{I}_{C,\mathcal{T}}{}'$ and $\mathcal{I}_{\mathcal{K}}{}'$ are the normalized canonical models of C and $\mathcal{A}$ w.r.t. the TBox $\mathcal{T}$. The canonical model $\mathcal{I}_{\mathcal{K}}$, in contrast to the fully expanded msc, is always finite.

However, we do not need to compute the similarity between the query concept Q and the msc(a) directly, but find the maximal similarity between Q and generalized concepts of msc(a). Generalizing a concept C is possible by removing concept names or existential restriction, which corresponds on the interpretation side to only taking subsets of the concept names $S_{\text{CN}} \subseteq \text{CN}(q)$ and successors $S_{\text{SC}} \subseteq \text{SC}(q)$ of the pointed interpretations $q = (\mathcal{I}_{C,\mathcal{T}}, d_C)$ and all its successors. This gives the algorithm in Figure 5 to iteratively compute the maximal similarity between a pointed interpretation p and all generalizations of the pointed interpretation q.

Using this, the algorithm to actually compute all relaxed instances of a query concept Q w.r.t. $\sim_c$ is conceptually quite easy, as it only needs to compute the maximal similarities between Q and all individuals a and check whether they are larger than t. The algorithm is depicted in Figure 6.

Example 20. Consider the the KB $\mathcal{K} = (\mathcal{T}, \mathcal{A})$ consisting of the following TBox $\mathcal{T}$ and knowledge base $\mathcal{A}$:

$$\begin{aligned}\mathcal{T} &= \{\, A \sqsubseteq \exists r.A \sqcap \exists s.B,\ \ C \sqsubseteq \exists s.B \,\},\\ \mathcal{A} &= \{\, A(e),\ \ A \sqcap C(f),\ \ B(d),\\ &\qquad r(e,f),\ \ r(f,f),\ \ s(f,d),\\ &\qquad s(e,d),\ \ s(d,d) \,\}.\end{aligned}$$

The similarity measure used is the same as in Example 15, with the default weighting function, the discounting factor $w = 0.8$ and the default primitive measure. Given the query concept $Q = A \sqcap \exists s.(B \sqcap C)$, the normalized canonical

Procedure: maxsim $(\mathcal{I}, \mathcal{J}, \sim_{\text{prim}}, g, w)$
Input: $\mathcal{I}, \mathcal{J}$: finite interpretations; $\sim_{\text{prim}}$: primitive measure; g: weighting function; $w \in (0,1)$: discount factor
Output: maximal similarities between $p = (\mathcal{I}, a)$ and all generalizations of $q = (\mathcal{J}, b)$

1: $\text{msim}_0(d, e) \leftarrow 0$ for all $d \in \Delta^{\mathcal{I}}$ and $e \in \Delta^{\mathcal{J}}$
2: **for** $i \leftarrow 1$ **to** n **do**
3: **for all** $d \in \Delta^{\mathcal{I}}$ and $e \in \Delta^{\mathcal{J}}$ **do**
4: $\text{msim}_i(d, e) \leftarrow \max_{\substack{S_{\text{CN}} \subseteq \text{CN}(e) \\ S_{\text{SC}} \subseteq \text{SC}(e)}} \Big(\max_{\substack{P_C \subseteq \text{CN}(d) \times S_{\text{CN}} \\ P_S \subseteq \text{SC}(d) \times S_{\text{SC}}}} \text{similarity}(P_C, P_S, \sim_{\text{prim}}, g, w, i) \Big)$
5: **end for**
6: **end for**

Procedure: similarity $(P_C, P_S, \sim_{\text{prim}}, g, w, i)$

1: $\text{sim}(P_C) \leftarrow \sum_{(A,B) \in P_C} g(A, B)(A \sim_{\text{prim}} B)$
2: $\text{sim}(P_S) \leftarrow \sum_{((r,p'),(s,q')) \in P_S} g(r, s)(r \sim_{\text{prim}} s)\big((1-w) + w \cdot \text{msim}_{i-1}(p', q)\big)$
3: **return** $\dfrac{\text{sim}(P_C) + \text{sim}(P_S)}{\sum_{(A,B) \in P_C} g(A, B) + \sum_{((r,p'),(s,q')) \in P_S} g(r, s)}$

Figure 5: Algorithm to compute the maximal similarities between all elements of two finite interpretations $\mathcal{I}$ and $\mathcal{J}$.

models $\mathcal{I}'_{Q,\mathcal{T}}$ and $\mathcal{I}'_{\mathcal{K}}$ are exactly the interpretations $\mathcal{I}$ and $\mathcal{J}$ found in Example 15, with $d_Q = a$. The algorithm maxsim will compute the following similarity values msim_i between d_Q and d, e, f in each iteration i:

i	$\text{msim}_i(d_Q, d)$	$\text{msim}_i(d_Q, e)$	$\text{msim}_i(d_Q, f)$
0	0	0	0
1	0.067	0.467	0.35
2	0.173	0.667	0.5
3	0.209	0.748	0.561
4	0.209	0.757	0.567
5	0.209	0.758	0.569

Since the both canonical models are cyclic, the similarity values will change slightly in further iterations, but already after the 5th, the maximal error is less than 0.05%. Using these values, we see that for the threshold $t = 0.5$, both e and f are relaxed instance of Q, while d is not.

The maxsim_i values computed in the algorithm monotonically converge from below to the maximal similarities between generalized concepts of the most specific concept of an individual and the query concept. Thus, for any individual a, which is a relaxed instance of Q with a threshold strictly larger than t, there exists $i \in \mathbb{N}$ such that for all $j > i$ we have $\text{maxsim}_j(Q, a) > t$. Thus, the algorithm is sound and complete in the following sense:

Theorem 21. *Let $\sim_c$ be the CSM derived from $\sim_i$ with the primitive measure $\sim_{\text{prim}}$, the weighting function g and the discounting factor w. Then the algorithm* relaxed-instances *is sound and complete:*

1. Soundness*: If $a \in$ relaxed-instances$(Q, \mathcal{K}, t, \sim_{\text{prim}}, g, w)$ for a number n of iterations, then $a \in Relax_t^{\sim_c}(Q)$.*
2. Completeness*: If $a \in Relax_t^{\sim_c}(Q)$, then there exists an $i \in \mathbb{N}$ such that for all $n \geq i$ iterations it holds that $a \in$ relaxed-instances$(Q, \mathcal{K}, t, \sim_{\text{prim}}, g, w)$.*

Furthermore, the algorithm converges quite fast: For any iteration, the difference between the actual similarity and the computed value reduces by a factor of w. This is again a direct consequence of the Banach fixed-point theorem, as w is an upper bound for the Lipschitz constant of the contraction mapping. This means that, to reduce the error tolerance of the solutions by a constant factor, e.g. one tenth, only a constant number of iterations need to be done additionally. However, one cannot compute how many iterations are needed beforehand and cannot be sure if, at any given point, the algorithm already found all relaxed instances, or if some relaxed instances with a maximal similarity very close to the threshold t are still missing.

If applying the algorithm relaxed-instances w.r.t. unfoldable TBoxes $\mathcal{T}$, then maxsim will however return the exact answer after exactly k iterations, where $k = \text{rd}(Q) + 1$ is the role-depth of the query concept Q expanded w.r.t. $\mathcal{T}$. In this case, the algorithm can be made deterministic and, since each iteration of maxsim only takes polynomial time in the size of $\mathcal{K}$ and Q, runs in PTIME.

Procedure: relaxed-instances $(Q, \mathcal{K}, t, \sim_{\text{prim}}, g, w)$
Input: Q: $\mathcal{EL}$-concept; $\mathcal{K} = (\mathcal{T}, \mathcal{A})$: $\mathcal{EL}$-KB; $t \in [0,1]$: threshold; $\sim_{\text{prim}}$: primitive measure; g: weighting function; $w \in (0,1)$: discounting factor
Output: individuals $a \in Relax_t^{\sim_c}(Q)$

1: compute canonical models $\mathcal{I}_{Q,\mathcal{T}}$ and $\mathcal{I}_{\mathcal{K}}$
2: $\text{maxsim}(d, e) \leftarrow \text{maxsim}(\mathcal{I}_{Q,\mathcal{T}}, \mathcal{I}_{\mathcal{K}}, \sim_{\text{prim}}, g, w)$
3: **return** $\{a \in N_I \cap \text{Sig}(\mathcal{A}) \mid \text{maxsim}(d_Q, d_a) > t\}$

Figure 6: Algorithm to compute all relaxed instances of a query concept Q w.r.t. a knowledge base $\mathcal{K}$ and threshold t.

6 Conclusions

We have proposed a new reasoning service that allows relaxed instance query answering for application-specific notions of similarity by the appropriate choice of a CSM. The inference has two main degrees of freedom: in the choice of the CSM, and in the degree of relaxation of the concept. Intuitively, different similarity measures yield different weights on specific criteria. For example, one could require that small changes inside existential restrictions produce a high level of dissimilarity.

Further we investigated necessary requirements for the CSMs to be employed. We devised computation algorithms for relaxed instances in the setting with unfoldable and with general TBoxes. For the latter setting we needed to introduce a new family of CSMs that take the whole information from

general TBoxes into account. The $\sim_c$ CSMs are, to the best of our knowledge, the first CSMs for general TBoxes. Based on these we gave an computation algorithm for relaxed instances w.r.t. general TBoxes.

There are many options for future work. On the theoretical side it would be interesting to explore how this approach can be extended to expressive DLs. We conjecture that our approach extends to Horn-DLs, since they induce canonical models as well. On the practical side there is plenty of room for optimizations. For instance, the use of a concept that states necessary conditions in combination with the query concept can considerably reduce the number of individuals to be checked in practice. Furthermore, while the complexity of each iteration in the general case is polynomial, the need to check every subset and every pairing is certainly inefficient. Methods to reduce the subsets and pairings that need to be considered are expedient to make this work in practice.

Abstract

We tackle a long-standing open research problem and prove the decidability of query answering under the stable model semantics for guarded existential rules, where rule bodies may contain negated atoms, and provide complexity results. The results extend to guarded Datalog$^{\pm}$ with negation, and thus provide a natural and decidable stable model semantics to description logics such as $\mathcal{ELHI}$ and *DL-Lite*$_{\mathcal{R}}$.

1 Introduction

1.1 Existential Rules, Datalog$^{\pm}$, and DLs

Existential rules have attracted much recent interest for knowledge representation and reasoning (see (Calì et al. 2010) for an overview). An example for an existential rule is

$$\textit{EmpProj(x,y), BaseLevel(x)} \rightarrow \exists z\ \textit{IsManagedBy(x,z)}, \quad (1)$$

which states that every base-level employee working in a project must be managed by somebody. Such rules are also well-known as *tuple-generating dependencies (TGDs)*, see (Beeri and Vardi 1984). In the Datalog$^{\pm}$ languages (Calì, Gottlob, and Kifer 2013; Calì, Gottlob, and Lukasiewicz 2012), TGDs are complemented by a few other types of rules, notably by *negative constraints (NCs)*, such as *Ceo(x), BaseLevel(x)* $\rightarrow \bot$, where $\bot$ stands for *false*.[1]

Query answering based on rule sets is the following decision problem: For a database D, a set of rules Σ, and a Boolean query Q, decide whether $D \cup \Sigma \models Q$. The queries considered in this paper are unions of Boolean conjunctive queries (UBCQs). Query answering with TGDs is undecidable (Beeri and Vardi 1981), even in the case of fixed sets Σ of TGDs (Calì, Gottlob, and Kifer 2013) and singleton sets of TGDs (Baget, Leclère, and Mugnier 2010). Therefore, to obtain decidability, restrictions need to be imposed on TGDs. Semantic conditions that lead to decidability were described in (Baget, Leclère, and Mugnier 2010; Baget et al. 2009; 2011; Thomazo 2011; Calì, Gottlob, and Pieris 2012; Gottlob, Manna, and Pieris 2013). Related syntactic conditions led to the Datalog$^{\pm}$ family (Calì, Gottlob, and Lukasiewicz 2012). A class of major relevance are *guarded* TGDs (GTGDs). A TGD is guarded if its body contains an atom, called *guard*, that covers all body variables. NCs may be safely used together with guarded TGDs; their bodies are not required to contain a guard atom.

A nice and important aspect of guarded rules is that they generalize well-known description logics (DLs). All the DLs of the *DL-Lite* family in (Calvanese et al. 2007; Poggi et al. 2008) and the DL $\mathcal{ELHI}$ (Baader, Brandt, and Lutz 2005) can be embedded into guarded Datalog$^{\pm}$ (Calì, Gottlob, and Lukasiewicz 2012). In particular, this holds for *DL-Lite*$_{\mathcal{R}}$, the theoretical basis of the QL profile of the Web ontology language OWL 2. To appreciate how easily DL axioms can be transformed into Datalog$^{\pm}$, note that rule (1) can be written as $\exists\text{EmpProj} \sqcap \text{BaseLevel} \sqsubseteq \exists\text{IsManagedBy}$.

1.2 The Main Problem: Stable Negation

The main goal of this paper is to add non-monotonic negation under the *stable model semantics (SMS)* (Gelfond and Lifschitz 1988) (see also (Subrahmanian 1999; Dantsin et al. 2001) for an overview of the semantic and computational properties of the SMS) to guarded rules (possibly with NCs) where body atoms may be negated. This is considered a hot open research problem, and has, to our knowledge, not been solved previously. Rules that may contain negated atoms of the form $notR(\mathbf{x})$ in their bodies, are called *normal TGDs (NTGDs)*. Guarded such rules are *guarded NTGDs* (*GNTGDs*). The standard way of defining the SMS for them is inherited from the well-known stable model semantics of normal logic programming with function symbols (Gelfond and Lifschitz 1988). In fact, we can replace existentially quantified variables in program heads by Skolem terms.

Example 1 Let $D_a = \{Person(mary)\}$ be a database and let Σ_a be the following rule set expressing that each person has at least one parent, and that each person belongs to either an odd generation or to an even generation, and that odd and even alternate between one generation and the next.

$$\begin{aligned} \textit{Person(x)} &\rightarrow \exists y\ \textit{Parent(x,y)}, \\ \textit{Parent(x,y)} &\rightarrow \textit{Person(y)}, \\ \textit{Person(x), not Even(x)} &\rightarrow \textit{Odd(x)}, \\ \textit{Person(x), not Odd(x)} &\rightarrow \textit{Even(x)}, \end{aligned}$$

Copyright © 2014, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

[1]Often also *equality-generating dependencies (EGDs)* are used, which may express key constraints (keys) or functional dependencies. Here, we do not consider EGDs. But, as will be explained in the full paper, all results of this paper carry over to the case where rule sets are complemented with a restricted class of EGDs, called *non-conflicting EGDs* (Calì, Gottlob, and Lukasiewicz 2012).

$$\textit{Parent(x,y),Odd(x)} \rightarrow \textit{Even(y)},$$
$$\textit{Parent(x,y), Even(x)} \rightarrow \textit{Odd(y)}.$$

After skolemization, the first rule becomes:

$$\textit{Person(x)} \rightarrow \textit{Parent(x,f(x))},$$

where f is a Skolem function. This program has exactly two stable models, each consisting of an infinite chain rooted in the constant *mary*, one containing (among others) the facts *Odd(mary), Even(f(mary)), Odd(f(f(mary)))*, and so on, the other containing the fact *Even(mary), Odd(f(mary)), Even(f(f(mary)))*. Let Q_a be the conjunctive query $\exists x, y, z$ *(Parent(x,y), Parent(y,z), Odd(x), Odd(z))*, and let Q'_a be the query $\exists x, y$ *(Parent(x,y), Odd(x), Odd(y))*. Then, under the SMS, $(D_a \cup \Sigma_a) \models Q_a$ but $(D_a \cup \Sigma_a) \not\models Q'_a$. ∎

Note that further examples are given in Section 7. It is easy to exhibit rule sets Σ that generate infinitely many infinite stable models, as illustrated by the following example.

Example 2 Let $D_b = D_a = \{Person(mary)\}$, and let Σ_b be obtained by taking just the first four rules of the rule set Σ_a of Example 1. Then, there is an uncountably infinite number of stable models of $D_b \cup \Sigma_b$, one for each possibility of having for each Skolem term $f^i(mary)$ either *Even(f^i(mary))* or *Odd(f^i(mary))*, where $1 \leqslant i \leqslant \infty$. For the query Q_a of Example 1, note that $(D_b \cup \Sigma_b) \not\models Q_a$. ∎

It seems that the interplay of nonmonotonic negation with these two types of infinity made it hard to understand how the SMS for GNTGDs could be brought under control. The main questions that we pose and tackle are thus: Is query answering under the stable model semantics for GNTGDs decidable? If so, what is the complexity of this problem and what kind of algorithms are appropriate for it?

1.3 Results

An insightful initial observation while addressing the above decidability problem was that if a guarded rule set with negated atoms admits a stable model, then it admits a tree-shaped one. In fact, each such stable model is a model of some Gelfond-Lifschitz transform of the ground version *ground*(Σ) of the original rule set. For the latter (which are guarded positive existential rule sets), we know that there are universal tree-shaped models (Calì, Gottlob, and Kifer 2013) that arise via the well-known chase procedure (Maier, Mendelzon, and Sagiv 1979; Beeri and Vardi 1984). We could thus encode query answering under the SMS for existential Datalog$^{\pm}$ in monadic second-order logic (MSO), making stable models correspond to binary trees. Decidability of this problem then follows from Rabin's Theorem (1969), by which satisfiability of MSO is decidable over the class of binary trees. This is very briefly described in Section 3.3 and fully proven in the extended paper (Gottlob et al. 2014). Related ideas for deciding other guarded logics or DLs via MSO can be found in (Eiter and Simkus 2010) and in (Motik, Horrocks, and Sattler 2009). We thus have shown:

Theorem. There is an algorithm that, given a database D, a finite set Σ of GNTGDs, and a BCQ Q, decides whether Q is true in all stable models for D and Σ.

Unfortunately, the MSO formula constructed for proving the above result does not give us a tight complexity upper bound for query evaluation with GNTGDs. To arrive at a matching bound, we pursued the following different ideas. Recall that finding a stable model essentially involves first guessing a model and then checking that this model is indeed the least fixpoint of the Gelfond-Lifschitz transform Σ^M of the original rule set Σ relative to the guessed model M. Given that query answering under the classical first-order (FO) semantics for guarded disjunctive TGDs (GDTGDs) has been recently defined and studied (Alviano et al. 2012; Gottlob et al. 2012b; Bourhis, Morak, and Pieris 2013), why not simulating the stable model semantics of GNTGDs by GDTGDs under the FO semantics? For the guessing phase, this turned out to be possible, as guessing the truth or falsehood of an atom can be encoded as a classical disjunction. But the checking phase requires computing the complement of Σ^M. This is an inherently nonmonotonic task not feasible in FO. But only one level of nonmotonic inference is needed. It would thus be sufficient to extend DGTDs under FO semantics by *stratified negation*, yielding the formalism of stratified sets of guarded disjunctive normal TGDs (GDNTGDs). In this setting, atom entailment within each stratum is the classical monotonic FO-entailment, but each stratum may access the lower strata nonmonotonically via the *not* operator, i.e., for each atom $\mathbf{a}$ of the Herbrand base, each stratum may assume that *not* $\mathbf{a}$ is true if the predicate of $\mathbf{a}$ belongs to a lower stratum, but $\mathbf{a}$ cannot be derived there.

We thus aimed at proving the decidability and determining the complexity of query answering with stratified GDNTGDs. This turned out to be much harder a challenge than the same problem for GTGDs (Calì, Gottlob, and Lukasiewicz 2012) or stratified GNTGDs. With GTGDs (or stratified GNTGDs), there is only a single, possibly infinite canonical model, and each query UBCQ Q is true in this model iff it is true in a finite part of this model. This finite part consists, for each stratum, of the atoms generated by the chase in that stratum that do not exceed a certain derivation depth. Unfortunately, this is no longer true for models generated by GDTGDs, and thus for stratified GDNTGDs. For a fixed rule set Σ and a fixed query Q, and any arbitrary positive integer d, in general, there may exist "tardive" models M such that $M \models Q$ but $M_d \not\models Q$, where M_d contains all atoms of M whose chase derivation depth is at most d. Not too surprisingly, tardive models may also arise with rules sets Σ of original formalism, namely, GNTGDs under the SMS. To illustrate this, consider the setting of Example 2, and let Q be the query $\exists x$*Even(x)*. Let d be an arbitrary positive integer. There are stable models M such that, for all $1 \leqslant i \leqslant d$, *Odd*$(f^i(mary))$ and *Even*(f^{d+1}). For such models M, it does not suffice to consider the initial part M_d containing all facts of M of chase derivation depth $\leqslant d$, for Q would be false in this initial part, while true in M.

Fortunately, we can cope with tardive models for a query Q due to the following observation. Whenever for a stratified GDNTGD set Σ and a query Q, a tardive model exists in which the query is not answered within a certain (doubly exponential) derivation depth, then there must exist *another model* in which Q is generally false, and thus Q must be

overall answered *false*, because Q is false in some model. It is thus still possible to reconduct query answering to a finitary setting. This insight led us to develop alternating algorithms for query answering under stratified sets of GDNTDGs, which give rise to the following results, where $\models_{\mathsf{strat}}$ is entailment under the described stratified semantics:

Theorem. Let $\mathcal{R}$ be a relational schema, D a database for $\mathcal{R}$, Σ a stratified set of GDNTGDs on $\mathcal{R}$, and Q a union of CQs over $\mathcal{R}$. Deciding $D \cup \Sigma \models_{\mathsf{strat}} Q$ has the following complexity:

1. 2-EXPTIME-complete in general;
2. EXPTIME-complete in case the maximum arity w of the relation symbols in $\mathcal{R}$ is fixed;
3. coNP-complete in case $|\mathcal{R}|$, w, and the number of atoms in Q are fixed.

In Section 6, we present the desired polynomial-time translation from GNTGDs under the SMS to GDNTGDs under FO semantics with stratified negation. This solves the main problem attacked in this paper. From this translation, and from easily obtained lower bounds, for query-answering for GNTGDs, we get exactly the same complexity bounds as those in the above theorem. This solves our main complexity problem. Moreover, all the above decidability and complexity results also hold in case negative constraints are added to the rule sets. (This is trivial: To simulate NCs, it suffices to add the body of each NC as a disjunct to the UCQ.)

In Section 7, we finally apply our results to DLs. We immediately obtain a stable model semantics for these DLs, as well as decidability results and complexity upper bounds. In particular, this provides a stable model semantics for the well-known DLs $\mathcal{ELHI}$ and *DL-Lite*$_{\mathcal{R}}$.

In the sequel, we use the letters "G", "D", and "N" in front of TGDs to abbreviate that the TGDs are "guarded", "disjunctive", and "normal", respectively. Other properties of TGDs are written out in textual form whenever necessary. Note that proofs of all results are given in the extended version of this paper (Gottlob et al. 2014).

1.4 Related Work on Rules with Negation

We now discuss a number of previous approaches to extend guarded TGDs with negation.

Stratified Negation. Stratified negation for guarded Datalog$^{\pm}$, and thus automatically for a number of important DLs was introduced in (Calì, Gottlob, and Lukasiewicz 2012) and further extended to the more expressive formalism of *weakly guarded Datalog*$^{\pm}$ in (Arenas, Gottlob, and Pieris 2014). These papers show that stratified negation is very well-behaved in the sense that its addition does not endanger decidability, and actually does not augment the complexity of reasoning and query answering. But this semantics does not apply to the (unstratified) rules in Examples 1 and 2.

Well-Founded Negation. Negation under the well-founded semantics (WFS) for guarded Datalog$^{\pm}$ and covered DLs was studied in (Hernich et al. 2013; Gottlob et al. 2012a) for two variants of the WFS. The version of (Hernich et al. 2013) studies the so-called *standard WFS*, which extends the well-known WFS for logic programming with function symbols, where it is assumed (as here) that different Skolem terms are not unifiable, which means that the *unique name assumption (UNA)* is applied to Skolem terms. The second variant, called *equality-friendly WFS* (Gottlob et al. 2012a) does not use the UNA. Note that both variants would be unsatisfactory for Examples 1 and 2, as they would simply leave the predicates *Odd* and *Even* undefined.

Stable Model Negation. In (Magka, Krötzsch, and Horrocks 2013), new acyclicity and stratification conditions are presented for existential rules with negation in rule bodies, which identify classes of rule sets that have finite and/or unique stable models, and constraints are added on the input facts to further extend these classes. Our work here, in contrast, is not restricted to finite and/or unique stable models, and thus much more general. The only syntactic restriction necessary here is guardedness (or the weaker weakly guardedness). The $\mathbb{FDNC}$ programs in (Eiter and Simkus 2010) combine nonmonotonic negation and rules, allowing also the use of function symbols. Decidability is obtained by restricting the structure of rules to one of seven predefined forms.

Hybrid Approaches. Less closely related approaches are loosely and tightly coupled dl-programs (Eiter et al. 2008; Lukasiewicz 2010), as well as the hybrid MKNF knowledge bases (Motik and Rosati 2010). More precisely, the former loosely and tightly, respectively, combine a description logic knowledge base L and a logic program P. Rule bodies in P may contain queries to L, which may also contain facts as additional input to L, in the loosely coupled case, while concepts and roles from L are used as predicates in P in the tightly coupled case. Decidability is based on the finiteness of stable models. The hybrid MKNF knowledge bases allow for querying a description logic knowledge base L via the operators $\mathbf{K}$ and $\mathbf{not}$. Decidability is obtained via the so-called DL-safety condition, which makes the rules applicable only to explicitly known individuals. In our approach here, in contrast, stable models may be infinite, and no restrictive DL-safety of rules is assumed.

In summary, none of the above approaches allows one to use the stable model semantics for the general class of guarded normal TGDs.

2 Preliminaries

We now briefly recall some basics on Datalog$^{\pm}$ (Calì, Gottlob, and Kifer 2013; Calì, Gottlob, and Lukasiewicz 2012), namely, on relational databases, (Boolean) conjunctive queries ((B)CQs), tuple-generating dependencies (TGDs), and negative constraints. For equality-generating dependencies (EGDs), in particular, non-conflicting keys, we refer to (Calì, Gottlob, and Lukasiewicz 2012).

Databases and Queries. We assume (i) an infinite universe of *(data) constants* Δ (which constitute the "normal" domain of a database), (ii) an infinite set of *(labeled) nulls* Δ_N (used as "fresh" Skolem terms, which are placeholders for unknown values), and (iii) an infinite set of variables $\mathcal{V}$ (used in queries and constraints). We denote by $\mathbf{X}$ sequences of variables $X_1, \ldots, X_k$ with $k \geqslant 0$. We assume a *relational schema* $\mathcal{R}$, which is a finite set of *relation names* (or *predicate symbols*, or simply *predicates*).

A *position* $P[i]$ identifies the i-th argument of a predicate P. A *term* t is a constant or variable. An *atomic formula* (or *atom*) $\mathbf{a}$ has the form $P(t_1, ..., t_n)$, where P is an n-ary predicate, and $t_1, ..., t_n$ are terms. A conjunction of atoms is often identified with the set of all its atoms.

A *database (instance)* D for a relational schema $\mathcal{R}$ is a (possibly infinite) set of atoms with predicates from $\mathcal{R}$ and arguments from Δ. We denote by $dom(D)$ the set of all elements of Δ that occur in D. A *conjunctive query (CQ)* over $\mathcal{R}$ has the form $Q(\mathbf{X}) = \exists \mathbf{Y}\, \Phi(\mathbf{X}, \mathbf{Y})$, where $\Phi(\mathbf{X}, \mathbf{Y})$ is a conjunction of atoms with the variables $\mathbf{X}$ and $\mathbf{Y}$ (and eventually constants). Note that $\Phi(\mathbf{X}, \mathbf{Y})$ may also contain equalities but no inequalities. A *Boolean CQ (BCQ)* over $\mathcal{R}$ is a CQ of the form $Q()$. We often write a BCQ as the set of all its atoms, having constants and variables as arguments, and omitting the quantifiers. Answers to CQs and BCQs are defined via *homomorphisms*, which are mappings $\mu\colon \Delta \cup \mathcal{V} \to \Delta \cup \mathcal{V}$ such that (i) $c \in \Delta$ implies $\mu(c) = c$, and (ii) μ is naturally extended to atoms, sets of atoms, and conjunctions of atoms. The set of all *answers* to a CQ $Q(\mathbf{X}) = \exists \mathbf{Y}\, \Phi(\mathbf{X}, \mathbf{Y})$ over a database D, denoted $Q(D)$, is the set of all tuples $\mathbf{t}$ over Δ for which there exists a homomorphism $\mu\colon \mathbf{X} \cup \mathbf{Y} \to \Delta$ such that $\mu(\Phi(\mathbf{X}, \mathbf{Y})) \subseteq D$ and $\mu(\mathbf{X}) = \mathbf{t}$. The *answer* to a BCQ $Q() = \exists \mathbf{Y}\, \Phi(\mathbf{Y})$ over a database D is *Yes*, denoted $D \models Q$, iff $Q(D) \neq \varnothing$, i.e., there is a homomorphism $\mu\colon \mathbf{Y} \to \Delta \cup \Delta_N$ such that $\mu(\Phi(\mathbf{Y})) \subseteq D$.

Tuple-Generating Dependencies (TGDs). Tuple-generating dependencies (TGDs) describe constraints on databases in the form of generalized Datalog rules with existentially quantified conjunctions of atoms in rule heads; their syntax and semantics are as follows. Given a relational schema $\mathcal{R}$, a *tuple-generating dependency (TGD)* σ is a first-order formula $\forall \mathbf{X} \forall \mathbf{Y}\ \Phi(\mathbf{X}, \mathbf{Y}) \to \exists \mathbf{Z}\, \Psi(\mathbf{X}, \mathbf{Z})$, where $\Phi(\mathbf{X}, \mathbf{Y})$ and $\Psi(\mathbf{X}, \mathbf{Z})$ are conjunctions of atoms over $\mathcal{R}$, called the *body* and the *head* of σ, denoted $body(\sigma)$ and $head(\sigma)$, respectively. Such σ is satisfied in a database D for $\mathcal{R}$ iff, whenever there is a homomorphism h that maps the atoms of $\Phi(\mathbf{X}, \mathbf{Y})$ to atoms of D, then h is extendable to a homomorphism h' that maps the atoms of $\Psi(\mathbf{X}, \mathbf{Z})$ to atoms of D. As TGDs can be reduced to TGDs with only single atoms in their heads, in the sequel, every TGD has w.l.o.g. a single atom in its head. A TGD σ is *guarded* iff it contains an atom in its body that contains all universally quantified variables of σ. The leftmost such atom is the *guard* of σ.

Query answering under TGDs, i.e., the evaluation of CQs and BCQs on databases under a set of TGDs is defined as follows. For a database D for $\mathcal{R}$, and a set of TGDs Σ on $\mathcal{R}$, the set of *models* of D and Σ, denoted $mods(D, \Sigma)$, is the set of all (possibly infinite) databases B such that (i) $D \subseteq B$ (ii) every $\sigma \in \Sigma$ is satisfied in B. The set of *answers* for a CQ Q to D and Σ, denoted $ans(Q, D, \Sigma)$, is the set of all tuples $\mathbf{a}$ such that $\mathbf{a} \in Q(B)$ for all $B \in mods(D, \Sigma)$. The *answer* for a BCQ Q to D and Σ is *Yes*, denoted $D \cup \Sigma \models Q$, iff $ans(Q, D, \Sigma) \neq \varnothing$.

Negative Constraints. Another crucial ingredient of Datalog$^{\pm}$ for ontological modeling are *negative constraints* (or simply *constraints*), which are first-order formulas of the form $\forall \mathbf{X}\ \Phi(\mathbf{X}) \to \bot$, where $\Phi(\mathbf{X})$ is a conjunction of atoms (not necessarily guarded), called its *body*.

We usually omit the universal quantifiers and implicitly assume all sets of dependencies/constraints to be finite here.

3 Stable Models for Normal Datalog$^{\pm}$

In this section, we recall normal TGDs and BCQs (Calì, Gottlob, and Lukasiewicz 2012), as well as stable models of normal (logic) programs (Gelfond and Lifschitz 1988), and we define the stable model semantics of guarded normal TGDs.

3.1 Normal TGDs and BCQs

Normal TGDs may also contain (default-)negated atoms in their bodies: Given a relational schema $\mathcal{R}$, a *normal TGD (NTGD)* σ has the form $\forall \mathbf{X} \forall \mathbf{Y}\ \Phi(\mathbf{X}, \mathbf{Y}) \to \exists \mathbf{Z}\, \Psi(\mathbf{X}, \mathbf{Z})$, where $\Phi(\mathbf{X}, \mathbf{Y})$ is a conjunction of atoms and negated atoms over $\mathcal{R}$, and $\Psi(\mathbf{X}, \mathbf{Z})$ is a conjunction of atoms over $\mathcal{R}$. It is also abbreviated as $\Phi(\mathbf{X}, \mathbf{Y}) \to \exists \mathbf{Z}\, \Psi(\mathbf{X}, \mathbf{Z})$. We denote by $head(\sigma)$ the atom in the head of σ, and by $body^+(\sigma)$ and $body^-(\sigma)$ the sets of all positive and negative ("$\neg$"-free) atoms in the body of σ, respectively. We say σ is *guarded* iff it contains a positive body atom, denoted $guard(\sigma)$, that contains all universally quantified variables of σ. W.l.o.g., every NTGD has a single atom in its head, and constants in the body of guarded σ occur only in guards. We say σ is *linear* iff σ is guarded and has exactly one positive atom in its body. As for the semantics, an NTGD σ is *satisfied* in a database D for $\mathcal{R}$ iff, whenever there exists a homomorphism h for all the variables and constants in the body of σ that maps (i) all atoms of $body^+(\sigma)$ to atoms of D and (ii) no atom of $body^-(\sigma)$ to atoms of D, then there exists an extension h' of h that maps all atoms of $head(\sigma)$ to atoms of D.

We next add negation to BCQs. A *normal Boolean conjunctive query (NBCQ)* Q is an existentially closed conjunction of atoms and negated atoms of the form

$$\exists \mathbf{X}\, p_1(\mathbf{X}) \wedge \cdots \wedge p_m(\mathbf{X}) \wedge \neg p_{m+1}(\mathbf{X}) \wedge \cdots \wedge \neg p_{m+n}(\mathbf{X}),$$

where $m \geqslant 1$, $n \geqslant 0$, and the variables of the p_i's are among $\mathbf{X}$. Let $Q^+ = \{p_1(\mathbf{X}), \ldots, p_m(\mathbf{X})\}$ and $Q^- = \{p_{m+1}(\mathbf{X}), \ldots, p_{m+n}(\mathbf{X})\}$. That is, Q^+ (resp., Q^-) is the set of all positive (resp., negative) ("$\neg$"-free) atoms of Q. We say Q is *safe* iff every variable in a negative atom in Q also occurs in a positive atom in Q. We say Q is *covered* iff for every negative atom α in Q, there is a positive atom β in Q such that every argument in α occurs in β. Note that the coveredness of Q implies also the safeness of Q, but not vice versa. In the sequel, w.l.o.g., NBCQs contain no constants. Note that disjunctive normal non-Boolean CQs over finite databases can be reduced to constant-free NBCQs, by first reducing them to NBCQs with constants, and then moving their constants into the TGDs by introducing new predicate symbols.

3.2 Stable Models of Normal Programs

A *normal rule* (or simply *rule*) r is of the form

$$\alpha \leftarrow \beta_1, \ldots, \beta_n, not\ \beta_{n+1}, \ldots, not\ \beta_{n+m}\,, \qquad (1)$$

where $\alpha, \beta_1, \ldots, \beta_{n+m}$ are atoms and $k, m, n \geqslant 0$. We call α the *head* of r, denoted *head*(r), while the conjunction

$\beta_1, \ldots, \beta_n, not\ \beta_{n+1}, \ldots, not\ \beta_{n+m}$ is its *body*. We define $body(r) = body^+(r) \cup body^-(r)$, where $body^+(r) = \{\beta_1, \ldots, \beta_n\}$ and $body^-(r) = \{\beta_{n+1}, \ldots, \beta_{n+m}\}$. We say r is *positive* iff $m = 0$. We say r is a *fact* iff $m = n = 0$. A *normal* (resp., *positive*) *program* P is a finite set of normal (resp., positive) rules.

Let P be a normal program. We denote by HU_P and HB_P the *Herbrand universe* and the *Herbrand base* for P, respectively. A *ground instance* of a rule $r \in P$ is obtained from r by replacing each variable in r by an element from HU_P. We denote by $ground(r)$ (resp., $ground(P)$) the set of all ground instances of r (resp., rules in P). An *interpretation* I for P is a subset of HB_P. Such I is a *model* of a ground rule r iff $\alpha \in I$ whenever $B^+(r) \subseteq I$ and $B^-(r) \cap I = \varnothing$. We say I is a *model* of a normal program P iff I is a model of every $r \in ground(P)$.

The *Gelfond-Lifschitz reduct* of a normal program P relative to $I \subseteq HB_P$, denoted P^I, is the (possibly infinite) ground positive program obtained from $ground(P)$ by

1. deleting every rule r such that $B^-(r) \cap I \neq \varnothing$, and
2. deleting the negative body from each remaining rule.

Since P^I is positive, it has a unique minimal model. A *stable model* of a normal program P is an interpretation $I \subseteq HB_P$ such that I is the minimal model of P^I. Note that every stable model of P is also a minimal model of P.

3.3 Stable Models for Guarded Normal TGDs

Let Σ be a finite set of guarded NTGDs, and let D be a database over the same schema as Σ. Given an NTGD $\sigma = \Phi(\mathbf{X}, \mathbf{Y}) \rightarrow \exists \mathbf{Z}\, \Psi(\mathbf{X}, \mathbf{Z})$, the *functional transformation* of σ, denoted σ^f, is the normal rule $\Phi(\mathbf{X}, \mathbf{Y}) \rightarrow \Psi(\mathbf{X}, \mathbf{f}_\sigma(\mathbf{X}, \mathbf{Y}))$, where $\mathbf{f}_\sigma$ is a vector of function symbols $f_{\sigma,Z}$ for σ, one for every variable Z in $\mathbf{Z}$. Given a set Σ of NTGDs, the *functional transformation* of Σ, denoted Σ^f, is obtained from Σ by replacing each TGD σ in Σ by σ^f. Note that the functional transformation of a finite set of guarded TGDs is a positive program.

Definition 1 Let Σ be a finite set of guarded NTGDs, and let D be a database over the same schema as Σ. Then, a *stable model* for D and Σ is a stable model of the normal program $P = D \cup \Sigma^f$, having D as a collection of ground facts.

Non-constant terms (i.e., those involving function symbols) that occur in stable models for D and Σ are henceforth considered as *nulls*. Let Σ^+ be the finite set of TGDs obtained from Σ by dropping all negative literals from the rules' bodies. Recall the definition of the guarded chase forest for D and Σ^+ from (Calì, Gottlob, and Kifer 2013; Calì, Gottlob, and Lukasiewicz 2012). The *upper guarded chase forest* for D and Σ, denoted *g-chase*(D, Σ), is the guarded chase forest for D and Σ^+. The following lemma shows that the set of atoms occurring in *g-chase*(D, Σ) provides an overapproximation for any stable model for D and Σ. From this, we infer below that query answering under guarded normal Datalog$^\pm$ with the stable models semantics is decidable. For the proof, we refer to (Gottlob et al. 2014).

Lemma 2 *Let Σ be a finite set of guarded NTGDs, and let D be a database over the same schema as Σ. If S is a stable model for D and Σ, then all atoms of S occur as the label of some node in g-chase(D, Σ).*

Decidability of query answering relative to the stable model semantics can be obtained as a consequence of Rabin's Theorem (1969) via an encoding into monadic second-order logic over the infinite m-ary tree (for suitable $m \in \mathbb{N}$).

Theorem 3 *There is an algorithm that, given a database D, a finite set Σ of guarded NTGDs, and a covered UNBCQ Q, decides whether Q is true in all stable models for D and Σ.*

Proof (Sketch). Given D, Σ, and Q, compute an MSO sentence $\varphi_{D,\Sigma,Q}$ such that Q is true in all stable models for D and Σ iff $T \models \varphi_{D,\Sigma,Q}$. The basic idea for constructing the MSO sentence is to label a subset of the nodes of the full m-ary tree T with a *type* (α, N) consisting of an atom α and a set N of atoms whose arguments occur in α, and then to verify that the subtree T' of T induced by all labelled nodes corresponds to a stable model. Due to space limitations, and because we obtain stricter complexity bounds for query answering in the coming sections, we omit the details of the MSO-translation, and refer the reader to the extended version of this paper (Gottlob et al. 2014). □

4 Disjunctive Rules with Stratified Negation

Disjunctive Normal TGDs and BCQs. Given a relational schema $\mathcal{R}$, a *disjunctive normal TGD (DNTGD)* σ has the form $\forall \mathbf{X} \forall \mathbf{Y}\ \Phi(\mathbf{X}, \mathbf{Y}) \rightarrow \exists \mathbf{Z}\, \Psi(\mathbf{X}, \mathbf{Z})$, where $\Phi(\mathbf{X}, \mathbf{Y})$ is a conjunction of atoms and negated atoms over $\mathcal{R}$, and $\Psi(\mathbf{X}, \mathbf{Z})$ is a disjunction of atoms over $\mathcal{R}$. We denote by $head(\sigma)$ the set of atoms in the head of σ. All other notions like $body^+(\sigma)$, $body^-(\sigma)$, guardedness, and $guard(\sigma)$ are defined as for NTGDs. A DNTGD σ is *satisfied* in a database D for $\mathcal{R}$ iff, whenever there exists a homomorphism h for all the variables and constants in the body of σ that maps (i) all atoms of $body^+(\sigma)$ to atoms of D and (ii) no atom of $body^-(\sigma)$ to atoms of D, then there exists an extension h' of h that maps some atoms of $head(\sigma)$ to atoms of D.

A *union of normal Boolean conjunctive queries (UNBCQ)* Q is a disjunction of $k > 0$ NBCQs Q_i. It is *safe* (resp., *covered*) iff all its NBCQs Q_i are safe (resp., covered).

We assume the reader to be familiar with the chase procedure. The *disjunctive normal chase* is an extension of the chase. It differs to the chase in that an application of a DNTGD σ to a database D via a homomorphism $h\colon body^+(\sigma) \rightarrow D$ (that maps atoms $\beta \in body^-(\sigma)$ to non-atoms in D) generates more than one possible successor database—one database $D \cup \{h(\psi)\}$ for each disjunct $\psi \in head(\sigma)$. The set of all databases obtained using this version of the chase is denoted by $chase(D, \Sigma)$. Note that DNTGDs may be applied several times with the same homomorphism, to introduce several of the head atoms.

Canonical Model Semantics. A *stratification* of a set Σ of disjunctive normal TGDs on $\mathcal{R}$ is a mapping $\mu\colon \mathcal{R} \rightarrow \{0, 1, \ldots, k\}$ such that for all $\sigma \in \Sigma$:

- for all positive literals $R(\bar{u})$ in the body of σ, and for all atoms $R'(\bar{u}')$ in the head of σ, we have $\mu(R) \leqslant \mu(R')$;

- for all negative literals $\neg R(\bar{u})$ in the body of σ, and for all atoms $R'(\bar{u}')$ in the head of σ, we have $\mu(R) < \mu(R')$.

We call k the *length* of μ. For each $i \in \{0, 1, \ldots, k\}$, let Σ_i be the set of all $\sigma \in \Sigma$ such that i is the minimum of $\mu(R)$, where R ranges over all the predicates in the head of σ. We say that Σ is *stratified* if there is a stratification of Σ.

Definition 4 *Let $\mathcal{R}$ be a relational schema, D a database for $\mathcal{R}$, Σ a set of DNTGDs on $\mathcal{R}$, and Q a UNBCQ over $\mathcal{R}$. Suppose that Σ has a stratification of length k. Define:*

- $\mathcal{S}^0(D, \Sigma) := \{D\}$;
- $\mathcal{S}^{i+1}(D, \Sigma) := \bigcup_{S \in \mathcal{S}^i(D,\Sigma)} chase^S(S, \Sigma_i)$, *if* $i \leqslant k$;
- $\mathcal{S}(D, \Sigma) := \mathcal{S}^{k+1}(D, \Sigma)$.

We write $D \cup \Sigma \models_{\mathsf{strat}} Q$ iff $S \models Q$ for all $S \in \mathcal{S}(D, \Sigma)$.

5 Query Answering under Disjunctive Rules with Stratified Negation

This section presents our results on answering queries over disjunctive guarded Datalog$^{\pm}$ programs with stratified negation. Our main result is:

Theorem 5 *Let $\mathcal{R}$ be a relational schema, D a database for $\mathcal{R}$, Σ a stratified set of guarded DNTGDs on $\mathcal{R}$, and Q a covered UNBCQ over $\mathcal{R}$. Deciding $D \cup \Sigma \models_{\mathsf{strat}} Q$ has the following complexity:*

1. 2-EXPTIME-*complete in general;*
2. EXPTIME-*complete in case the maximum arity w of the relation symbols in $\mathcal{R}$ is fixed;*
3. coNP-*complete in case $|\mathcal{R}|$, w, and the number of atoms in Q are fixed.*

Thus, extending guarded Datalog$^{\pm}$ by the feature of disjunction and stratified negation—even allowing negative literals in the query—does not change the complexity of query answering in the general and in the bounded arity case, while it increases the data complexity. The data complexity is coNP already for the extension of guarded Datalog$^{\pm}$ by disjunction (Bourhis, Morak, and Pieris 2013), which proves coNP-hardness in Theorem 5. The other hardness results of Theorem 5 follow from answering BCQs under guarded TGDs being 2-EXPTIME-hard in general and EXPTIME-hard for bounded arities (Calì, Gottlob, and Kifer 2013).

For the upper bounds, we devise an algorithm to answer UNBCQs over stratified sets of guarded DNTGDs. The algorithm extends the QCHECK algorithm in (Calì, Gottlob, and Kifer 2013), but requires significantly new ideas. Our exposition follows the one of QCHECK in that paper in that we first explain how to decide entailment or non-entailment of atoms, and then describe the general algorithm.

5.1 Checking Entailment of Ground Atoms

One of the first steps of our algorithm is to decide if certain ground atoms are true in some "stratified model" or false in all "stratified models" $S \in \mathcal{S}(D, \Sigma)$. Here, an atom α is *ground* (relative to a database D, which, however, will always be clear from the context) iff $dom(\alpha) \subseteq dom(D)$.

Proposition 6 below states that (non-)entailment of ground atoms can be checked within the desired complexity bounds. For stating and proving it, we need the following definitions. For atoms α, let $dom(\alpha) := dom(\{\alpha\})$. The databases D_1 and D_2 are *consistent* iff, for all α with $dom(\alpha) \subseteq dom(D_1) \cap dom(D_2)$, we have that $\alpha \in D_1$ iff $\alpha \in D_2$. We say that D_2 *embeds* D_1 iff $D_1 \subseteq D_2$, and D_1 and D_2 are consistent. Let $\mathcal{S}^*(D, \Sigma)$ be the set of all $S \in \mathcal{S}(D, \Sigma)$ that embed D.

Proposition 6 *Let $\mathcal{R}$ be a relational schema, D a database for $\mathcal{R}$, Σ a stratified set of guarded DNTGDs on $\mathcal{R}$, and α a ground atom over $\mathcal{R}$. Deciding whether some model in $\mathcal{S}^*(D, \Sigma)$ contains α, or if none of the models in $\mathcal{S}^*(D, \Sigma)$ contains α is in:*

- 2-EXPTIME *in general;*
- EXPTIME *in case the maximum arity w of a predicate in $\mathcal{R}$ is bounded;*
- PTIME *in case w and $|\mathcal{R}|$ are bounded.*

Proof (Sketch). We extend the ACHECK algorithm from (Calì, Gottlob, and Kifer 2013). ACHECK checks if an atom (atomic BCQ, in general) α is entailed by a database D and a set Σ of guarded TGDs. To do this, it guesses a sequence $\alpha_1, \ldots, \alpha_n$ of atoms such that $\alpha_1 \in D$, $\alpha_n = \alpha$, and each α_i, $i > 1$, can be obtained by a TGD σ_i in Σ whose guard is matched to α_{i-1}. To ensure that the *side atoms* β of each σ_i (i.e., the non-guard atoms in the body of σ_i required to "fire" σ_i) can be derived as well, it launches side computations that check (similarly as for α) if there is a similar path for β etc.

Our algorithm, called $\mathsf{ACHECK}_{\vee,\mathsf{strat}}$, generalizes this approach. The main difficulty is that under a stratified set Σ of guarded DNTGDs, there is not a single model (namely, the chase model) to explore, but many models $S \in \mathcal{S}^*(D, \Sigma)$. However, every such model can be constructed on the fly by applying the DNTGDs in Σ, which is enough to search for a model that contains α, or—by duality—to check that no model contains α. To be a bit more precise, each disjunct in the head of a DNTGD represents a possible way of extending the part of a model derived so far. Thus, when faced with a disjunction in the head of a DNTGD, it suffices to guess the disjunct β that leads to a model S containing α (and the set of all atoms in such an S with $dom(\gamma) \subseteq dom(\beta)$); this guess is verified by appropriate subcomputations. Negative literals in the bodies of DNTGDs pose no problem, since negation is stratified in Σ. We only have to ensure that the stratification is respected when applying the DNTGDs. For details, see the extended paper (Gottlob et al. 2014).

As in (Calì, Gottlob, and Kifer 2013), it is possible to reduce the space required to represent the configurations of $\mathsf{ACHECK}_{\vee,\mathsf{strat}}$ to $|\mathcal{R}| \cdot 2^{O(w)} \cdot \log |D|$, where w is the maximum arity of a predicate in $\mathcal{R}$, via *canonization*. As alternating logarithmic (resp., polynomial, exponential) space corresponds to polynomial (resp., exponential, doubly exponential) time, this yields the complexity bounds. □

5.2 Main Algorithm

We now complete the proof of Theorem 5 by proving the corresponding upper bounds.

Proposition 7 *Let $\mathcal{R}$ be a relational schema, D a database for $\mathcal{R}$, Σ a stratified set of guarded DNTGDs on $\mathcal{R}$, and Q a covered UNBCQ over $\mathcal{R}$. Deciding $D \cup \Sigma \models_{\mathsf{strat}} Q$ can be done within the upper bounds indicated in Theorem 5.*

Proof (Sketch). First, w.l.o.g., Q is a union of BCQs. Indeed, if $\neg\beta = \neg R(x_1, \ldots, x_k)$ occurs in Q, and α is the positive literal in Q covering β, then $\neg\beta$ can be simulated by $\alpha \wedge \neg\beta \rightarrow \bar{R}(x_1, \ldots, x_k)$, where $\bar{R}$ is a fresh predicate. This increases the length of a stratification of Σ only by one. In Q, we replace $\neg\beta$ by the atom $\bar{R}(x_1, \ldots, x_k)$.

To obtain the complexity bounds, we extend the QCHECK algorithm in (Calì, Gottlob, and Kifer 2013). Handling stratified DNTGDs requires significantly new ideas, though. The original QCHECK algorithm checks if a BCQ is entailed by a database and a set of (weakly) guarded TGDs. It starts by computing the extension $\hat{D}$ of D with all ground atoms entailed by D and the TGDs. Next, it guesses a *squid decomposition* δ of Q. Intuitively, a squid decomposition of Q describes how Q may be mapped to a model S in $\mathcal{S}(D, \Sigma)$. For our purposes, a squid decomposition of Q may be defined as a tuple (Q^+, h, H, T, V), where:

- Q^+ is a *cover* of Q (a BCQ that contains all atoms of Q and at most $|Q|$ other atoms);
- $h\colon var(Q^+) \rightarrow var(Q^+)$,
- $H \subseteq Q^+$ and $T := Q^+ \setminus H$ are the *head* and *tentacles*,
- and T is *acyclic* (i.e., T has a join tree).

It can be shown (Calì, Gottlob, and Kifer 2013) that Q is true in the chase model iff there is a squid decomposition whose head can be mapped to the ground part of the database, and whose tentacles can be mapped to the non-ground part. Thus, the QCHECK algorithm also guesses a homomorphism μ from the head of δ to $\hat{D}$. In the rest of the computation, it checks that μ can be extended to a homomorphism from the tentacles to the result of the chase with D and the TGDs. In our case, we do not have a single "chase model", but many such models $S \in \mathcal{S}(D, \Sigma)$ into which we have to map Q. In particular, there are many extensions $\hat{D}$ of D with ground atoms such that some $S \in \mathcal{S}(D, \Sigma)$ embeds $\hat{D}$. Our algorithm thus starts by universally branching over all such extensions $\hat{D}$ of D with ground atoms, and checks that there is a model $S \in \mathcal{S}(D, \Sigma)$ that embeds $\hat{D}$. The latter can be done within the desired complexity bounds by using the algorithm as guaranteed by Proposition 6. In a parallel subcomputation, the algorithm then checks that Q is true in all models $S \in \mathcal{S}^*(\hat{D}, \Sigma)$. Clearly, this algorithm decides $D \cup \Sigma \models_{\mathsf{strat}} Q$ (i.e., if Q is true in all $S \in \mathcal{S}(D, \Sigma)$).

It remains to explain how truth of Q in all $S \in \mathcal{S}^*(\hat{D}, \Sigma)$ can be decided within the desired complexity bounds. To this end, we extend the TCHECK algorithm in (Calì, Gottlob, and Kifer 2013). We highlight only the main changes to TCHECK; (Gottlob et al. 2014) contains a more detailed description. For details regarding TCHECK, see the proof of Theorem 5.9 in (Calì, Gottlob, and Kifer 2013).

The idea of TCHECK is as follows. Given a squid decomposition δ (for which we have found a homomorphism h from its head to the ground part of the chase in the initialization phase of QCHECK), a maximal subtree t of the tentacles of δ, the root v of t, and the assignment h restricted to the *exported variables* of v (i.e., those variables that occur in v but also outside the subtree below v), TCHECK tries to extend the assignment to a homomorphism from the subtree rooted at v to the chase model by deriving an atom where v can be matched to, then deriving the atoms where the children of v can be matched to, and so on. In our case, each model $S \in \mathcal{S}(\hat{D}, \Sigma)$ might satisfy Q via a different embedding or squid decomposition of Q. Thus, rather than maintaining information about the progress of extending the initial homomorphism to a single subtree of a squid decomposition's tentacles throughout the computation, we store information about all possible squid decompositions of Q, and the parts of the squid decompositions that still need to be matched (i.e., have not been mapped into the part of the model constructed so far). Once we are in a state where one squid decomposition is complete (i.e., no part of it is left to be checked), we accept. Thus, if all computation branches accept, we have successfully checked that each $S \in \mathcal{S}^*(\hat{D}, \Sigma)$ satisfies Q. □

6 Simulating Normal Datalog$^{\pm}$ under Stable Models with Stratified Disjunctive Rules

The following theorem shows that NBCQ answering over a database and a finite set of guarded NTGDs under the stable model semantics can be translated in polynomial time into NBCQ answering over the same database and a finite set of guarded DNTGDs with stratified negation.

Theorem 8 *Let D be a database for some schema $\mathcal{R}$, let Σ be a finite set of guarded NTGDs over $\mathcal{R}$, and let Q be an NBCQ over $\mathcal{R}$. Then, Σ and Q can be translated in polynomial time into a stratified finite set of guarded DNTGDs Σ' and an NBCQ Q' such that Q is true in all stable models of D and Σ iff Q' is true in all canonical models of D and Σ'.*

Proof. We define the stratified finite set of guarded DNTGDs $\Sigma' = \Sigma'_1 \cup \Sigma'_2 \cup \Sigma'_3 \cup \Sigma'_4$ and the NBCQ Q' as follows:
• Σ'_1 generates the potential atoms that may occur in a stable model for D and Σ. To this end, it "executes" the program $P^+ = (D \cup \Sigma^f)^+$. For each $R \in \mathcal{R}$, let R^* be a fresh predicate of the same arity as R. Then, Σ'_1 consists of all TGDs that are obtained from an NTGD in Σ by dropping all negative literals from its body, and replacing each predicate R by R^*. Furthermore, for each k-ary predicate $R \in \mathcal{R}$, the set Σ'_1 contains the TGD $R(x_1, \ldots, x_k) \rightarrow R^*(x_1, \ldots, x_k)$.
• Σ'_2 "guesses" a partition of the set of all atoms derivable from P^+ into two parts. For each predicate $R \in \mathcal{R}$, let R^+ and R^- be fresh predicates of the same arity as R. The idea is that R^+ and R^--atoms are those belonging to the first and second part of the partition, respectively. To "guess" the partition, for each k-ary predicate $R \in \mathcal{R}$, we add the following disjunctive TGD and negative constraint to Σ'_2:

$$R^*(x_1, \ldots, x_k) \rightarrow R^+(x_1, \ldots, x_k) \vee R^-(x_1, \ldots, x_k),$$
$$R^+(x_1, \ldots, x_k) \wedge R^-(x_1, \ldots, x_k) \rightarrow \bot.$$

• Σ'_3 generates all consequences of the program P^S, where S is the set of all the R^+-atoms (with R^+ renamed to R). More precisely, for each predicate $R \in \mathcal{R}$, let $\hat{R}$ be a predicate of the same arity as R. Consider an NTGD in Σ:

$$R_1(\mathbf{x}_1) \wedge \cdots \wedge R_k(\mathbf{x}_k) \wedge \neg S_1(\mathbf{y}_1) \wedge \cdots \wedge \neg S_\ell(\mathbf{y}_\ell) \rightarrow \exists \mathbf{z}\, T(\mathbf{u}).$$

• Then, Σ'_3 contains the following NTGD:

$$\hat{R}_1(\mathbf{x}_1) \wedge \cdots \wedge \hat{R}_k(\mathbf{x}_k) \wedge S_1^-(\mathbf{y}_1) \wedge \cdots \wedge S_\ell^-(\mathbf{y}_\ell) \rightarrow \exists \mathbf{z}\, \hat{T}(\mathbf{u}).$$

Furthermore, for each k-ary predicate $R \in \mathcal{R}$, the set Σ'_3 contains the TGD $R(x_1, \ldots, x_k) \rightarrow \hat{R}(x_1, \ldots, x_k)$.

• Σ'_4 verifies that the consequences of P^S (represented by all the $\hat{R}$-atoms) coincide with the set S (represented by all the R^+-atoms). To this end, for each k-ary predicate $R \in \mathcal{R}$, it contains the following negative constraints:

$$\hat{R}(x_1, \ldots, x_k) \wedge R^-(x_1, \ldots, x_k) \rightarrow \bot \qquad (\text{“}\hat{R} \subseteq R^+\text{”})$$
$$R^+(x_1, \ldots, x_k) \wedge \neg \hat{R}(x_1, \ldots, x_k) \rightarrow \bot \qquad (\text{“}R^+ \subseteq \hat{R}\text{”}).$$

• Finally, Q' is obtained from Q by replacing every positive (resp., negative) literal $R(\mathbf{x})$ (resp., $\neg R(\mathbf{x})$) by $R^+(\mathbf{x})$ (resp., $\neg R^+(\mathbf{x})$).

We now show that Q is false in some stable model for D and Σ iff Q' is false in some canonical model for D and Σ'. We here consider only the case that Q is a BCQ; the line of argumentation can easily be generalized to NBCQs.

“$\Rightarrow$” Let S be a stable model for D and Σ such that $S \not\models Q$. Let T be the least fixpoint of P^+. Define:

$$S' = \{R^*(\mathbf{a}) \mid R(\mathbf{a}) \in T\} \cup \{R^+(\mathbf{a}) \mid R(\mathbf{a}) \in S\} \cup \{R^-(\mathbf{a}) \mid R(\mathbf{a}) \in T \setminus S\} \cup \{\hat{R}(\mathbf{a}) \mid R(\mathbf{a}) \in S\}.$$

It is then not difficult to verify that S' is a model of D and Σ' under stratified semantics, and $S' \not\models Q'$ (since $\{\mathbf{a} \mid R(\mathbf{a}) \in S\} = \{\mathbf{a} \mid R^+(\mathbf{a}) \in S'\}$).

“$\Leftarrow$” Let S' be a model for D and Σ' obtained using the chase (for disjunctive TGDs with stratified negation) such that $S' \not\models Q'$. For a predicate R and a database D, let $D(R)$ be the set of all the tuples $\mathbf{a}$ with $R(\mathbf{a}) \in D$. Then, $T := \{R(\mathbf{a}) \mid \mathbf{a} \in S'(R^*)\}$ is the unique minimal model for P^+, and $\{S'(R^+), S'(R^-)\}$ forms a partition of $S'(R^*)$. Moreover, the NTGDs in Σ'_4 enforce $S'(\hat{R}) \cap S'(R^-) = \varnothing$ and $S'(R^+) \subseteq S'(\hat{R})$. Since $S'(\hat{R}) \subseteq S'(R^*)$ (only a subset of the rules which generate R^* are triggered), and $S'(R^-) = S'(R^*) \setminus S'(R^+)$, we thus have $S'(\hat{R}) = S'(R^+)$. By the construction of the rules Σ'_3, it follows that $S := \{R(\mathbf{a}) \mid \mathbf{a} \in S'(R^+)\}$ is a stable model for D and Σ. Moreover, since $S' \not\models Q'$, and $S(R) = S'(R^+)$, we have $S \not\models Q$. □

The following example illustrates the above translation.

Example 3 Consider the database $D = \{P(a)\}$ and the following finite set of NTGDs Σ:

$$P(x) \wedge \neg R(x) \rightarrow Q(x), \qquad P(x) \wedge \neg Q(x) \rightarrow R(x).$$

Then, Σ' consists of the following DNTGDs (note that some of the rules (like $R^*(x) \rightarrow R^*(x)$) are omitted, because they would add nothing to Σ' under D):

$$P(x) \rightarrow P^*(x), \quad P^*(x) \rightarrow Q^*(x), \quad P^*(x) \rightarrow R^*(x),$$
$$P^*(x) \rightarrow P^+(x) \vee P^-(x), \qquad P^+(x) \wedge P^-(x) \rightarrow \bot,$$
$$Q^*(x) \rightarrow Q^+(x) \vee Q^-(x), \qquad Q^+(x) \wedge Q^-(x) \rightarrow \bot,$$
$$R^*(x) \rightarrow R^+(x) \vee R^-(x), \qquad R^+(x) \wedge R^-(x) \rightarrow \bot,$$
$$P(x) \rightarrow \hat{P}(x),$$
$$\hat{P}(x) \wedge R^-(x) \rightarrow \hat{Q}(x), \quad \hat{P}(x) \wedge Q^-(x) \rightarrow \hat{R}(x),$$
$$\hat{P}(x) \wedge P^-(x) \rightarrow \bot, \qquad P^+(x) \wedge \neg \hat{P}(x) \rightarrow \bot,$$
$$\hat{Q}(x) \wedge Q^-(x) \rightarrow \bot, \qquad Q^+(x) \wedge \neg \hat{Q}(x) \rightarrow \bot,$$
$$\hat{R}(x) \wedge R^-(x) \rightarrow \bot, \qquad R^+(x) \wedge \neg \hat{R}(x) \rightarrow \bot.$$

To obtain a proper stratified program, we could replace falsum ($\bot$) in the head of $P^+(x) \wedge \neg \hat{P}(x) \rightarrow \bot$ and the corresponding rules for Q and R by an atom $F(x)$ over a fresh predicate F, and put $F(x)$ as a disjunct to our query. Then, F would be in the upper stratum, and all other predicates would be in the lower stratum. ■

The following complexity results for UNBCQ answering in guarded normal Datalog$^\pm$ under the stable model semantics are an immediate corollary of Theorems 8 and 5.

Corollary 9 *Let $\mathcal{R}$ be a relational schema, D a database for $\mathcal{R}$, Σ a finite set of guarded NTGDs on $\mathcal{R}$, and Q a covered UNBCQ over $\mathcal{R}$. Then, deciding whether Q is true in all stable models of D and Σ has the following complexity:*

1. 2-EXPTIME-*complete in general;*
2. EXPTIME-*complete in case the maximum arity w of the relation symbols in $\mathcal{R}$ is fixed;*
3. coNP-*complete in case $|\mathcal{R}|$, w, and the number of atoms in Q are fixed.*

7 Stable Model Semantics for DLs

We now discuss how our decidability results for the stable model semantics can directly be applied to obtain extensions of DLs with non-monotonic negation. The proposed logics are essentially the same as in (Gottlob et al. 2012a), but the crucial difference is that non-monotonic negation is now interpreted via the stable model semantics. This can lead to better query answers, as Example 5 below demonstrates.

We extend *DL-Lite*$_\mathcal{R}$ (which is underlying the OWL 2 QL profile) and *DL-Lite*$_{\mathcal{R},\sqcap}$ (Calvanese et al. 2007; Poggi et al. 2008), and $\mathcal{ELHI}$ (Baader, Brandt, and Lutz 2005) with nonmonotonic negation under the stable model semantics.

Definition 10 Recall that a *DL-Lite*$_{\mathcal{R},\sqcap}$ knowledge base consists of a pair $(\mathcal{T}, \mathcal{A})$, where the TBox $\mathcal{T}$ is a finite set of concept and role inclusion axioms $U_1 \sqcap \cdots \sqcap U_n \sqsubseteq V$, and the ABox $\mathcal{A}$ is a finite set of concept and role membership axioms $C(a)$ and $R(a, b)$, respectively. A *DL-Lite*$_{\mathcal{R},\sqcap,\text{not}}$ knowledge base $(\mathcal{T}, \mathcal{A})$ consists of a finite set of inclusion axioms $\mathcal{T}$ and a finite set of membership axioms $\mathcal{A}$, where:

- Any *DL-Lite*$_{\mathcal{R},\sqcap}$ inclusion axiom is a *DL-Lite*$_{\mathcal{R},\sqcap,\text{not}}$ inclusion axiom.
- If $U_1 \sqcap \cdots \sqcap U_n \sqsubseteq V$ and $U'_1 \sqcap \cdots \sqcap U'_m \sqsubseteq V$ with $n, m > 0$ are both either concept or role inclusion axioms in *DL-Lite*$_{\mathcal{R},\sqcap}$, and V is positive (i.e., not of the form $V = \neg V'$), then $U_1 \sqcap \cdots \sqcap U_n \sqcap \text{not}\, U'_1 \sqcap \cdots \sqcap \text{not}\, U'_m \sqsubseteq V$ is

a *DL-Lite*$_{\mathcal{R},\sqcap,\mathrm{not}}$ concept or role inclusion axiom, respectively. Here, the U_i's and U_i''s contain no conjunction, and $\mathrm{not}\, U_i'$ denotes the negation as failure (as opposed to the classical negation "$\neg$" in *DL-Lite*).

- For any concept A, any role R, and any individuals a, b, the expressions $A(a)$ and $R(a, b)$ are concept and role membership axioms, respectively.

A *DL-Lite*$_{\mathcal{R},\sqcap,\mathrm{not}}$ knowledge base $(\mathcal{T}, \mathcal{A})$ is a *DL-Lite*$_{\mathcal{R},\mathrm{not}}$ knowledge base iff all inclusion axioms in $\mathcal{T}$ contain precisely one positive atom on the left-hand side.

Finally, we define $\mathcal{ELHI}_{\mathrm{not}}$ as the extension of $\mathcal{ELHI}$ that allows formulas of the form $\mathrm{not}\, C$ for atomic concepts $C = A$ and for concepts $C = \exists R.B$ to occur in top-level conjunctions on the left-hand side of concept inclusions and formulas $\mathrm{not}R$ and $\mathrm{not}R^-$ for any role R on the left hand side of role inclusions (in addition to at least one positive concept or one positive role, respectively, to ensure guardedness). ■

The semantics of *DL-Lite*$_{\mathcal{R},\mathrm{not}}$ (resp., *DL-Lite*$_{\mathcal{R},\sqcap,\mathrm{not}}$) is defined by translating a given *DL-Lite*$_{\mathcal{R},\mathrm{not}}$ (resp., *DL-Lite*$_{\mathcal{R},\sqcap,\mathrm{not}}$) knowledge base KB into a normal guarded Datalog$^{\pm}$ program P_{KB} and by computing the stable model semantics of P_{KB}. More details on the translation into normal Datalog$^{\pm}$ can be found in (Gottlob et al. 2012a). Similarly it is straightforward to translate $\mathcal{ELHI}_{\mathrm{not}}$ knowledge bases into normal guarded Datalog$^{\pm}$-programs in order to obtain a stable semantics for $\mathcal{ELHI}_{\mathrm{not}}$.

The following example demonstrates how Example 1 from the introduction can be formalized in $\mathcal{ELHI}_{\mathrm{not}}$.

Example 4

$$\begin{aligned} \mathrm{Person} \sqcap \mathrm{notEven} &\sqsubseteq \mathrm{Odd} \\ \mathrm{Person} \sqcap \mathrm{notOdd} &\sqsubseteq \mathrm{Even} \\ \mathrm{Person} \sqcap \mathrm{Even} &\sqsubseteq \exists \mathrm{hasParent.Odd} \\ \mathrm{Person} \sqcap \mathrm{Odd} &\sqsubseteq \exists \mathrm{hasParent.Even}. \end{aligned}$$

If we consider the ABox $\{\mathrm{Person}(\mathrm{mary})\}$, we obtain two (infinite) stable models for the knowledge base that look very similar to the models obtained in Example 1, the two models correspond to the case in which $\mathrm{Odd}(\mathrm{mary})$ and to the case in which $\mathrm{Even}(\mathrm{mary})$ holds. ■

In the next example, the stable model semantics leads to better query answers than the well-founded semantics.

Example 5

$$\begin{aligned} \mathrm{Hotel} \sqcap \mathrm{Perfect} &\sqsubseteq \exists \mathrm{Beach} \sqcap \exists \mathrm{Pool} \\ \mathrm{FiveStar} &\sqsubseteq \mathrm{Hotel} \\ \mathrm{FiveStar} \sqcap \mathrm{not}\exists \mathrm{Pool} &\sqsubseteq \exists \mathrm{Beach} \\ \mathrm{FiveStar} \sqcap \mathrm{not}\exists \mathrm{Beach} &\sqsubseteq \exists \mathrm{Pool} \\ \exists \mathrm{Beach} &\sqsubseteq \exists \mathrm{SwimOpp} \\ \exists \mathrm{Pool} &\sqsubseteq \exists \mathrm{SwimOpp} \\ \mathrm{Hotel} \sqcap \exists \mathrm{SwimOpp} &\sqsubseteq \mathrm{Excellent}. \end{aligned}$$

Given the ABox $\{\mathrm{FiveStar}(\mathrm{ritz})\}$, the well-founded semantics for the knowledge base would only contain the atoms $\{\mathrm{FiveStar}(\mathrm{ritz}), \mathrm{Hotel}(\mathrm{ritz})\}$. In contrast to that, all stable models of the same knowledge base contain in addition the atoms $\exists \mathrm{SwimOpp}(\mathrm{ritz})$ and $\mathrm{Excellent}(\mathrm{ritz})$. This correctly reflects the fact that, while we are unable to know whether a given five star hotel has a swimming pool or a beach, we can be sure that one of these facts is true. ■

The decidability results for query answering relative to the stable model semantics can directly be applied to DLs.

Theorem 11 *Let $\mathcal{L}$ be DL-Lite*$_{\mathcal{R},\mathrm{not}}$*, DL-Lite*$_{\mathcal{R},\sqcap,\mathrm{not}}$ *or $\mathcal{ELHI}_{\mathrm{not}}$. Then, given a knowledge base $\mathcal{K} = (\mathcal{T}, \mathcal{A})$ and a covered UNBCQ[2] Q, deciding whether Q is true under the stable model semantics of $\mathcal{K}$ is in EXPTIME (resp., coNP) in the combined (resp., data) complexity. For $\mathcal{ELHI}_{\mathrm{not}}$ the combined complexity is EXPTIME-complete. In all cases, the data complexity is coNP-complete.*

Proof (Sketch). The upper bounds for the complexity are an immediate consequence of Corollary 9. The lower bound for combined complexity of query answering over a $\mathcal{ELHI}_{\mathrm{not}}$ knowledge base is a consequence of the EXPTIME lower bound for subsumption checking in $\mathcal{ELI}$ (Baader, Brandt, and Lutz 2008, Theorem 3), as a subsumption $C \sqsubseteq D$ can be checked by answering the query $C \sqcap \mathrm{not}D$. The lower bound for the data complexity follows from a reduction of the UNSAT-problem; see (Gottlob et al. 2014). □

8 Summary and Outlook

This paper has provided the first fully general stable model semantics for guarded existential rules with negation. We proved that query answering is decidable under this semantics, and we determined the complexity of this problem for various settings. On the way to these results, we defined disjunctive rule sets under FO semantics augmented by stratified negation, and also studied the complexity of query answering based on this formalism, which is of interest in its own right. Finally, we showed how our results can be used for adorning well-known DLs with stable model negation.

For space reasons, many aspects and possible extensions of our work had to remain undiscussed and will be given more attention in the full paper. One feature that we already mentioned are EGDs. Another issue is the unique name assumption (UNA). Our approach for defining the SMS follows the standard semantics for logic programming with function symbols, where different Skolem terms are considered to be different elements that cannot be unified. In a precise sense, this means that our semantics applies the UNA not only to database constants, but also to invented null values, i.e., Skolem terms. As long as negation is not used, this does not matter. But with negation, this may become an issue in some cases. Reconsider Example 1 and let $\Sigma_c = \Sigma_a \cup \{$*Person(x), not Parent(x,x)*$\rightarrow ok\}$. Under our current semantics, $\{$*Person(mary)*$\} \cup \Sigma_c \models ok$. However, if one does not apply the UNA, then ok would not be derivable, because there would exist models in which, e.g., *mary = f(mary)*. We are able to define a version of the stable model semantics without the UNA, too, and we call this the *equality-friendly SMS*, in analogy to (Gottlob et al. 2012a). This semantics is defined in a totally analogous way to the one defined here, except that instead of using stratified GDNTGDs, we use guarded fixpoint logic. As will be shown in the full paper, decidability and the same complexity results hold.

[2] See (Gottlob et al. 2014) for a definition.

Ongoing work includes in particular the SMS for disjunctive guarded TGDs with negation (GDNTGDs). The semantics for this is, again, directly inherited from the corresponding SMS for disjunctive logic programming with function symbols. As this can be encoded into MSO in a similar way as the normal stable semantics, query answering is decidable. By a similar encoding into MSO, we have also obtained decidability for the SMS for disjunctive weakly guarded and weakly frontier-guarded TGDs with negation. We are currently still exploring the precise complexity of all these problems. We also plan to extend suitable versions of the interesting MKNF approach (Motik and Rosati 2010) by our techniques, so to achieve larger decidable classes.

Acknowledgments. This work was supported by the EPSRC under the grant EP/H051511/1 "ExODA", by the European Research Council under the FP7/2007-2013/ERC grant 246858 "DIADEM", and by a Yahoo! Research Fellowship. Georg Gottlob is a James Martin Senior Fellow, and also gratefully acknowledges a Royal Society Wolfson Research Merit Award. The work was carried out in the context of the James Martin Institute for the Future of Computing.

Abstract

We consider the scenario of ontology-based data access where a conjunctive query is evaluated against a database enriched with intensional knowledge via an ontology. It is generally accepted that true scalability of query answering in this setting can only be achieved by using standard relational database management systems (RDBMSs). An approach to query answering that enables the use of RDBMSs is the so-called polynomial combined approach. We investigate this approach for the main guarded- and sticky-based classes of existential rules, and we highlight the assumptions on the underlying schema which are sufficient for the polynomial combined first-order rewritability of those classes. To the best of our knowledge, this is the first work which explicitly studies the polynomial combined approach for existential rules.

1 Introduction

An ontology is an explicit specification of a conceptualization of an area of interest. One of the main applications of ontologies nowadays is in *ontology-based data access (OBDA)* (Poggi *et al.* 2008), where they are used to enrich the extensional data with intensional knowledge. In this setting, Description Logics (DLs) and rule-based formalisms such as existential rules are popular ontology languages, while conjunctive queries (CQs) are used as a vital querying tool. Therefore, efficient approaches to CQ answering over such languages are of great importance.

It is widely accepted that currently true scalability in OBDA can only be achieved by exploiting standard relational database management systems (RDBMSs), which provide mature and efficient technology for answering queries. A significant step forward in this direction was the introduction of the DL-Lite family of DLs (Calvanese *et al.* 2007; Poggi *et al.* 2008) — the logical underpinning of the OWL 2 QL profile of OWL 2 — and the proposal of the first practical approach to OBDA via query rewriting. Most of the languages of the DL-Lite family have been designed with the aim of being *first-order rewritable*, namely a TBox $\mathcal{T}$ can be incorporated together with a given CQ q into a first-order query $q_{\mathcal{T}}$ such that, for every ABox $\mathcal{A}$, $q_{\mathcal{T}}$ evaluated over $\mathcal{A}$ yields exactly the same result as q evaluated against $\mathcal{A}$ and $\mathcal{T}$. Clearly, $q_{\mathcal{T}}$ can be translated into a standard SQL query, and then submitted to the RDBMS holding $\mathcal{A}$ (as a relational database), where it is evaluated and optimized in the usual way.

Although first-order rewritability is a most desirable property, it suffers from two serious shortcomings: *(i)* rewriting algorithms, in general, generate from a reasonably sized CQ an exponentially sized SQL query — even for simple cases such as OWL 2 QL this blowup is unavoidable (Kikot *et al.* 2012) — which can be prohibitive for efficient execution by an RDBMS, and *(ii)* it applies only to lightweight ontology languages for which the data complexity of CQ answering is below LOGSPACE, and thus useful formalisms with PTIME-hard data complexity are excluded a priori.

A more refined approach to query answering, which overcomes the inherent limitations of first-order rewritability, is the *polynomial combined approach* (Lutz *et al.* 2009), that allows the encoding of the consequences of the ontology in the given database (or ABox). This approach applies to languages which are *polynomially combined first-order rewritable*, i.e., for every CQ q, database D, and ontology Σ, it is possible to rewrite in *polynomial time (i)* q and Σ into a first-order query q_Σ, and *(ii)* D and Σ into a database D_Σ, in such a way that the answer to q_Σ over D_Σ is the same as the answer to q over D and Σ.

The polynomial combined approach has been successfully applied to the DL $\mathcal{ELH}^{dr}_{\bot}$ (Lutz *et al.* 2009), i.e., the extension of $\mathcal{EL}$ with the inconsistent concept, role inclusions, and domain and range restrictions, and also to DL-Lite$^{\mathcal{N}}_{horn}$ (Kontchakov *et al.* 2010; 2011), one the most commonly used DL-Lite formalisms without role inclusions. Notice that DL-Lite$^{(\mathcal{HN})}_{horn}$, the extension DL-Lite$^{\mathcal{N}}_{horn}$ with role hierarchies, has been also considered in (Kontchakov *et al.* 2010) but, while the new database can be constructed in polynomial time, the rewritten query is of exponential size in the number of roles occurring in the ontology.

Although the polynomial combined approach has been already applied to several DLs, this is not the case for existential (a.k.a. Datalog$^{\exists}$) rules of the form $\forall \mathbf{X}\, \varphi(\mathbf{X}) \rightarrow \exists \mathbf{Z} p(\mathbf{X}, \mathbf{Z})$. Notice that the investigation of expressive fragments of existential rules that can be employed as an alternative way to represent ontologies is currently a field of intense research (Baget *et al.* 2011a; 2011b; Krötzsch and Rudolph

$c \geqslant 1$	$d \geqslant 0$	✓	✓*	✓	✓*

Table 1: Polynomial combined first-order rewritablity of (L)inear, (G)uarded, (S)ticky and (T)ame rules. The symbol ∞ (resp., $c \geqslant i$ and $d \geqslant i$) asserts that the parameter under consideration is unbounded (resp., bounded by the constants c and d). The expression $d \leqslant 1$ implies that the arity is either 0 or 1. The symbol ? refers to an open problem. The symbol ✓(resp., $\times$) refers to a positive (resp., negative) case. The symbol $[\times]$ refers to a negative case, assuming that PSPACE $\neq$ EXPTIME. Our results are marked with $\star$.

2011; Calì *et al.* 2012a; 2012b; 2013; Leone *et al.* 2012). The only known cases of existential rules which are polynomially combined first-order rewritable are the class of *linear* rules when the arity of the schema is bounded, and the class of *sticky* rules when both the size and the arity of the schema are bounded. Those results are implicit in (Gottlob and Schwentick 2012); however, the goal of that paper was not the investigation of the polynomial combined approach for linear and sticky rules, but the construction of a non-recursive Datalog rewriting of polynomial size.

To the best of our knowledge, this is the first work which explicitly studies the combined approach for existential rules. This problem is considered, by the KR community, an interesting research direction that should be investigated (Kontchakov *et al.* 2011). Towards this direction, we explore guarded- and sticky-based classes of existential rules. Both guardedness and stickiness are well-accepted paradigms. On the one hand, guarded rules form a robust language which captures important DLs such as DL-Lite and $\mathcal{EL}$ (Calì *et al.* 2012a) — a rule is *guarded* if it has a body-atom, called guard, which contains all the body-variables. On the other hand, sticky rules allow for joins in rule-bodies which are not always expressible via guarded rules, and they are able to capture well-known data modeling constructs such as inclusion and multivalued dependencies (Calì *et al.* 2012b). Recently, a class called *tame*, which combines guardedness and stickiness by taming the interaction between the sticky rules and the guard atoms occurring in guarded rules, has been proposed (Gottlob *et al.* 2013).

It is well-known that the problem of evaluating first-order queries over a database is feasible in polynomial space. Therefore, the polynomial combined approach is applicable only to ontology languages for which the combined complexity of CQ answering is at most PSPACE (assuming that PSPACE $\neq$ EXPTIME). Since CQ answering under guarded and tame rules is 2EXPTIME-hard, and under sticky rules is EXPTIME-hard, it is interesting to investigate which assumptions on the underlying schema are sufficient for the polynomial combined first-order rewritability of the above classes. The techniques employed for $\mathcal{ELH}_\bot^{dr}$ and DL-Lite$_{horn}^{\mathcal{N}}$, although quite insightful, leverage specificities of DLs, such as the limit to unary and binary predicates and the special form of DL axioms, so that is not clear how they can be extended to general rule-based languages. Thus, we had to come up with novel techniques beyond the state of the art. Our contributions can be summarized as follows:

- We first show that guarded rules are, in general, not polynomially combined first-order rewritable, even if the underlying schema contains a single predicate. The same holds even if we concentrate on unary and binary predicates (unless PSPACE = EXPTIME). However, guarded rules are polynomially combined first-order rewritable if we consider only unary predicates, or when the size and the arity of the underlying schema are bounded.
- We show that sticky rules are, in general, not polynomially combined first-order rewritable, even if the underlying schema contains a single predicate (unless PSPACE = EXPTIME). Sticky rules are polynomially combined first-order rewritable if we consider schemas of bounded arity.
- Finally, we show that the results for guarded rules described above can be extended to tame rules.

In summary, we form an (almost) complete picture, depicted in Table 1, of the polynomial combined first-order rewritability for the main guarded- and sticky-based classes of existential rules. Notice that the case of linear rules, even when the schema contains a single predicate, is still open. We believe that linear rules are polynomially combined first-order rewritable, and we give some evidence for this in Section 7. At this point, let us clarify that guarded and tame rules are not first-order rewritable since the data complexity of CQ answering under those classes is PTIME-hard, even when the size and the arity of the underlying schema are bounded. Moreover, sticky rules are strictly more expressive than OWL 2 QL, and thus they are not polynomially first-order rewritable, even if the arity is fixed. Hence, our results enlarge the family of ontology languages which are suitable for OBDA purposes. Full proofs can be found in *https://www.mat.unical.it/datalog-exists/pub/gmp14.pdf*.

2 Preliminaries

Technical Definitions. We define the following pairwise disjoint (infinite countable) sets: a set $\mathbf{C}$ of *constants*, a set $\mathbf{N}$ of *labeled nulls*, and a set $\mathbf{V}$ of regular *variables*. A *term* t is a constant, null, or variable. An *atom* has the form $p(t_1, \ldots, t_n)$, where p is an n-ary predicate, and $t_1, \ldots, t_n$ are terms. Let $arity(p)$ be the arity of the predicate p. For an atom $\underline{a}$, we denote $dom(\underline{a})$ and $var(\underline{a})$ the set of its terms and the set of its variables, respectively; these extend to sets of atoms. Conjunctions of atoms are often identified with the sets of their atoms. An *instance* I is a (possibly infinite) set of atoms $p(\mathbf{t})$, where $\mathbf{t}$ is a tuple of constants and nulls. Given a set of predicates $\mathcal{R}$, let $I_{|\mathcal{R}} = \{p(\mathbf{t}) \in I \mid p \in \mathcal{R}\}$, i.e., the restriction of I on $\mathcal{R}$. A *database* D is a finite instance such that $dom(D) \subset \mathbf{C}$. Given a set T of terms, we denote by $base(T, \mathcal{R})$ the set of atoms that can be formed using terms of T and predicates of $\mathcal{R}$. A *homomorphism* is a substitution $h : \mathbf{C} \cup \mathbf{N} \cup \mathbf{V} \to \mathbf{C} \cup \mathbf{N} \cup \mathbf{V}$ which is the identity on $\mathbf{C}$. Two sets of atoms A, A' are *homomorphically equivalent*, written $A \longleftrightarrow A'$, if there exist homomorphisms h and h' such that $h(A) \subseteq A'$ and $h'(A') \subseteq A$. We assume the reader is familiar with *conjunctive queries (CQs)*. The

answer to q over an instance I is denoted $q(I)$. A Boolean CQ (BCQ) q has a positive answer over I, denoted $I \models q$, if $() \in q(I)$.

A *Datalog*$^\exists$ *rule* (or simply *rule*) σ is a constant-free first-order formula of the form $\forall \mathbf{X} \forall \mathbf{Y}\, \varphi(\mathbf{X}, \mathbf{Y}) \rightarrow \exists \mathbf{Z}\, p(\mathbf{X}, \mathbf{Z})$, where $\mathbf{X} \cup \mathbf{Y} \cup \mathbf{Z} \subset \mathbf{V}$, $\varphi(\mathbf{X}, \mathbf{Y})$ is a conjunction of atoms, and $p(\mathbf{X}, \mathbf{Z})$ is a single atom; $\varphi(\mathbf{X}, \mathbf{Y})$ is the *body* of σ, denoted $body(\sigma)$, while $p(\mathbf{X}, \mathbf{Z})$ is the *head* of σ, denoted $head(\sigma)$. Given a set Σ of rules, $sch(\Sigma)$ is the set of predicates occurring in Σ, and $arity(\Sigma)$ is defined as $\max_{p \in sch(\Sigma)}\{arity(p)\}$. For brevity, we will omit the universal quantifiers in front of rules. An instance I satisfies σ, written $I \models \sigma$, if the following holds: whenever there exists a homomorphism h such that $h(\varphi(\mathbf{X}, \mathbf{Y})) \subseteq I$, then there exists $h' \supseteq h_{|\mathbf{X}}$, where $h_{|\mathbf{X}}$ is the restriction of h on $\mathbf{X}$, such that $h'(p(\mathbf{X}, \mathbf{Z})) \in I$; I satisfies a set Σ of rules, denoted $I \models \Sigma$, if I satisfies each σ of Σ. The *models* of a database D and a set Σ of rules, denoted $mods(D, \Sigma)$, is the set of instances $\{I \mid I \supseteq D \text{ and } I \models \Sigma\}$. The *answer* to a CQ q w.r.t. D and Σ is defined as the set of tuples $ans(q, D, \Sigma) = \bigcap_{I \in mods(D,\Sigma)}\{\mathbf{t} \mid \mathbf{t} \in q(I)\}$. The answer to a BCQ q is *positive*, denoted $D \cup \Sigma \models q$, if $ans(q, D, \Sigma) \neq \varnothing$. The problem of *CQ answering* is defined as follows: given a CQ q, a database D, a set Σ of rules, and a tuple of constants $\mathbf{t}$, decide whether $\mathbf{t} \in ans(q, D, \Sigma)$. In case q is a BCQ, the above problem is called *BCQ answering*. These decision problems are LOGSPACE-equivalent (implicit in (Chandra and Merlin 1977)), and we thus focus only on BCQ answering. For query answering purposes, we can assume, w.l.o.g., that both the BCQ q and the database D contain only predicates of $sch(\Sigma)$.

We are going to employ the *chase procedure*, which works on an instance through the so-called *chase rule* defined as follows. Consider an instance I, and a rule σ as defined above. Then, σ is *applicable* to I if there exists a homomorphism h such that $h(\varphi(\mathbf{X}, \mathbf{Y})) \subseteq I$. Let $I' = I \cup \{h'(p(\mathbf{X}, \mathbf{Z}))\}$, where $h' \supseteq h_{|\mathbf{X}}$ is such that $h'(Z)$ is a "fresh" null not occurring in I, for each $Z \in \mathbf{Z}$. The result of applying σ to I with h is I', and we write $I\langle\sigma, h\rangle I'$; in fact, $I\langle\sigma, h\rangle I'$ defines a single *chase step*. The chase algorithm for a database D and a set Σ of rules consists of an exhaustive application of chase steps in a fair fashion, which leads to a (possibly infinite) model of D and Σ, denoted $chase(D, \Sigma)$; for more details see, e.g., (Calì *et al.* 2012b). The instance $chase(D, \Sigma)$ is a *universal model* of D and Σ, i.e., for each $I \in mods(D, \Sigma)$, there exists a homomorphism that maps $chase(D, \Sigma)$ to I, and thus $D \cup \Sigma \models q$ iff $chase(D, \Sigma) \models q$, for each BCQ q (implicit in (Fagin *et al.* 2005)).

Fragments of Datalog$^\exists$. A rule σ is called *guarded* if there exists $\underline{a} \in body(\sigma)$ which contains all the variables occurring in $body(\sigma)$ (Calì *et al.* 2013). Conventionally, the leftmost such an atom is the *guard* of σ, denoted $guard(\sigma)$, while the non-guard atoms are called the *side* atoms of σ. The class of guarded Datalog$^\exists$, denoted GUARDED, is defined as the family of all possible sets of guarded rules. Given a set $\Sigma \in$ GUARDED, we denote by $sch(\Sigma)^-$ the predicates of Σ which occur in at least one side atom in Σ; clearly, $sch(\Sigma)^- \subseteq sch(\Sigma)$. Guarded rules with one body-atom are called *linear* (Calì *et al.* 2012a), and the corresponding class is denoted LINEAR.

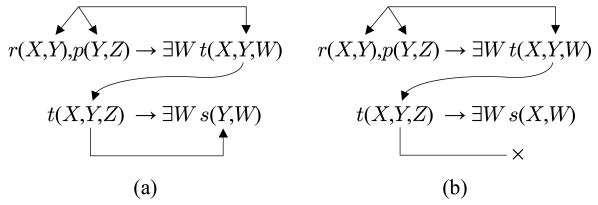

Figure 1: The Sticky Property.

Sticky sets of rules have been proposed in (Calì *et al.* 2012b). The central property of stickiness is that, during the chase, terms which are associated with body-variables that appear more than once (i.e., join variables) always are propagated (or "stick") to the inferred atoms. This is illustrated in Figure 1; the first case is sticky, while the second is not. The associated class is denoted STICKY.

Towards the identification of even more expressive decidable fragments of Datalog$^\exists$, a condition, called *tameness*, which allows the consolidation of guardedness with stickiness has been recently proposed (Gottlob *et al.* 2013). In particular, a set Σ of rules is called *tame* if it can be partitioned into $\{\Sigma[g], \Sigma[s]\}$, where $\Sigma[g]$ is a set of guarded rules and $\Sigma[s]$ is a sticky set of rules, and in addition, none of the rules of $\Sigma[s]$ "feeds" the guard atom of a guarded rule during the construction of the chase. In other words, whenever a guarded rule σ is applied with homomorphism h, then its guard must be mapped by h into an atom obtained from a guarded rule. The corresponding class is denoted TAME.

Fix a class $\mathbb{C} \in \{\mathsf{GUARDED}, \mathsf{LINEAR}, \mathsf{STICKY}, \mathsf{TAME}\}$. Given two integer constants $c > 0$ and $d \geqslant 0$, we define $\mathbb{C}[c, d] = \{\Sigma \in \mathbb{C} \mid |sch(\Sigma)| \leqslant c \text{ and } arity(\Sigma) \leqslant d\}$ as the subclass of $\mathbb{C}$ where the size and the maximum arity of the underlying schema are bounded by c and d, respectively. We define the subclass of $\mathbb{C}$ where the size of the underlying schema is bounded by c as $\mathbb{C}[c, \infty] = \bigcup_{j \geqslant 0} \mathbb{C}[c, j]$, and the subclass of $\mathbb{C}$ where the maximum arity of the underlying schema is bounded by d as $\mathbb{C}[\infty, d] = \bigcup_{i > 0} \mathbb{C}[i, d]$.

3 The Polynomial Combined Approach

The formal definition of polynomial combined first-order rewritability, introduced in (Lutz *et al.* 2009), which is at the basis of the polynomial combined approach, is as follows:

Definition 1 *A Datalog*$^\exists$ *class* $\mathbb{C}$ *is* combined first-order rewritable *if, for every BCQ q, for every database D, and for every $\Sigma \in \mathbb{C}$, it is possible to rewrite:*

- *q and Σ, independently of D, into a first-order query q_Σ,*
- *D and Σ, independently of q, into a database D_Σ,*

such that $D \cup \Sigma \models q$ iff $D_\Sigma \models q_\Sigma$. If q_Σ and D_Σ are constructible in polynomial time, then $\mathbb{C}$ is polynomially combined (P-combined) first-order rewritable.

Combined Reducibility. To show that a Datalog$^\exists$ class is P-combined first-order rewritable, one may exploit the

fact that existing formalisms already enjoy this property. Towards this direction, we introduce the notion of polynomial combined reducibility:

Definition 2 *Consider two Datalog$^\exists$ classes $\mathbb{C}$ and $\mathbb{C}'$. We say that $\mathbb{C}$ is* combined reducible *to $\mathbb{C}'$ if, for every BCQ q, database D, and $\Sigma \in \mathbb{C}$, we can construct:*

- *a BCQ q' independently of D,*
- *a database D' independently of q, and*
- *a set $\Sigma' \in \mathbb{C}'$ independently of q and D,*

such that $D \cup \Sigma \models q$ iff $D' \cup \Sigma' \models q'$. If q', D' and Σ' are constructible in polynomial time, then $\mathbb{C}$ is polynomially combined (P-combined) reducible *to $\mathbb{C}'$, and the employed reduction is called P-combined.*

Obviously, the set of P-combined first-order rewritable Datalog$^\exists$ classes is closed under P-combined reductions:

Theorem 3 *Consider two Datalog$^\exists$ classes $\mathbb{C}, \mathbb{C}'$. If $\mathbb{C}$ is P-combined reducible to $\mathbb{C}'$, and $\mathbb{C}'$ is P-combined first-order rewritable, then also $\mathbb{C}$ is P-combined first-order rewritable.*

The above result suggests the following: to show that a Datalog$^\exists$ class $\mathbb{C}$ is P-combined first-order rewritable, it suffices to reduce query answering under $\mathbb{C}$ to query answering under some P-combined first-order rewritable formalism via a P-combined reduction.

Polynomial Witness Property. A semantic property which is sufficient for P-combined first-order rewritability is the *polynomial witness property*, introduced in (Gottlob and Schwentick 2012). Roughly, a Datalog$^\exists$ class $\mathbb{C}$ enjoys this property if, whenever a query q is entailed by a database D and a set $\Sigma \in \mathbb{C}$, then q is already entailed by a finite part of $chase(D, \Sigma)$ (the witness) of polynomial size in q and Σ.

Definition 4 *A Datalog$^\exists$ class $\mathbb{C}$ enjoys the* polynomial witness property (PWP) *if there exists a polynomial f such that, for every BCQ q, database D, and $\Sigma \in \mathbb{C}$, $D \cup \Sigma \models q$ implies the existence of a chase sequence $I_i \langle h_i, \sigma_i \rangle I_{i+1}$ of D w.r.t. Σ, for $0 \leqslant i < f(|q|, |\Sigma|)$, such that $I_{f(|q|,|\Sigma|)} \models q$.*

The following key result is implicit in (Gottlob and Schwentick 2012):

Proposition 5 *If a Datalog$^\exists$ class $\mathbb{C}$ enjoys the PWP, then $\mathbb{C}$ is P-combined first-order rewritable.*

4 Guarded Datalog$^\exists$

By making different assumptions on the underlying schema, we trace the frontier between those sets of guarded rules which are P-combined first-order rewritable and those which are not. On the one hand, we show that guarded Datalog$^\exists$ is not P-combined first-order rewritable even if the underlying schema contains a single predicate, or even if we focus on unary and binary predicates. On the other hand, guarded Datalog$^\exists$ is P-combined first-order rewritable if we consider only unary predicates, or if the size and the arity of the underlying schema are bounded by an integer constant; the latter forms one of the main results of this paper.

It is well-known that query answering under guarded rules is 2EXPTIME-hard (Calì *et al.* 2013). Since the evaluation of a first-order query is feasible in polynomial space, and also PSPACE $\subsetneq$ 2EXPTIME, we get that GUARDED is not P-combined first-order rewritable. Interestingly, the same argument applies when the underlying schema contains only one predicate. More precisely, query answering under GUARDED$[1, \infty]$ is already 2EXPTIME-hard. This can be shown by a reduction from query answering under arbitrary guarded rules; let us explain the reduction by means of a simple example. Consider the following instance of query answering under guarded Datalog$^\exists$:

$$\begin{array}{rcl} D & = & \{p(a), s(a, b, c)\} \\ \Sigma & = & \{p(X), s(X, Y, Z) \rightarrow \exists W\, r(X, W)\} \\ q & = & \exists X \exists Y\, p(X), r(X, Y). \end{array}$$

The idea is to simulate the predicates p, r and s using a single predicate sim of higher arity; in fact, the atom $p(a)$ can be encoded as $sim(p, a, \diamond_1, \diamond_2, p, r, s, \diamond_1, \diamond_2)$, where $\diamond_1, \diamond_2$ are "dummy" constants not occurring in D, while $s(a, b, c)$ can be encoded as $sim(s, a, b, c, p, r, s, \diamond_1, \diamond_2)$. Then, the rule of Σ will be rewritten as

$$sim(P_1, X, V_1, V_2, \mathbf{T}), sim(P_3, X, Y, Z, \mathbf{T}) \rightarrow \exists W\, sim(P_2, X, W, V_2, \mathbf{T}),$$

where $\mathbf{T} = (P_1, P_2, P_3, V_1, V_2)$, while the query q will be rewritten as

$$\exists X \exists Y \exists \mathbf{T}\, sim(P_1, X, V_1, V_2, \mathbf{T}), sim(P_2, X, Y, V_2, \mathbf{T}).$$

From the above discussion, we get the following result:

Theorem 6 GUARDED$[1, \infty]$ *is not P-combined first-order rewritable.*

The above result follows also from Theorem 3 and the fact that the reduction from multiple predicates to a single predicate is P-combined.

Let us now consider the bounded arity case. Query answering under the description logic $\mathcal{ELI}$, i.e., $\mathcal{EL}$ extended with inverse roles, is EXPTIME-hard (implicit in (Baader *et al.* 2008)). Since each $\mathcal{ELI}$-TBox $\mathcal{T}$ can be translated into a set $\Sigma_\mathcal{T}$ of guarded rules, where $sch(\Sigma_\mathcal{T})$ contains only unary and binary predicates, the next result follows:

Theorem 7 *If* PSPACE $\neq$ EXPTIME*, then* GUARDED$[\infty, 2]$ *is not P-combined first-order rewritable.*

It is believed that PSPACE $\subsetneq$ EXPTIME, and therefore it is unlikely for GUARDED$[\infty, 2]$ to be P-combined first-order rewritable. However, if we concentrate on unary predicates, then it is possible to establish a positive result. In particular, a set $\Sigma \in$ GUARDED$[\infty, 1]$ may contain only rules of the form $p_1(X), \ldots, p_n(X) \rightarrow \underline{a}$, for $n \geqslant 1$, where $\underline{a}$ is either $p(X)$ or $\exists Z\, p(Z)$. This fact allows us to show that GUARDED$[\infty, 1]$ enjoys the PWP. Hence, by Proposition 5, we immediately get the following result:

Theorem 8 GUARDED$[\infty, 1]$ *is P-combined first-order rewritable.*

Let us now investigate whether guarded Datalog$^\exists$ is P-combined first-order rewritable if we bound both the size and the arity of the schema. Notice that query answering under GUARDED$[c, d]$ is NP-complete (Calì *et al.* 2013), and thus the answer to this question is likely to be affirmative; the rest of this section is devoted to show that this is the case. Towards this direction, we exploit the following result established in (Gottlob and Schwentick 2012):

Proposition 9 $\mathsf{LINEAR}[\infty, d]$ *enjoys the PWP.*

The above result, together with Proposition 5, implies that $\mathsf{LINEAR}[\infty, d]$ is P-combined first-order rewritable. Therefore, to establish our desired result, by Theorem 3, it suffices to show that $\mathsf{GUARDED}[c, d]$ is P-combined reducible to $\mathsf{LINEAR}[\infty, d]$. A key notion employed in the studies of query answering under guarded rules is the *type* of an atom. Given a database D and a set $\Sigma \in \mathsf{GUARDED}$, the type of an atom $\underline{a} \in \mathit{chase}(D, \Sigma)$ is defined as $\mathit{type}(\underline{a}, D, \Sigma) = \{\underline{b} \in \mathit{chase}(D, \Sigma) \mid \mathit{dom}(\underline{b}) \subseteq \mathit{dom}(\underline{a})\}$. Intuitively, whenever $\underline{a}$ is associated with the guard atom of a rule σ during a chase step application, then the side atoms of σ are necessarily associated with atoms of $\mathit{type}(\underline{a}, D, \Sigma)$. The abstract idea underlying our P-combined reduction of query answering under $\mathsf{GUARDED}$ to query answering under LINEAR is as follows: given a guarded rule σ, encode the shape of the type τ of $\mathit{guard}(\sigma)$ in a predicate $[\tau]$, and then replace σ with a linear rule of the form $[\tau](\mathbf{X}, \mathbf{Y}) \rightarrow \exists Z\, p(\mathbf{X}, Z)$. Let us now give some extra terminology which is needed for the definition of the reduction.

4.1 Technical Definitions and Notation

Fix two sets $\mathcal{R}, \mathcal{R}'$ of predicates, where $\mathcal{R}' \subseteq \mathcal{R}$. A *guarded type* for a predicate $p \in \mathcal{R}$ w.r.t. $\mathcal{R}'$ is defined as a pair $(\underline{a}, S)$, where $\underline{a}$ is an atom of the form $p(t_1, \ldots, t_n)$ with $t_i \in \{1, \ldots, \mathit{arity}(p)\}$, and $S \subseteq \mathit{base}(\mathit{dom}(\underline{a}), \mathcal{R}') \setminus \{\underline{a}\}$. Let $\mathit{gtypes}(p, \mathcal{R}')$ be the set of all possible guarded types for p w.r.t. $\mathcal{R}'$. We define the guarded types of $\mathcal{R}$ w.r.t. $\mathcal{R}'$ as the set $\mathit{gtypes}(\mathcal{R}, \mathcal{R}') = \{\mathit{gtypes}(p, \mathcal{R}')\}_{p \in \mathcal{R}}$. Given $\tau = (\underline{a}, S) \in \mathit{gtypes}(\mathcal{R}, \mathcal{R}')$, we refer to $\underline{a}$ by $\mathit{guard}(\tau)$ and to $(\{\underline{a}\} \cup S)$ as $\mathit{atoms}(\tau)$, respectively. The arity of τ, denoted $\mathit{arity}(\tau)$, is the maximum integer occurring in $\mathit{guard}(\tau)$.

Example 1 Let $\mathcal{R} = \{p, s, r\}$ and $\mathcal{R}' = \{s, r\}$, where p is a ternary predicate, while s and r are binary predicates. A possible guarded type τ for p w.r.t. $\mathcal{R}'$ is the pair

$$(p(1,1,2), \{s(1,2), s(1,1), r(2,1), r(2,2)\}),$$

with $\mathit{arity}(\tau) = 2$. ∎

Roughly speaking, a guarded type describes the equality type of a guard-atom and a set of further side atoms which are "covered" by the guard. The integer arguments occurring in a guarded type, which can be seen as constants, are mere indicators of equalities among arguments. It is important to clarify that their actual values have no semantic meaning beyond this. For normalization reasons, we adopt the convention that the integers appearing in $\mathit{guard}(\tau)$, for some guarded type τ, will always start by 1, and will be consecutive, except for repeated integers. Thus, when constructing new guarded types from existing ones, we will have to rename the arguments of a newly constructed set of atoms in order to follow the above convention. To this purpose, we use a renaming function ρ whose formal definition is obvious and is omitted; for example, given $\tau = (\underline{a}, S)$, where $\underline{a} = p(2, 2, 4, 1)$ and $S = \{s(1,2), s(4,1)\}$, $\rho(\mathit{atoms}(\tau)) = \{p(1,1,2,3), s(3,1), s(2,3)\}$.

Given a guarded type $\tau = (\underline{a}, S)$, and a tuple of terms $\mathbf{t} = (t_1, \ldots, t_n)$, where $n = \mathit{arity}(\tau)$, the *instantiation* of τ over $\mathbf{t}$, denoted $\tau(\mathbf{t})$, is the set of atoms $\{h_{\mathbf{t}}(\underline{b}) \mid \underline{b} \in \mathit{atoms}(\tau)\}$, where $h_{\mathbf{t}} = \{i \rightarrow t_i\}_{i \in [n]}$; for brevity, $[n] = \{1, \ldots, n\}$.

Example 2 Let τ be the guarded type for p given in Example 1. Then, $\tau((a, b))$ is the pair

$$\{p(a,a,b), s(a,b), s(a,a), r(b,a), r(b,b)\}$$

with $h_{(a,b)} = \{1 \rightarrow a, 2 \rightarrow b\}$. ∎

The *projection* of $\tau = (\underline{a}, S)$ over $I \subseteq [\mathit{arity}(\tau)]$ is the set of atoms $\Pi_I(\tau) = \{\underline{b} \in \mathit{atoms}(\tau) \mid \mathit{dom}(\underline{b}) \subseteq I\}$. E.g., given $\tau = (p(1,2,3), \{r(1), s(2)\})$, then $\Pi_{\{1,2\}}(\tau) = \{r(1), s(2)\}$. Having the above notions in place, we are now ready to show that $\mathsf{GUARDED}[c, d]$ is P-combined reducible to $\mathsf{LINEAR}[\infty, d]$.

4.2 A Reduction from GUARDED to LINEAR

Let us first give a general reduction GL of query answering under guarded to query answering under linear Datalog$^\exists$. Fix a database D and a set $\Sigma_0 \in \mathsf{GUARDED}$. We are going to construct a database $D^\star$ and a set $\Sigma^\star \in \mathsf{LINEAR}$ such that, for every BCQ q, $D \cup \Sigma_0 \models q$ iff $D^\star \cup \Sigma^\star \models q$.

Step 1: Normalization. The first step is to normalize Σ_0 in such a way that each rule contains at most one existentially quantified variable which occurs at the last position of the head-atom. More precisely, for a rule $\sigma \in \Sigma_0$, if σ is already in normal form, then $\mathsf{N}(\sigma) = \{\sigma\}$; otherwise, assuming that $\mathit{head}(\sigma) = \underline{a}$, $\mathbf{X} = \mathit{var}(\mathit{body}(\sigma)) \cap \mathit{var}(\mathit{head}(\sigma))$, and $Z_1, \ldots, Z_m$ are the existentially quantified variables of σ, let $\mathsf{N}(\sigma)$ be the set of rules

$$\begin{array}{rcl}
\mathit{body}(\sigma) & \rightarrow & \exists Z_1\, p^1_\sigma(\mathbf{X}, Z_1) \\
p^1_\sigma(\mathbf{X}, Z_1) & \rightarrow & \exists Z_2\, p^2_\sigma(\mathbf{X}, Z_1, Z_2) \\
& \ldots & \\
p^{m-1}_\sigma(\mathbf{X}, Z_1, \ldots, Z_{m-1}) & \rightarrow & \exists Z_m\, p^m_\sigma(\mathbf{X}, Z_1, \ldots, Z_m) \\
p^m_\sigma(\mathbf{X}, Z_1, \ldots, Z_m) & \rightarrow & \underline{a},
\end{array}$$

where p^i_σ is an $(|\mathbf{X}|+i)$-ary auxiliary predicate not occurring in $\mathit{sch}(\Sigma_0)$, for each $i \in [m]$. Let $\Sigma = \bigcup_{\sigma \in \Sigma_0} \mathsf{N}(\sigma)$. □

A key tool that we shall use in our reduction is the *completion* of a (finite) instance I w.r.t. Σ, i.e., the process of enriching I with all the possible atoms that can be entailed from I and Σ without altering the domain of I. Formally, the result of such a process, denoted $\mathit{complete}(I, \Sigma)$, is the set of atoms $\{\underline{a} \mid \mathit{dom}(a) \subseteq \mathit{dom}(I)$ and $(I \cup \Sigma) \models \underline{a}\}$. It is important to say that the atom entailment problem under guarded rules is decidable (Calì *et al.* 2013), and thus the (finite) set $\mathit{complete}(I, \Sigma)$ can be explicitly computed. Henceforth, a guarded type for a predicate $p \in \mathit{sch}(\Sigma)$ is always w.r.t. $\mathit{sch}(\Sigma)^-$, and we will simply write $\mathit{gtypes}(p)$ for the set $\mathit{gtypes}(p, \mathit{sch}(\Sigma)^-)$. Moreover, we will refer to $\mathit{gtypes}(\mathit{sch}(\Sigma), \mathit{sch}(\Sigma)^-)$ as $\mathit{gtypes}(\Sigma)$.

Step 2: Database Construction. We define

$$D^\star = \left\{ [\tau](\mathbf{t}^1) \;\middle|\; \begin{array}{l} p(\mathbf{t}) \in D, \\ \tau \in \mathit{gtypes}(p), \\ \mathit{guard}(\tau) \simeq p(\mathbf{t}), \\ \tau(\mathbf{t}^1) \subseteq \mathit{complete}(D, \Sigma) \end{array} \right\},$$

where $[\tau]$, for some guarded type τ, is a new $arity(\tau)$-ary predicate not occurring in $sch(\Sigma)$, $guard(\tau) \simeq p(\mathbf{t})$ means that $guard(\tau)$ and $p(\mathbf{t})$ have the same equality type (e.g., $p(1,2,1,3,2) \simeq p(t_1,t_2,t_1,t_3,t_2)$), and $\mathbf{t}^1$ is obtained from $\mathbf{t}$ by keeping only the first occurrence of each term occurring in $\mathbf{t}$ (e.g., if $\mathbf{t} = (t_1,t_2,t_1,t_3,t_2)$, then $\mathbf{t}^1 = (t_1,t_2,t_3)$). Intuitively, an atom $[\tau](\mathbf{t}^1)$, occurring in $D^\star$ due to an atom $p(\mathbf{t}) \in D$, encodes a possible subset of $chase(D,\Sigma)$ which contains the atoms that may act as side atoms whenever $p(\mathbf{t})$ plays the role of the guard in a chase application. □

Example 3 Assume that $D = \{p(a,a), p(a,b), s(b)\}$ and $\Sigma = \{p(X,Y), s(Y) \rightarrow s(X)\}$. For the atom $p(a,a) \in D$, an atom $[\tau](a)$ will be added in $D^\star$, where τ is a guarded type of the form $(p(1,1), S)$. Observe that the only atom, apart from $p(a,a)$, which is entailed by D and Σ, and contains only the term a, is $s(a)$; therefore, S is either empty or is the set $\{s(1)\}$. Consequently, for $p(a,a)$, the atoms $[(p(1,1),\varnothing)](a)$, $[(p(1,1),\{s(1)\})](a)$ will be added in $D^\star$. Consider now the atom $p(a,b) \in D$. It is easy to verify that the set of atoms $\bigcup_{S \in \mathcal{P}(\{p(1,1),s(1),s(2)\})}\{[(p(1,2),S)]\}$, where $\mathcal{P}(X)$ denotes the powerset of X, will be added in $D^\star$. Finally, for $s(b) \in D$, only the atom $[(s(1),\varnothing)](b)$ will be added in $D^\star$, since no other atom than $s(b)$, which contains only the term b, is entailed by D and Σ. ■

Step 3: Rules Construction. The set $\Sigma^\star$ consists of the following two groups of rules:

1. The *type generator*, denoted $\Sigma^\star_G$, which is responsible for generating new guarded types from existing ones, and
2. The *unfolder*, denoted $\Sigma^\star_U$, that is responsible for unfolding a derived guarded type τ, i.e., to explicitly construct the atoms over the original schema $sch(\Sigma_0)$ which are encoded in τ so that they can be queried directly.

Let us now define formally $\Sigma^\star_G$ and $\Sigma^\star_U$; let $w = arity(\Sigma)$.

Step 3.1: Type Generator. For each $\sigma \in \Sigma$ of the form

$$body(\sigma) \rightarrow \exists Z\, p(X_1,\ldots,X_n,Z),$$

and for each guarded type $\tau \in gtypes(\Sigma)$ for which there exists a homomorphism h such that $h(body(\sigma)) \subseteq atoms(\tau)$ and $h(guard(\sigma)) = guard(\tau)$, in $\Sigma^\star_G$ there exists the rule:

$$[\tau](V_1,\ldots,V_m) \rightarrow \exists Z\, [\tau'](W_1,\ldots,W_k,Z),$$

where $m = arity(\tau)$, and

- $\{V_1,\ldots,V_m\} \subseteq var(body(\sigma))$, and $h(V_i) = i$, for each $i \in [m]$,
- $\{W_\ell\}_{\ell\in[k]} \subseteq \{X_\ell\}_{\ell\in[n]}$ and $(h(W_1),\ldots,h(W_k)) = (h(X_1),\ldots,h(X_n))^1$,
- $\tau' = (\rho(\underline{a}), (complete(\rho(\{\underline{a}\}\cup S),\Sigma)\setminus\{\rho(\underline{a})\})_{|sch(\Sigma)^-})$, where $\underline{a}$ is the atom $p(h(X_1),\ldots,h(X_n),w+1)$ and S is the set of atoms $\Pi_{\{h(X_1),\ldots,h(X_n)\}}(\tau)$.

No other rules occur in $\Sigma^\star_G$. □

Example 4 Assume that Σ consists of the rules

$$\sigma_1 \;:\; p(X,Y,X,Z,W), s(X,Z) \rightarrow \exists U\, r(Z,Y,X,U)$$
$$\sigma_2 \;:\; r(X,X,Y,Z) \rightarrow t(X,Z).$$

Let us focus our attention on σ_1. A possible guarded type τ for the predicate of the guard of σ_1, that is, the predicate p, for which there exists a homomorphism that maps $body(\sigma_1)$ to $atoms(\tau)$, and $guard(\sigma_1)$ to $guard(\tau)$ is:

$$\tau = (p(1,2,1,2,3), \{s(1,1), s(1,2)\}).$$

Therefore, in $\Sigma^\star_G$ we have the linear rule:

$$[\tau](X,Y,W) \rightarrow \exists U\, [\tau'](Y,X,U),$$

where $\tau' = (r(1,1,2,3), \{s(2,2), s(2,1), t(1,3)\})$. ■

Step 3.2: Unfolder. For each $\tau \in gtypes(\Sigma_0)$, if $guard(\tau)$ is of the form $p(t_1,\ldots,t_n)$, in $\Sigma^\star_U$ there exists the rule:

$$[\tau](V_1,\ldots,V_m) \rightarrow p(W_1,\ldots,W_n),$$

where

- $\{V_1,\ldots,V_m\} \subset \mathbf{V}$ and $(V_1,\ldots,V_m) = (W_1,\ldots,W_n)^1$,
- $t_i = t_j$ implies $W_i = W_j$, for each $i,j \in [n]$.

No other rules occur in $\Sigma^\star_U$. □

Example 5 Consider the guarded type

$$\tau = (p(1,2,1,2,3), \{s(1,1), s(1,2)\}).$$

Due to τ, in $\Sigma^\star_U$ we have the linear rule:

$$[\tau](X,Y,Z) \rightarrow p(X,Y,X,Y,Z).$$

Notice that, for any type of the form $(p(1,2,1,2,3), S)$, i.e., that has the same guard as τ, the rule added to $\Sigma^\star_U$ is the same as the one above. ■

We proceed to show that GL is indeed a reduction of query answering under guarded Datalog$^\exists$ to query answering under linear Datalog$^\exists$. To this aim, we exploit the central property of the type of an atom. In particular, the subtree of the *guarded chase forest* of D and Σ — the forest obtained from $chase(D,\Sigma)$ by keeping only the guards and their children — rooted at $\underline{a}$ is determined by $type(\underline{a},D,\Sigma)$ (modulo renaming of nulls) (Calì *et al.* 2013). This implies that, given an atom $\underline{a} = p(t_1,\ldots,t_n,z)$, where z is a null value invented in $\underline{a}$, we can construct $type(a,D,\Sigma)$ from $\underline{a}$ and the restriction of $type(a,D,\Sigma)$ to $\{t_1,\ldots,t_n\}$. This justifies the definition of the type generator, where we complete the known part of the type, denoted S, of a generated atom $\underline{a}$ by calling the procedure $complete$ using as a database the instance $(\{\underline{a}\} \cup S)$.

The above property allows us to show two useful lemmas. The first one asserts that, for each $\underline{a} \in chase(D,\Sigma)$, GL encodes $type(\underline{a},D,\Sigma)$ in a complete way. The function $\gamma_{\underline{a}}$ renames the arguments of an atom of $type(\underline{a},D,\Sigma)$ into integers. For example, given $\underline{a} = p(a,z_1,a,b)$, then $\gamma_{\underline{a}}(\underline{a}) = p(1,2,1,3)$; the definition of $\gamma_{\underline{a}}$ is obvious and it is omitted. Let $\tau_{\underline{a}} = (\gamma_{\underline{a}}(\underline{a}), \gamma_{\underline{a}}(type(\underline{a},D,\Sigma)\setminus\{\underline{a}\}))$.

Lemma 10 *There is a homomorphism h such that, $p(\mathbf{t}) \in chase(D, \Sigma)$ implies $[\tau_{p(\mathbf{t})}](h(\mathbf{t}^1)) \in chase(D^\star, \Sigma^\star_G)$.*

The second technical lemma states that the reduction GL encodes in a sound way the various types that can be realized in the instance constructed by the chase:

Lemma 11 *There is a homomorphism h such that, $[\tau](\mathbf{t}) \in chase(D^\star, \Sigma^\star_G)$ implies $h(\tau(\mathbf{t})) \subseteq chase(D, \Sigma)$.*

By exploiting the above technical lemmas, we can show that $chase(D, \Sigma_0)$ and $chase(D^\star, \Sigma^\star)$, after eliminating the atoms with predicates not occurring in $sch(\Sigma_0)$, are homomorphically equivalent:

Proposition 12 *It holds that,*

$$chase(D, \Sigma_0) \longleftrightarrow chase(D^\star, \Sigma^\star)_{|sch(\Sigma_0)}.$$

Proof (sketch). By construction, there exists a homomorphism μ that maps $chase(D, \Sigma_0)$ to $chase(D, \Sigma)_{|sch(\Sigma_0)}$. Due to $\Sigma^\star_U$, we get that h_1, provided by Lemma 10, maps $chase(D, \Sigma)_{|sch(\Sigma_0)}$ to $chase(D^\star, \Sigma^\star)_{|sch(\Sigma_0)}$. Therefore,

$$h_1(\mu(chase(D, \Sigma_0))) \subseteq chase(D^\star, \Sigma^\star)_{|sch(\Sigma_0)}.$$

Conversely, let h_2 be the homomorphism as in Lemma 11. Since $chase(D^\star, \Sigma^\star)_{|sch(\Sigma_0)} \subseteq \cup_{[\tau](\mathbf{t}) \in chase(D^\star, \Sigma^\star_G)} \tau(\mathbf{t})$, h_2 maps $chase(D^\star, \Sigma^\star)_{|sch(\Sigma_0)}$ to $chase(D, \Sigma)_{|sch(\Sigma_0)}$. Clearly, by construction, there exists a homomorphism μ' that maps $chase(D, \Sigma)_{|sch(\Sigma_0)}$ to $chase(D, \Sigma_0)$. Thus,

$$\mu'(h_2(chase(D^\star, \Sigma^\star)_{|sch(\Sigma_0)})) \subseteq chase(D, \Sigma_0).$$

Consequently, due to $(h_1 \circ \mu)$ and $(\mu' \circ h_2)$, we get that $chase(D, \Sigma_0) \longleftrightarrow chase(D^\star, \Sigma^\star)_{|sch(\Sigma_0)}$. □

Using Proposition 12, we can show that, for every BCQ q, $chase(D, \Sigma_0) \models q$ iff $chase(D^\star, \Sigma^\star) \models q$, since q contains only predicates of $sch(\Sigma_0)$, and the next result follows:

Theorem 13 *For every BCQ q, $D \cup \Sigma_0 \models q$ iff $D^\star \cup \Sigma^\star \models q$.*

A natural question is whether GL is a P-combined reduction. Recall that we are interested in sets of guarded rules where the size and the maximum arity of the underlying schema are bounded by a constant. In this case, as we show below, indeed GL is P-combined.

4.3 The Reduction GL is P-combined

By construction, $D^\star$ depends only on D and Σ_0, while $\Sigma^\star$ depends only on Σ_0; hence, GL is a combined reduction. Thus, to establish the desired result, it remains to show that, if $\Sigma_0 \in \mathsf{GUARDED}[c, d]$, then $D^\star$ and $\Sigma^\star$ are constructible in polynomial time. Via a combinatorial analysis, we can establish some upper bounds on the number of all possible guarded types, and also on the size of a guarded type τ, denoted $|\tau|$, and defined as $|atoms(\tau)|$.

Lemma 14 *It holds that,*

1. $|gtypes(p)| \leqslant arity(p)^{arity(p)} \cdot 2^{|sch(\Sigma)^-| \cdot arity(p)^w}$, *for each $p \in sch(\Sigma)$,*
2. $|gtypes(\Sigma)| \leqslant |sch(\Sigma)| \cdot w^w \cdot 2^{|sch(\Sigma)^-| \cdot w^w}$, *and*
3. $|\tau| \leqslant |sch(\Sigma)| \cdot w^w$, *for each $\tau \in gtypes(\Sigma)$.*

Henceforth, we assume that $\Sigma_0 \in \mathsf{GUARDED}[c, d]$. Observe that the maximum number of existentially quantified variables that can appear in a rule of Σ_0 is $arity(\Sigma_0)$. Therefore, $|\Sigma| \in \mathcal{O}(|\Sigma_0|)$ and $|sch(\Sigma)| \in \mathcal{O}(|\Sigma_0|)$. Since the auxiliary predicates introduced during the normalization procedure do not appear in side atoms, we get that $sch(\Sigma)^- \subseteq sch(\Sigma_0)$, and thus $|sch(\Sigma)^-| \leqslant c$. It is important to note that $arity(\Sigma) = arity(\Sigma_0) \leqslant d$.

To construct $D^\star$ we need, for each atom $p(\mathbf{t}) \in D$, and for each $\tau \in gtypes(p)$ such that $guard(\tau) \simeq p(\mathbf{t})$, to check whether $D \cup \Sigma \models \underline{a}$, for each $\underline{a} \in \tau(\mathbf{t}^1)$. Importantly, the latter (atom entailment) check is feasible in polynomial time; this follows from the fact that atomic query answering under $\mathsf{GUARDED}[c, d]$ can be performed in polynomial time in D and Σ (Calì *et al.* 2013). In the worst case, we need to apply this polynomial check $\sum_{p(\mathbf{t}) \in D} \sum_{\tau \in gtypes(p)} |\tau|$ times. By Lemma 14, and since $|sch(\Sigma)^-| \leqslant c$ and $arity(p) \leqslant d$, for each $p \in sch(\Sigma)$, the crucial entailment check must be performed $|D| \cdot |sch(\Sigma)| \cdot 2^{c \cdot d^d} \cdot d^{2d} \in \mathcal{O}(|D| \cdot |\Sigma_0|)$ times, and hence $D^\star$ is constructible in polynomial time.

We now consider the construction of $\Sigma^\star$. By exploiting Lemma 14, one can show that the maximum number of rules that can appear in $\Sigma^\star_G$ is $\mathcal{O}(|\Sigma_0|^2)$. The construction of each linear rule (apart from some easy steps) amounts to compute the set of atoms $complete(I, \Sigma)_{|sch(\Sigma)^-}$, where I is an instance of size bounded by $|\tau|$ with τ the guarded type under consideration. This requires $\mathcal{O}(|\Sigma_0|^d)$ polynomial entailment checks, and hence $\Sigma^\star_G$ is constructible in polynomial time. To construct the unfolder $\Sigma^\star_U$, we actually need to construct $|gtypes(\Sigma_0)|$ linear rules, each of which can be constructed in time $\mathcal{O}(1)$. Thus, by Lemma 14, the construction of $\Sigma^\star_U$ can be carried out in time $\mathcal{O}(1)$.

From the above analysis, we conclude that $D^\star$ and $\Sigma^\star$ are constructible in polynomial time, and the next result follows:

Proposition 15 $\mathsf{GUARDED}[c, d]$ *is P-combined reducible to* $\mathsf{LINEAR}[\infty, d]$.

By combining Theorem 3 with Propositions 5, 9 and 15, the main result of this section follows:

Theorem 16 $\mathsf{GUARDED}[c, d]$ *is P-combined first-order rewritable.*

5 Tame Datalog$^\exists$

In this section, we investigate the question whether the class of tame rules is P-combined first-order rewritable whenever the size and the arity of the schema are bounded. One may claim that the technique proposed for guarded rules can be directly applied on tame rules in order to obtain the desired result. More precisely, one can suggest the following: it can be shown that $\mathsf{TAME}[c, d]$ is P-combined reducible to a P-combined first-order rewritable class — which in turn implies that $\mathsf{TAME}[c, d]$ is P-combined first-order rewritable — by rewriting the given database D into $D^\star$, and the guarded part $\Sigma[g]$ of the given tame set $\Sigma \in \mathsf{TAME}[c, d]$ into $\Sigma[g]^\star$, while keeping the sticky part $\Sigma[s]$ of Σ untouched. Although this approach is quite promising, there are two non-trivial difficulties:

- $(\Sigma[g]^\star \cup \Sigma[s])$ is sticky, and it is not known whether $\mathsf{STICKY}[\infty, d]$ is P-combined first-order rewritable, and
- GL is not complete on tame rules since a side atom of a guarded rule may depend on the sticky part.

In what follows, we explore the combined approach for sticky rules, and we show that $\mathsf{STICKY}[\infty, d]$ is P-combined first-order rewritable. We also reveal the key reason of the incompleteness of GL, and we briefly explain how it can be adapted in order to regain completeness.

5.1 Stickiness and the Combined Approach

Query answering under sticky sets of rules is EXPTIME-complete (Calì *et al.* 2012b). Interestingly, the problem remains EXPTIME-hard even if the underlying schema contains only one predicate. This can be established by employing the same construction given in the previous section to show an analogous result for guarded rules. Thus, we get the following impossibility result:

Theorem 17 *If* PSPACE $\neq$ EXPTIME*, then* $\mathsf{STICKY}[1, \infty]$ *is not P-combined first-order rewritable.*

Let us now show that $\mathsf{STICKY}[\infty, d]$ is P-combined first-order rewritable by showing first that it enjoys the polynomial witness property. Consider a BCQ q, a database D, and a set $\Sigma \in \mathsf{STICKY}[\infty, d]$. Assume that $D \cup \Sigma \models q$. This implies that there exists a homomorphism h such that $h(q) = H \subseteq \mathit{chase}(D, \Sigma)$. Consider now the proof of H, i.e., the (finite) part $P \subseteq \mathit{chase}(D, \Sigma)$ due to which H is generated. Because of stickiness, apart from the terms occurring in H, all the other terms in P do not participate in a join operation during the construction of P, and therefore can be seen as "don't care" terms. Given an atom $\underline{a} \in P$, let $\underline{a}_\star$ be the atom obtained from $\underline{a}$ by replacing the "don't care" terms, i.e., the terms of $\mathit{dom}(\underline{a}) \setminus \mathit{dom}(H)$, with $\star$. It is possible to show that a witness P' of q can always be constructed such that, for every $\underline{a}, \underline{a}' \in P'$, $\underline{a} \neq \underline{a}'$ implies $\underline{a}_\star \neq \underline{a}'_\star$. Since $|P'| \leqslant n \cdot (|\mathit{dom}(H)| + 1)^d$, where $n = |\mathit{sch}(\Sigma)|$, and $|\mathit{dom}(H)| \leqslant |q| \cdot d$, we conclude that a witness of size $\mathcal{O}(n \cdot |q|^d)$ always exists, and the next result follows:

Lemma 18 $\mathsf{STICKY}[\infty, d]$ *enjoys the PWP.*

The above result improves an existing one asserting that $\mathsf{STICKY}[c, d]$ enjoys the PWP (Gottlob and Schwentick 2012). By Proposition 5 and Lemma 18 we get that:

Theorem 19 $\mathsf{STICKY}[\infty, d]$ *is P-combined first-order rewritable.*

5.2 A Reduction from TAME to STICKY

We now concentrate on the reduction GL. We first show that it is not complete on tame rules. Let $D = \{p(a, b), p(b, c)\}$, and Σ be the tame set of rules consisting of:

$$\begin{array}{lcl} \sigma_1 & : & p(X, Y) \rightarrow \exists Z\, r(Y, Z) \\ \sigma_2 & : & r(X, Y), s(Y, X) \rightarrow \exists Z\, r(Y, Z) \\ \sigma_3 & : & r(X, Y), p(X, Z) \rightarrow s(Y, X), \end{array}$$

where the guarded part $\Sigma[g] = \{\sigma_1, \sigma_2\}$ and the sticky part $\Sigma[s] = \{\sigma_3\}$. The chase of D w.r.t. Σ is

$$C = \{p(a, b), p(b, c), r(b, z_1), r(c, z_2), s(z_1, b), r(z_1, z_3)\}.$$

Let us now construct $D^\star$ and $\Sigma[g]^\star$. It is easy to verify that

$$D^\star = \{[(p(1, 2), \varnothing)](a, b), [(p(1, 2), \varnothing)](b, c)\}.$$

Due to σ_1 and the guarded type $(p(1, 2), \varnothing)$ for p, in $\Sigma[g]^\star$ we have the linear rule

$$[(p(1, 2), \varnothing)](X, Y) \rightarrow \exists Z\, [(r(1, 2), \varnothing)](Y, Z).$$

Moreover, due to σ_2 and the type $(r(1, 2), \{s(2, 1)\})$ for r, in $\Sigma[g]^\star$ we have the linear rule

$$[(r(1, 2), \{s(2, 1)\})](X, Y) \rightarrow \exists Z\, [(r(1, 2), \varnothing)](Y, Z).$$

Notice that several other rules occur in $\Sigma[g]^\star$. However, for this particular example they are meaningless, and therefore they are omitted for brevity; e.g., rules that must occur in $\Sigma[g]^\star$ due to σ_1 and a type of the form $(p(1, 1), S)$ will never be triggered. In addition, in $\Sigma[g]^\star$ we have the linear rules

$$\begin{array}{l} [(p(1, 2), \varnothing)](X, Y) \rightarrow p(X, Y) \\ [(r(1, 2), \varnothing)](X, Y) \rightarrow r(X, Y) \\ [(r(1, 2), \{s(2, 1)\})](X, Y) \rightarrow r(X, Y). \end{array}$$

Observe that $\mathit{chase}(D^\star, \Sigma[g]^\star \cup \Sigma[s])_{|\mathit{sch}(\Sigma)}$ is

$$C^\star = \{p(a, b), p(b, c), r(b, z_1^\star), r(c, z_2^\star), s(z_1^\star, b)\}.$$

The fact that there exists a homomorphism that maps $C^\star$ to C implies that, for every BCQ q, $C^\star \models q$ implies $C \models q$. Actually, the reduction GL is sound even if we consider tame rules. However, it is not also complete: consider the BCQ $q = \exists X \exists Y \exists Z\, r(X, Y), r(Y, Z)$, and observe that $C \models q$ but $C^\star \not\models q$. The reason why $C^\star \not\models q$ is because GL failed to encode the fact that an atom $r(z_1^\star, z_3^\star)$ must also be generated during the construction of $\mathit{chase}(D^\star, \Sigma[g]^\star \cup \Sigma[s])$. More precisely, the crucial linear rule σ of the form

$$[(p(1, 2), \varnothing)](X, Y) \rightarrow \exists Z\, [(r(1, 2), \{s(2, 1)\})](Y, Z)$$

is missing from $\Sigma[g]^\star$. Because of the above rule, the atom $[(r(1, 2), \{s(2, 1)\}](b, z_1^\star)$ will be obtained during the construction of the chase, which in turn will trigger the rule

$$[(r(1, 2), \{s(2, 1)\})](X, Y) \rightarrow \exists Z\, [(r(1, 2), \varnothing)](Y, Z)$$

and the atom $[(r(1, 2), \varnothing)](z_1^\star, z_3^\star)$ will be generated. Then, due to the rule

$$[(r(1, 2), \varnothing)](X, Y) \rightarrow r(X, Y)$$

the desired atom $r(z_1^\star, z_3^\star)$ will be eventually obtained. Thus, in order to reveal the real reason why GL is not complete on tame rules, we need to understand why the crucial rule σ does not occur in $\Sigma[g]^\star$. Clearly, σ should exist in $\Sigma[g]^\star$ due to σ_1 and a guarded type τ of the form $(p(1, 2), S)$, where $S \subseteq \mathit{base}(\{1, 2\}, \mathit{sch}(\Sigma))$. However,

$$\begin{array}{rcl} \tau' & = & (r(1, 2), \mathit{complete}(\{r(1, 2)\} \cup \Pi_{\{2\}}(\tau), \Sigma)) \\ & = & (r(1, 2), \varnothing), \end{array}$$

even if $S = \mathit{base}(\{1, 2\}, \mathit{sch}(\Sigma))$, and therefore there is no way to obtain the head atom $\exists Z\, [(r(1, 2), \{s(1, 2)\})](Y, Z)$. This is because, in order to obtain $s(2, 1)$ during the completion of $(\{r(1, 2)\} \cup \Pi_{\{2\}}(\tau))$ w.r.t. Σ, an atom of the form $p(1, X)$ is needed. However, such an atom does not occur

in $\mathit{complete}(\{r(1,2)\} \cup \Pi_{\{2\}}(\tau), \Sigma)$, and this is exactly the source of incompleteness. It is important to observe that the atom $p(1, X)$ is needed to trigger the rule σ_3, i.e., the sticky rule of Σ, and since X is not propagated in the inferred atom, by stickiness, we can safely conclude that such a term X will never participate in a join operation during the completion process. Hence, what is important is not the actual value of X but the existence of a witness for X.

From the above discussion, we conclude that the way to regain completeness is to add in $\mathit{side}(\tau)$ a witness atom $p(1, \star)$ for $p(1, X)$, and let

$$\tau' = (r(1,2), \mathit{complete}(\{r(1,2)\} \cup \Pi_{\{2,\star\}}(\tau), \Sigma)),$$

and also add an additional unfold rule of the form

$$[(r(1,2), \{s(2,1), p(1,\star)\})](X,Y) \rightarrow \exists Z\, p(X,Z)$$

in order to explicitly unfold the witness atom $p(1, \star)$ by inventing a "fresh" null for each occurrence of $\star$. Notice that in this particular example, the above rule is not needed since $p(1, \star)$ is a witness of the database atom $p(b, c)$, and thus it is not necessary to regenerate it. However, in general, such unfolding rules are crucial.

The above approach can be generalized in order to obtain a combined reduction, denoted TS, of query answering under tame sets of rules to query answering under sticky sets of rules. Let us clarify that $(\Sigma[g]^\star \cup \Sigma[s])$ is indeed sticky since, by construction, for each $\sigma \in \Sigma[g]^\star$, every variable in $\mathit{body}(\sigma)$ occurs only once, and thus there is no way to violate stickiness after the merging of $\Sigma[g]^\star$ and $\Sigma[s]$. Moreover, if the size and arity of the underlying schema is fixed, then TS is P-combined, and the next result follows:

Proposition 20 $\mathsf{TAME}[c, d]$ *is P-combined reducible to* $\mathsf{STICKY}[\infty, d]$.

From Theorem 3, Theorem 19 and Proposition 20, we immediately get the main result of this section:

Theorem 21 $\mathsf{TAME}[c, d]$ *is P-combined first-order rewritable.*

6 Linear Datalog$^\exists$: The Missing Tile

It is open whether Linear Datalog$^\exists$ is P-combined first-order rewritable, and we are currently investigating this problem. The purpose of this section is to show that the solution to the above open problem cannot benefit from existing tools, and therefore novel techniques must be devised.

By exploiting the reduction in the proof of Theorem 6, we can show that LINEAR and $\mathsf{LINEAR}[1, \infty]$ coincide w.r.t. P-combined first-order rewritability. Therefore, in order to establish the desired result, it suffices to focus our attention on sets of linear rules which contain exactly one predicate. Since query answering under LINEAR is PSPACE-hard, the same problem under $\mathsf{LINEAR}[1, \infty]$ is also PSPACE-hard. Thus, in view of the fact that query answering under the (currently) known Datalog$^\exists$ languages which are P-combined first-order rewritable — i.e., the languages considered in this paper — is in NP, the P-combined reducibility approach cannot be applied (unless NP = PSPACE).

Unfortunately, as shown below, the existing techniques of establishing that $\mathsf{LINEAR}[\infty, d]$ is P-combined first-order rewritable, which are based on the PWP, are also not useful, or, at least, immediately applicable. We define the class $\mathsf{SUCC} = \{\Sigma_n\}_{n>0}$, where Σ_n is the set of linear rules

$$\{\mathit{num}(Z, O, \mathbf{B}_{n-i}, Z, O^{i-1}) \rightarrow \mathit{num}(Z, O, \mathbf{B}_{n-i}, O, Z^{i-1})\}_{i \in [n]}$$

with $\mathbf{B}_k = B_1, \ldots, B_k$. Roughly speaking, Σ_n simulates the successor operator on m-digit binary numbers, where $m = n - 2$. The binary number $b_1 b_2 \ldots b_m$ is encoded as $\mathit{num}(Z, O, b_1, \ldots, b_m)$, where Z, O are auxiliary variables that allow us to have access to the bits 0 and 1, respectively. Given the atomic query $q = \mathit{num}(0, 1, 1, \ldots, 1)$ and the database $D = \{\mathit{num}(0, 1, 0, \ldots, 0)\}$, we need to apply $\mathcal{O}(2^m)$ times the chase step in order to entail q. Consequently, SUCC does not enjoy the PWP. Since $\mathsf{SUCC} \subset \mathsf{LINEAR}[1, \infty]$, the next result follows:

Lemma 22 $\mathsf{LINEAR}[1, \infty]$ *does not enjoy the PWP.*

One may think that Lemma 22 implies that $\mathsf{LINEAR}[1, \infty]$ is not P-combined first-order rewritable. However, the PWP is not a necessary condition for the P-combined first-order rewritability. This is established by showing first that a class for which query answering is PTIME-hard does not enjoy the PWP. Since there exist PTIME-hard classes which are P-combined first-order rewritable, e.g., $\mathsf{GUARDED}[c, d]$, the next result follows:

Lemma 23 *There exists a Datalog$^\exists$ class which does not enjoy the PWP, but it is P-combined first-order rewritable.*

All the known formalisms that are P-combined first-order rewritable, enjoy a property close to the PWP which we call *weakly PWP (wPWP)*. Roughly, this property is defined as the PWP, with the difference that the polynomial size witness may depend on the given database. Clearly, SUCC, and thus $\mathsf{LINEAR}[1, \infty]$, does not enjoy the wPWP. However, it is possible to show that SUCC is P-combined first-order rewritable, and thus obtaining the first example which does not ensure a witness of polynomial size, but it is P-combined first-order rewritable.

From the above discussion, we conclude that LINEAR, although it does not guarantee witnesses of polynomial size, is likely to be P-combined first-order rewritable. However, the existing tools are not powerful enough for establishing such a result, and novel techniques must be developed.

7 Conclusion

We considered the polynomial combined approach to query answering under expressive classes of existential rules. To the best of our knowledge, this work is the first attempt to explicitly apply the combined approach to existential rules. We established that guarded and tame rules are polynomially combined first-order rewritable, whenever the size and the arity of the underlying schema are bounded. The same holds also for sticky rules, even if the size of the underlying schema is not bounded. Notice that our techniques immediately show that guarded and tame rules are combined first-order rewritable. The results of this work are, for the moment, of theoretical nature and we do not claim that they

will directly lead to better practical algorithms. A smart implementation and an evaluation of the obtained rewritings will be the subject of future research. We are also planning to investigate the notion of *output-polynomial* combined first-order rewritability, i.e., when the rewriting is of polynomial size but not necessarily constructible in polynomial time.

Abstract

We study branching-time temporal description logics (BTDLs) based on the temporal logic CTL in the presence of rigid (*time-invariant*) roles and general TBoxes. There is evidence that, if full CTL is combined with the classical $\mathcal{ALC}$ in this way, reasoning becomes undecidable. In this paper, we begin by substantiating this claim, establishing undecidability for a fragment of this combination. In view of this negative result, we then investigate BTDLs that emerge from combining fragments of CTL with lightweight DLs from the $\mathcal{EL}$ and *DL-Lite* families. We show that even rather inexpressive BTDLs based on $\mathcal{EL}$ exhibit very high complexity. Most notably, we identify two *convex* fragments which are undecidable and hard for non-elementary time, respectively. For BTDLs based on *DL-Lite*$_{bool}^{\mathcal{N}}$, we obtain tight complexity bounds that range from PSPACE to EXPTIME.

1 Introduction

Classical description logics (DLs) such as those that underlie the W3C recommendation OWL, are decidable fragments of first order logic and aim at the representation of and reasoning about *static* knowledge. With the objective of enhancing DLs with means to capture temporal aspects of knowledge, over the last 20 years much effort has been spent on the study of temporal description logics (TDLs) as discussed in detail in the surveys (Artale and Franconi 2000; Lutz, Wolter, and Zakharyaschev 2008) and the references therein. TDLs are useful for applications requiring to describe dynamic aspects of the application domain. For example, in the medical domain the description of a term might refer to temporal patterns; hence a medical ontology like SNOMED CT (Baader, Ghilardi, and Lutz 2008) should model the knowledge that, for example, the disease *diabetes* may potentially lead to several ocular disorders in the future.

A prominent approach to TDLs, following Schild's original proposal (Schild 1993), is to combine classical DLs with the standard temporal logics LTL, CTL and CTL* based on a two-dimensional product-like semantics in the style of many-dimensional DLs (Gabbay et al. 2003). In the construction of temporal DLs, besides the logics used in the temporal and DL component, there are a number of further design choices. For example, we can choose whether we apply temporal operators to concepts, roles or TBoxes. We can moreover define some DL roles or concepts as rigid, meaning that they will not change their interpretation over time: for example, since every human has the same genetic disorders during their life, the relation "has genetic disorder" between humans and diseases should be modelled by a rigid role hasGeneticDisease. Consequently, it has been argued that applications of TDLs require rigid roles and general TBoxes; e.g., in temporal data modeling (Artale et al. 2012) or in medical ontologies such as SNOMED CT.

Remarkably, the landscape of the expressivity and computational complexity of linear-time TDLs based on LTL (LTDLs) is well-understood today (Artale et al. 2007; Baader, Ghilardi, and Lutz 2008; Franconi and Toman 2011; Artale et al. 2012). In particular, various design choices have been explored, and both lightweight and expressive DLs have been considered. Notably, it has been shown that LTDLs based on the basic DL $\mathcal{ALC}$ become undecidable in the presence of a general TBox as soon as temporal operators are applied not only to concepts but also to roles, or rigid roles are allowed.

It is interesting to note that, more generally, combinations of DLs and modal logics allowing for rigid roles and general TBoxes tend to have very high computational complexity. Indeed, the standard reasoning problem for DLs is concept satisfiability with respect to a TBox. Via the well-known correspondence of DL combinations with product modal logics (PMLs) (Gabbay et al. 2003, Chapters 3, 14), this reasoning problem relates to the global consequence problem in a product modal logic. For many PMLs, global consequence is known to be undecidable (Gabbay et al. 2003).

In the context of LTDLs, with the aim to attain decidability in the presence of rigid roles and general TBoxes, recent work investigates lightweight DLs from the $\mathcal{EL}$ and *DL-Lite* families as the DL component (Artale et al. 2007; 2012). This choice is supported by the fact that lightweight DLs typically allow for tractable reasoning, and motivated by their importance in applications such as ontology-based data access or the representation of huge bio- and medical ontologies (Baader, Brandt, and Lutz 2005; Artale et al. 2009). The results of this work on LTDLs are two-fold: the studied LTDLs based on *DL-Lite* are decidable while those based on $\mathcal{EL}$ are undecidable. Undecidability in the $\mathcal{EL}$ case is explained by an interaction of two phenomena: the first is

Copyright © 2014, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

non-convexity – roughly speaking, the ability to simulate disjunctions, here using properties of linear-time, as $\Diamond \mathsf{X} \sqcap \Diamond \mathsf{Y}$ implies that one of $\Diamond(\mathsf{X} \sqcap \Diamond \mathsf{Y})$ and $\Diamond(\mathsf{Y} \sqcap \Diamond \mathsf{X})$ is true, where $\Diamond \mathsf{X}$ reads as *eventually* in the future X holds. The second is the known fact that $\mathcal{EL}$ with disjunctions can encode $\mathcal{ALC}$; hence TDLs based on $\mathcal{EL}$ are as hard as the corresponding $\mathcal{ALC}$ variant, which is undecidable in the case of LTDLs.

From the viewpoint of some DL applications, it has been argued that representing the existence of different *possible futures*, inherent to a branching-time structure, is necessary for a more appropriate modeling (Gutiérrez-Basulto, Jung, and Lutz 2012); for example, in medical ontologies where a symptom or disease might evolve in different ways in the future. For instance consider the statement *'each patient having the autoimmune disorder diabetes will* possibly *develop glaucoma in the future'*. In LTDLs this can be modeled as

$$\mathsf{Patient} \sqcap \exists \mathsf{hasAutoDis}.\mathsf{Diabetes} \sqsubseteq \Diamond \exists \mathsf{develops}.\mathsf{Glaucoma},$$

meaning that each diabetes patient will *eventually* develop glaucoma, thus excluding the possibility that a glaucoma will never be developed if diabetes is controlled. In branching-time TDLs we can use the existential path quantifier $\mathbf{E}$ together with $\Diamond$ to more carefully state that there exists a *possible future* where the patient develops glaucoma, leaving open the existence of other possible futures.

Interestingly, opposite to LTDLs, the study of TDLs based on branching-time temporal logics (BTDLs) has been rather limited; mainly focusing on decidability boundaries obtained in the context of first-order branching temporal logic (Hodkinson, Wolter, and Zakharyaschev 2002; Bauer et al. 2004). Only recently tight elementary bounds were presented for combinations with the DLs $\mathcal{ALC}$ and $\mathcal{EL}$ in the case where only *local* roles are allowed (Gutiérrez-Basulto, Jung, and Lutz 2012). Hence, the aim of this paper is to deepen the study of BTDLs by considering rigid roles, that is, we study the case where temporal operators are applied to concepts, and rigid roles and general TBoxes are allowed. In particular, we will analyze the decidability and complexity of the standard reasoning problems. In the light of the known results from the literature, we will focus on BTDLs based on lightweight DLs from the $\mathcal{EL}$ and *DL-Lite* families, but we will lay the groundwork by reconsidering $\mathcal{ALC}$.

Our study starts with the combination of CTL and $\mathcal{ALC}$. We show that its fragment with only the $\mathbf{E}\Diamond$, $\mathbf{A}\Box$ operators is undecidable, combining results for products of 'transitive' modal logics with a well-known DL-technique for reasoning about transitive roles (Tobies 2001). Notably, we obtain a more general result, covering a whole family of PMLs.

We continue by investigating several BTDLs based on $\mathcal{EL}$. We identify non-convex BTDLs based on $\mathcal{EL}$ and thus show undecidability of their subsumption problem similarly to the results described above. As a next step, we focus on identifying convex BTDLs based on $\mathcal{EL}$. Studying them is motivated by the fact that convex logics have a good chance to be computationally well-behaved: examples of convex combinations of DLs with modal logics are the tractable combination of $\mathcal{EL}$ with the CTL operator $\mathbf{E}\Diamond$ in the case where only *local* roles are allowed (Gutiérrez-Basulto, Jung, and Lutz 2012), and various combinations of the modal logic $\mathsf{S5}$ with $\mathcal{EL}$, which have been shown to be easier than the $\mathcal{ALC}$ variant (Lutz and Schröder 2010; Gutiérrez-Basulto et al. 2011). For BTDLs, we indeed identify three convex fragments, based on the temporal operator sets $\{\mathbf{E}\bigcirc\}$, $\{\mathbf{E}\Diamond\}$, and $\{\mathbf{E}\Diamond, \mathbf{A}\Box\}$. Surprisingly, we then show that these fragments exhibit very high complexity: undecidable and hard for non-elementary for the $\mathbf{E}\bigcirc$ and $\mathbf{E}\Diamond$ cases, respectively. The proofs of these results are challenging and technically involved because the absence of disjunction makes it difficult to use standard techniques for establishing lower complexity bounds, such as tilings.

Finally, we investigate BTDLs based on *DL-Lite*$^{\mathcal{N}}_{bool}$, showing that the technique developed by Artale et al. (2012) to prove decidability of LTDLs based on *DL-Lite* is robust in the sense that it can be carried over to *most* BTDLs based on CTL. We obtain tight complexity bounds, namely PSPACE- and EXPTIME-completeness.

Throughout the paper, we will omit most technical proof details which, together with additional technical notation, can be found in the long version available online: http://tinyurl.com/kr14tdl

2 Preliminaries

We introduce CTL$_{\mathcal{ALC}}$, a temporal DL based on the classical DL $\mathcal{ALC}$. The other temporal DLs studied in this paper are fragments or variants of CTL$_{\mathcal{ALC}}$, introduced later as needed. Let $\mathsf{N_C}$ and $\mathsf{N_R}$ be countably infinite sets of *concept names* and *role names*, respectively. We assume that $\mathsf{N_R}$ is partitioned into two countably infinite sets $\mathsf{N_{rig}}$ and $\mathsf{N_{loc}}$ of *rigid role names* and *local role names*, respectively. CTL$_{\mathcal{ALC}}$*-concepts* C are defined by the following grammar

$$C := \top \mid A \mid \neg C \mid C \sqcap D \mid \exists r.C \mid \mathbf{E}\bigcirc C \mid \mathbf{E}\Box C \mid \mathbf{E}(C \mathcal{U} D)$$

where A ranges over $\mathsf{N_C}$, r over $\mathsf{N_R}$. As usual, we use $\bot$ to abbreviate the concept $\neg\top$, $C \sqcup D$ for $\neg(\neg C \sqcap \neg D)$, and $\forall r.C$ for $\neg\exists r.\neg C$. We additionally have the following temporal abbreviations (Clarke, Grumberg, and Peled 1999): $\mathbf{E}\Diamond C = \mathbf{E}(\top \mathcal{U} C)$, $\mathbf{A}\Box C = \neg\mathbf{E}\Diamond\neg C$, $\mathbf{A}\Diamond C = \neg\mathbf{E}\Box\neg C$, $\mathbf{A}(C \mathcal{U} D) = \neg\mathbf{E}(\neg D \mathcal{U} (\neg C \wedge \neg D)) \wedge \neg\mathbf{E}\Box\neg D$. We moreover consider the *strict* $(\cdot^{<})$ versions of the temporal operators: $\mathbf{E}\Box^{<} C = \mathbf{E}\bigcirc\mathbf{E}\Box C$, $\mathbf{E}(C \mathcal{U}^{<} D) = \mathbf{E}\bigcirc\mathbf{E}(C \mathcal{U} D)$.

The semantics of classical, non-temporal DLs, such as $\mathcal{ALC}$ is given in terms of *interpretations* of the form $\mathcal{I} = (\Delta, \cdot^{\mathcal{I}})$, where Δ is a non-empty set called the *domain* and $\cdot^{\mathcal{I}}$ is an *interpretation function* that maps each $A \in \mathsf{N_C}$ to a subset $A^{\mathcal{I}} \subseteq \Delta$ and each $r \in \mathsf{N_R}$ to a binary relation $r^{\mathcal{I}} \subseteq \Delta \times \Delta$. The semantics of CTL$_{\mathcal{ALC}}$ is given in terms of temporal interpretations, which are infinite trees in which every node is associated with a classical interpretation. For the purposes of this paper, a *tree* is a directed graph $T = (W, E)$ where $W \subseteq (\mathbb{N} \setminus \{0\})^*$ is a prefix-closed non-empty set of *nodes* and $E = \{(w, wc) \mid wc \in W, w \in \mathbb{N}^*, c \in \mathbb{N}\}$ a set of *edges*; we generally assume that $wc \in W$ and $c' < c$ implies $wc' \in W$ and that E is a total relation. The node $\varepsilon \in W$ is the *root* of T. For brevity and since E can be reconstructed from W, we will usually identify T with W. In the context of temporal DLs we refer to nodes of T as *time points or worlds*.

A *temporal interpretation* is a structure $\mathfrak{I} = (\Delta, T, \{\mathcal{I}_w\}_{w \in W})$ where $T = (W, E)$ is a tree, and for each $w \in W$, $\mathcal{I}_w$ is an interpretation with domain Δ, such that $r^{\mathcal{I}_w} = r^{\mathcal{I}_{w'}}$ for all $r \in \mathsf{N_{rig}}$ and $w, w' \in W$. We usually write $A^{\mathfrak{I},w}$ instead of $A^{\mathcal{I}_w}$, and intuitively $d \in A^{\mathfrak{I},w}$ means that in the interpretation $\mathfrak{I}$, the object d is an instance of the concept name A *at time point* w. Moreover, note that we make the *constant domain assumption*, that is, all time points share the same domain Δ. Intuitively, this means that objects are not created or destroyed over time.

We now define the semantics of CTL$_{\mathcal{ALC}}$-concepts. A *path* in a tree $T = (W, E)$ starting at a node w is a minimal set $\pi \subseteq W$ such that $w \in \pi$ and for each $w' \in \pi$, there is a $c \in \mathbb{N}$ with $w'c \in \pi$. We use $\mathsf{Paths}(w)$ to denote the set of all paths starting at the node w. For a path $\pi = w_0 w_1 w_1 \cdots$ and $i \geq 0$, we use $\pi[i]$ to denote w_i. The mapping $\cdot^{\mathfrak{I},w}$ is extended from concept names to CTL$_{\mathcal{ALC}}$-concepts as follows:

$$\begin{aligned}
\top^{\mathfrak{I},w} &= \Delta; \qquad (C \sqcap D)^{\mathfrak{I},w} = C^{\mathfrak{I},w} \cap D^{\mathfrak{I},w};\\
(\exists r.C)^{\mathfrak{I},w} &= \{d \in \Delta \mid \exists e.(d,e) \in r^{\mathfrak{I},w} \wedge e \in C^{\mathfrak{I},w}\};\\
(\mathbf{E}\bigcirc C)^{\mathfrak{I},w} &= \{d \in \Delta \mid d \in C^{\mathfrak{I},\pi[1]} \text{ for some } \pi \in \mathsf{Paths}(w)\};\\
(\mathbf{E}\Box C)^{\mathfrak{I},w} &= \{d \in \Delta \mid \forall j \geq 0. d \in C^{\mathfrak{I},\pi[j]} \text{ for some } \pi \in \mathsf{Paths}(w)\};\\
(\mathbf{E}(C \mathcal{U} D))^{\mathfrak{I},w} &= \{d \in \Delta \mid \exists\, j \geq 0.(d \in D^{\mathfrak{I},\pi[j]} \wedge\\
&\qquad (\forall\, 0 \leq k < j.\, d \in C^{\mathfrak{I},\pi[k]})) \text{ for some } \pi \in \mathsf{Paths}(w)\}.
\end{aligned}$$

A *general CTL$_{\mathcal{ALC}}$-TBox* $\mathcal{T}$ is a finite set of *concept inclusions (CIs)* $C \sqsubseteq D$ with C, D CTL$_{\mathcal{ALC}}$ concepts.

A temporal interpretation $\mathfrak{I}$ is a *model* of a concept C if $C^{\mathfrak{I},\varepsilon} \neq \emptyset$; it is a *model* of $C \sqsubseteq D$, written $\mathfrak{I} \models C \sqsubseteq D$, if $C^{\mathfrak{I},w} \subseteq D^{\mathfrak{I},w}$ for all $w \in W$; it is a model of a TBox $\mathcal{T}$ if it satisfies all CIs in $\mathcal{T}$. Thus, a TBox $\mathcal{T}$ is interpreted globally in the sense that it has to be satisfied at *every* time point.

We say that a concept C is *satisfiable with respect to a CTL$_{\mathcal{ALC}}$-TBox* $\mathcal{T}$ if there is a common model of C and $\mathcal{T}$. We then consider the following *concept satisfiability problem*: given a concept C and a TBox $\mathcal{T}$, decide whether there is a common model of C and $\mathcal{T}$.

We will denote fragments of CTL$_{\mathcal{ALC}}$ by putting the available temporal operators as a superscript; for example, CTL$^{\mathbf{E}\Diamond,\mathbf{A}\Box}_{\mathcal{ALC}}$ denotes the fragment having as the only operators available $\mathbf{E}\Diamond$ and $\mathbf{A}\Box$.

3 Undecidability of CTL combined with $\mathcal{ALC}$

We begin our study by looking at CTL$_{\mathcal{ALC}}$. To our knowledge, there are no decidability or complexity results specifically for this combination in the literature. However, there are two results about logics that are close to CTL$_{\mathcal{ALC}}$: On the one hand, it follows from results by (Hodkinson, Wolter, and Zakharyaschev 2002) that a combination of the two-variable guarded fragment of first-order logic (which subsumes $\mathcal{ALC}$) with CTL is undecidable, but that logic is more expressive than our CTL$_{\mathcal{ALC}}$: for example, it allows for CIs in the scope of temporal operators. On the other hand, there is a close correspondence between CTL$^{\mathbf{E}\Diamond,\mathbf{A}\Box}_{\mathcal{ALC}}$ and the PML $\mathsf{S4} \times \mathsf{K}$, whose classical satisfiability problem is decidable (Gabbay et al. 2003), though hard for non-elementary time (Göller, Jung, and Lohrey 2012). This correspondence is based on the fact that $\mathsf{S4} \times \mathsf{K}$ has the tree model property and thus $\mathsf{S4} \times \mathsf{K}$ is the logic of all bi-modal Kripke frames (relational structures) that are the product of the reflexive and transitive closure of a tree ($\mathsf{S4}$) and a tree (K). Therefore, in CTL$^{\mathbf{E}\Diamond,\mathbf{A}\Box}_{\mathcal{ALC}}$ with one rigid role and no further roles, the CTL branching time structures correspond to the $\mathsf{S4}$-dimension and $\mathcal{ALC}$ corresponds to K.

The correspondence with PMLs, however, is only of restricted use for our study of the concept satisfiability problem *relative to global TBoxes:* this problem corresponds to the global consequence problem in modal logic which, to the best of our knowledge, has not been studied for $\mathsf{S4} \times \mathsf{K}$. Therefore, the above result for classical satisfiability cannot easily be transferred to CTL$^{\mathbf{E}\Diamond,\mathbf{A}\Box}_{\mathcal{ALC}}$. We will in fact show that concept satisfiability relative to global TBoxes in CTL$^{\mathbf{E}\Diamond,\mathbf{A}\Box}_{\mathcal{ALC}}$ is undecidable, exploiting undecidability of satisfiability for a family of transitive PMLs which includes $\mathsf{S4} \times \mathsf{K4}$ (Gabelaia et al. 2005). We prove that the global consequence problem of $\mathsf{S4} \times \mathsf{K}$ can encode the satisfiability problem of $\mathsf{S4} \times \mathsf{K4}$, using a technique by Tobies (2001).

We first rephrase a consequence of Gabelaia et al.'s result in BTDL notation and will then sketch how to employ Tobies's technique to establish undecidability of CTL$^{\mathbf{E}\Diamond,\mathbf{A}\Box}_{\mathcal{ALC}}$.

Theorem 1 (Gabelaia et al. 2005) *The following problem is undecidable for $\mathcal{L} \in \{CTL^{\mathbf{E}\Diamond,\mathbf{A}\Box}_{\mathcal{ALC}}, CTL^{\mathbf{E}\Diamond^<,\mathbf{A}\Box^<}_{\mathcal{ALC}}\}$. Given an $\mathcal{L}$-concept C that uses at most one rigid role r and no other roles, is C satisfiable in a temporal interpretation $\mathfrak{I} = (\Delta, T, \{\mathcal{I}_w\}_{w \in W})$ where $r^{\mathfrak{I},w}$ is transitive for all w ?*

We sketch how to employ Tobies's technique to transfer this result to our standard concept satisfiability problem for CTL$^{\mathbf{E}\Diamond,\mathbf{A}\Box}_{\mathcal{ALC}}$ and CTL$^{\mathbf{E}\Diamond^<,\mathbf{A}\Box^<}_{\mathcal{ALC}}$.

Theorem 2 *Concept satisfiability w.r.t. general TBoxes for CTL$^{\mathbf{E}\Diamond,\mathbf{A}\Box}_{\mathcal{ALC}}$ and CTL$^{\mathbf{E}\Diamond^<,\mathbf{A}\Box^<}_{\mathcal{ALC}}$ with rigid roles is undecidable.*

Proof. We only sketch the proof for CTL$^{\mathbf{E}\Diamond,\mathbf{A}\Box}_{\mathcal{ALC}}$; the strict variant can be treated using the same arguments. Consider a CTL$^{\mathbf{E}\Diamond,\mathbf{A}\Box}_{\mathcal{ALC}}$-concept C that uses at most one rigid role r and no other roles, and assume that C is in negation normal form (NNF), i.e., negation occurs only in front of atomic concepts in C. We use $\mathsf{cl}(C)$ to denote the set of NNFs of all subconcepts of C and of their negations, and $\sim D$ to denote the NNF of $\neg D$ for any $D \in \mathsf{cl}(C)$. For every $\forall r.D \in \mathsf{cl}(C)$, reserve a fresh concept name X_D. We define a translation $\cdot^{\mathsf{tr}}$ from CTL$^{\mathbf{E}\Diamond,\mathbf{A}\Box}_{\mathcal{ALC}}$-concepts to CTL$^{\mathbf{E}\Diamond,\mathbf{A}\Box}_{\mathcal{ALC}}$-concepts.

$$\begin{aligned}
A^{\mathsf{tr}} &= A^{\mathsf{tr}} & (\forall r.D)^{\mathsf{tr}} &= X_D\\
(\neg A)^{\mathsf{tr}} &= \neg A^{\mathsf{tr}} & (\exists r.D)^{\mathsf{tr}} &= \neg X_{\sim D}\\
(D_1 \sqcap D_2)^{\mathsf{tr}} &= D_1^{\mathsf{tr}} \sqcap D_2^{\mathsf{tr}} & (\mathbf{E}\Diamond D)^{\mathsf{tr}} &= \mathbf{E}\Diamond D\\
(D_1 \sqcup D_2)^{\mathsf{tr}} &= D_1^{\mathsf{tr}} \sqcup D_2^{\mathsf{tr}} & (\mathbf{A}\Box D)^{\mathsf{tr}} &= \mathbf{A}\Box D
\end{aligned}$$

Let $\mathcal{T}_C$ be the following TBox.

$$\mathcal{T}_C = \{X_D \equiv \forall r.D^{\mathsf{tr}},\ X_D \sqsubseteq \forall r.X_D \mid \forall r.D \in \mathsf{cl}(C)\}$$

It suffices to show that C is satisfiable in an interpretation that makes r transitive everywhere iff C^{tr} is satisfiable w.r.t. $\mathcal{T}_C$ in $\mathrm{CTL}^{\mathbf{E}\Diamond,\mathbf{A}\Box}_{\mathcal{ALC}}$. For the "$\Rightarrow$" direction, take a model $\mathfrak{I}$ of C with r being transitive, and additionally interpret X_D as $\forall r.D$. Then a standard induction shows that the modified $\mathfrak{I}$ satisfies C^{tr}, and transitivity of r ensures that it is a model of $\mathcal{T}_C$. For the "$\Leftarrow$" direction, take a model $\mathfrak{J}$ of C^{tr} and $\mathcal{T}_C$ and extend the interpretation of r in every world to its transitive closure. Then $\mathfrak{J}$ being a model of $\mathcal{T}_C$ can be used to show that the modified $\mathfrak{J}$ still satisfies C. ❑

In fact, we are able to prove a more general result of independent interest in the field of PMLs. All notation used in the following theorem is standard for PMLs (Gabbay et al. 2003), except for $\mathfrak{C}^+$, which refers to the class of all transitive frames in the frame class $\mathfrak{C}$.

Theorem 3 *For any classes $\mathfrak{C}_1, \mathfrak{C}_2$ of frames, where $\mathfrak{C}_2$ contains only transitive frames and both $\mathfrak{C}_1^+, \mathfrak{C}_2$ contain frames of arbitrarily large finite or infinite depth, the global satisfiability problem for $\mathsf{Log}(\mathfrak{C}_1 \times \mathfrak{C}_2)$ is undecidable.*

4 CTL combined with $\mathcal{EL}$

In this section, we consider fragments of $\mathrm{CTL}_{\mathcal{EL}}$, the fragment of $\mathrm{CTL}_{\mathcal{ALC}}$ that disallows the constructor $\neg$ (and thus also the abbreviations $C \sqcup D$, $\forall r.C$, $\mathbf{A}\Box$, ...). As an example, consider the following $\mathrm{CTL}_{\mathcal{EL}}$-TBox:

$$\exists \mathsf{hasAutoDis.Diabetes} \sqsubseteq \mathbf{E}\Diamond(\exists \mathsf{develops.Glaucoma} \sqcap \mathbf{E}\Diamond \exists \mathsf{hasTreat.EyeDrops})$$
$$\mathbf{E}\Diamond \exists \mathsf{hasTreat.EyeDrops} \sqsubseteq \mathbf{E}\Diamond \exists \mathsf{hasEffect.ChangeEyeColor}$$

It says that everyone with diabetes may eventually develop a glaucoma which may eventually be treated using eye drops, and that such a treatment may lead to a change in eye color.

Because of the absence of negation, satisfiability in $\mathrm{CTL}_{\mathcal{EL}}$ is trivial; as in non-temporal $\mathcal{EL}$, we therefore consider subsumption as the central reasoning problem. Formally, a concept D *subsumes* a concept C w.r.t. a $\mathrm{CTL}_{\mathcal{EL}}$ TBox $\mathcal{T}$, written $\mathcal{T} \models C \sqsubseteq D$, if $C^{\mathfrak{I}} \subseteq D^{\mathfrak{I}}$ for all temporal interpretations $\mathfrak{I}$ that are a model of $\mathcal{T}$. For example, the TBox above implies that $\exists \mathsf{hasAutoDis.Diabetes} \sqsubseteq \mathbf{E}\Diamond \exists \mathsf{hasEffect.ChangeEyeColor}$. We then consider the following *concept subsumption problem:* given concepts C, D and a $\mathrm{CTL}_{\mathcal{EL}}$ TBox $\mathcal{T}$, decide whether $\mathcal{T} \models C \sqsubseteq D$.

In the rest of the section we focus on the study of several fragments of $\mathrm{CTL}_{\mathcal{EL}}$. In this context, we view each of the operators $\mathbf{E}\bigcirc$, $\mathbf{E}\Diamond$, $\mathbf{E}\Box$, $\mathbf{A}\Diamond$, $\mathbf{A}\Box$, $\mathbf{E}\mathcal{U}$ and their strict versions as primitive instead of as an abbreviation.

4.1 Non-Convex Fragments

We next show undecidability of certain fragments of $\mathrm{CTL}_{\mathcal{EL}}$ using techniques developed in the context of *linear-time* temporal extensions of $\mathcal{EL}$ (Artale et al. 2007). In particular, the non-convexity of these extensions, and therefore their capability to 'express' disjunction, is exploited to show that they are as complex as the corresponding $\mathcal{ALC}$ variant.

Before we present the undecidability results we recall the standard notion of convexity.

Definition 1 *A logic $\mathcal{L}$ is called* convex *if, for all $\mathcal{L}$-TBoxes $\mathcal{T}$ and all $\mathcal{L}$-concepts $C, D_1, \ldots, D_n$, $n \geq 2$, whenever $\mathcal{T} \models C \sqsubseteq D_1 \sqcup \cdots \sqcup D_n$, then $\mathcal{T} \models C \sqsubseteq D_i$ for some $i \in \{1, \ldots, n\}$.*

Theorem 4 *Concept subsumption w.r.t. general TBoxes is undecidable for*

(a) $\mathrm{CTL}^{\mathbf{E}\Diamond,\mathbf{A}\Diamond}_{\mathcal{EL}}$ (b) $\mathrm{CTL}^{\mathbf{E}\Diamond,\mathbf{E}\bigcirc}_{\mathcal{EL}}$ (c) $\mathrm{CTL}^{\mathbf{E}\mathcal{U}}_{\mathcal{EL}}$
(d) $\mathrm{CTL}^{\mathbf{E}\mathcal{U}^<}_{\mathcal{EL}}$ (e) $\mathrm{CTL}^{\mathbf{E}\Diamond^<,\mathbf{E}\Box^<}_{\mathcal{EL}}$ (f) $\mathrm{CTL}^{\mathbf{E}\Diamond,\mathbf{E}\Box}_{\mathcal{EL}}$

Proof. The proof is in two steps. First, we show the non-convexity (in opposition to convexity) of these fragments of $\mathrm{CTL}_{\mathcal{EL}}$. Second, we reduce from satisfiability w.r.t. TBoxes in the corresponding $\mathrm{CTL}_{\mathcal{ALC}}$ fragment.

Lemma 5 *The fragments* (a)–(f) *of $\mathrm{CTL}_{\mathcal{EL}}$ are non-convex.*

Proof. The non-convexity of (a)–(d) was previously established in (Gutiérrez-Basulto, Jung, and Lutz 2012), for the witnesses see Figure 1. In the same place, the fragments (e) and (f) were stated to be convex, too; however, we show here that this is not the case. Interestingly, this shows that the convexity of $\mathrm{CTL}^{\mathbf{E}\Diamond}_{\mathcal{EL}}$, which we show later (Theorem 6), is rather fragile since $\mathbf{E}\Diamond$ and $\mathbf{E}\Box$ allow only for existential quantification and there is no possibility of talking about 'next' time points, which in principle might make us think of $\mathrm{CTL}^{\mathbf{E}\Diamond,\mathbf{E}\Box}_{\mathcal{EL}}$ as a temporal analog of $\mathcal{EL}$. Alas, the presence of both operators makes it non-convex. We begin by presenting the witnesses used to prove non-convexity and their intuition.

To show non-convexity of $\mathrm{CTL}^{\mathbf{E}\Diamond,\mathbf{E}\Box}_{\mathcal{EL}}$ we use the following witness.

$$\mathcal{T} = \{C \sqsubseteq \mathbf{E}\Diamond(D \sqcap A),\ D \sqsubseteq \mathbf{E}\Diamond(C \sqcap A)\} \text{ and}$$
$$D_1 = \mathbf{E}\Diamond(C \sqcap D),\ D_2 = \mathbf{E}\Box\mathbf{E}\Diamond A.$$

Intuitively, $\mathcal{T}$ stipulates that every instance d of C has the possibility of eventually being an instance of D and A, and thereafter has the possibility of eventually being an instance of C and A, but there is a choice on whether d becomes an instance of C and D at the same time point, or whether d infinitely alternates between C and D.

Although the disjunction expressed in $\mathrm{CTL}^{\mathbf{E}\Diamond,\mathbf{E}\Box}_{\mathcal{EL}}$ relies on the non-strict interpretation of $\mathbf{E}\Diamond$ and $\mathbf{E}\Box$, the following shows that the strict version is also non-convex.

$$\mathcal{T} = \{C \sqsubseteq \mathbf{E}\Diamond^< B,\ B \sqsubseteq D \sqcap \mathbf{E}\Box^< D\} \text{ and}$$
$$D_1 = \mathbf{E}\Diamond^<\mathbf{E}\Diamond^< B,\ D_2 = \mathbf{E}\Box^< D$$

Intuitively, every instance d of C has two choices on becoming an instance of B for the first time, namely, either it does it at the immediate successor, or at some point after it.

Formally, in both cases we show non-convexity by proving that $\mathcal{T} \models C \sqsubseteq \bigsqcup D_i$, but $\mathcal{T} \not\models C \sqsubseteq D_i$. ❑

Having established the non-convexity of the above logics we can devise a reduction from the satisfiability problem w.r.t. TBoxes in the corresponding $\mathcal{ALC}$ variant. First, recall that $\mathrm{CTL}^{\mathbf{E}\Diamond,\mathbf{A}\Box}_{\mathcal{ALC}}$ and $\mathrm{CTL}^{\mathbf{E}\Diamond^<,\mathbf{A}\Box^<}_{\mathcal{ALC}}$ are undecidable (Theorem 2). Note moreover that all fragments above contain at least the $\mathbf{E}\Diamond$ or $\mathbf{E}\Diamond^<$ operator. Hence all the $\mathcal{ALC}$ variants of these fragments are undecidable.

$\mathbf{E}\Diamond\mathbf{A}\Diamond$	$\mathcal{T}=\emptyset,\ C=\mathbf{A}\Diamond A\sqcap\mathbf{A}\Diamond B$ $D_1=\mathbf{E}\Diamond(A\sqcap\mathbf{E}\Diamond B),\ D_2=\mathbf{E}\Diamond(B\sqcap\mathbf{E}\Diamond A)$
$\mathbf{E}\Diamond\mathbf{E}\bigcirc$	$\mathcal{T}=\emptyset,\ C=\mathbf{E}\Diamond A,\ D_1=A,\ D_2=\mathbf{E}\bigcirc\mathbf{E}\Diamond A$
$\mathbf{E}\mathcal{U}$	$\mathcal{T}=\emptyset,\ C=\mathbf{E}(A\mathcal{U}B),\ D_1=B,\ D_2=A$
$\mathbf{E}\mathcal{U}^<$	$\mathcal{T}=\emptyset,\ C=\mathbf{E}(A\mathcal{U}^<B),\ D_1=\mathbf{E}(A\mathcal{U}^<A),$ $D_2=\mathbf{E}(B\mathcal{U}^<B)$

Figure 1: Non-convexity witnesses

The crucial point of the reduction is the elimination of disjunction, that is, encoding CIs $C\sqsubseteq A\sqcup B$ present in the $\mathcal{ALC}$ variants. To this aim, we use the non-convexity witnesses (*cf.* witnesses presented above and Fig. 1) which, as discussed, allow to describe 'choices'. ❑

4.2 Convex Fragments

In this section, we will show that the logics $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\bigcirc}$, $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\Diamond}$, and $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\Diamond\mathbf{A}\Box}$ are convex, which suggests that they have limited expressive power. Indeed, convex logics are typically computationally well-behaved (Oppen 1980; Baader, Brandt, and Lutz 2005; Lutz and Wolter 2012). Our convexity result is contrasted by two observations: first, the linear-time TDL based on $\Diamond$ and $\mathcal{EL}$ with rigid roles is non-convex (Artale et al. 2007) which, intuitively, is due to the linear structure of time. Second, we will show later that $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\bigcirc}$ is undecidable because its expressive power is sufficient to encode the halting problem for two-counter machines, which is equivalent to that of Turing machines.

Theorem 6 *$\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\bigcirc}$, $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\Diamond}$, and $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\Diamond,\mathbf{A}\Box}$ are convex.*

Proof. (sketch) We start with $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\bigcirc}$ and first observe that $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\bigcirc}$, if restricted to a single role that is rigid, is a notational variant of a fragment of the product modal logic $\mathsf{KD}\times\mathsf{K}$, where K is the basic (uni-)modal logic and KD is the modal logic of the class of frames where every state has a successor. We can therefore use standard results and machinery from product modal logics – namely unravelling tolerance, the standard translation to first-order logic, and first-order axiomatizations of product frames – to achieve two things: we will translate $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\bigcirc}$-TBoxes and -concepts into a fragment of first-order logic that generalizes the Horn fragment, and we will axiomatize the rigidity of roles and the properties of the temporal successor relation in the same fragment. This will allow us to encode logical consequence in $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\bigcirc}$, even with multiple non-rigid roles, as first-order formulas in this fragment. Using the fact that such formulas are preserved under a standard operation on structures called *direct product*, it will then be easy to establish convexity.

In the following, we sketch some details of this argument. Consider a $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\bigcirc}$-TBox $\mathcal{T}$ and $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\bigcirc}$-concepts $C, D_1, \dots, D_n$, $n\geq 2$. Let $r_1,\dots,r_k$ be the rigid roles occurring in $\mathcal{T}, C, D_1, \dots, D_n$, and let $r_{k+1},\dots,r_\ell$ be the non-rigid roles. We denote by $\mathsf{ST}(\mathcal{T})$ the standard translation of $\mathcal{T}$ into first-order logic. Assuming $\mathcal{T}$ to be in a normal form that extends the usual one for $\mathcal{EL}$ (cf. Baader, Brandt, and Lutz 2005), it is easy to see that $\mathsf{ST}(\mathcal{T})$ is equivalent to a conjunction of embedded implicational dependencies (EIDs) (Fagin 1982), i.e., to a conjunction of FO-sentences

$$\forall x_1\dots x_m.((E_1\wedge\dots\wedge E_n)\rightarrow\exists x_{m+1}\dots x_k.(F_1\wedge\dots\wedge F_\ell))$$

where each E_i is a relational formula $Px_{j_1}\dots x_{j_d}$ and each F_i is either a relational formula or an equality $x_j=x_{j'}$.

Furthermore, we need to express rigidity of the roles $r_1,\dots,r_k$ as well as the property that the temporal "direct successor" relation is a total tree. For rigidity, we borrow from the theory of product modal logics (Gabbay et al. 2003): we have to say that each pair (R_i, S) of binary predicates representing the rigid role r_i and the temporal successor relation is left-commutative, right-commutative and satisfies the Church-Rosser property. For example, left-commutativity is given by the following EID.

$$\mathsf{LC}=\textstyle\bigwedge_{i=1}^{k}\forall xyz(R_ixy\wedge Syz\rightarrow\exists u(Sxu\wedge R_iuz))$$

The other two properties can be expressed via analogous EIDs RC and CRP. For enforcing the total tree, we only need to say that S is total because standard translations of $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\bigcirc}$-TBoxes are preserved under unravelling and under taking point-generated substructures. Totality of S can be expressed by the EID $\mathsf{D}=\forall x\exists y(Sxy)$.

We now consider the conjunction

$$\varphi(\mathcal{T})=\mathsf{LC}\wedge\mathsf{RC}\wedge\mathsf{CRP}\wedge\mathsf{D}\wedge\mathsf{ST}(\mathcal{T})$$

which, by classical results (Chang and Keisler 1990; Fagin 1982) is preserved under *direct products*: If n structures $\mathcal{M}_1,\dots,\mathcal{M}_n$ satisfy an EID, then so does their direct product, which has as its domain the cross-product of the domains of $\mathcal{M}_1,\dots,\mathcal{M}_n$ and interprets every m-ary predicate P as the set of m-tuples whose projections to the domain of each $\mathcal{M}_i$ are in the interpretation of P.

In order to show convexity of $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\bigcirc}$ via the contrapositive, we observe that the statement

$$\mathcal{T}\not\models C\sqsubseteq D_i\text{ for all }i\ \text{ implies }\ \mathcal{T}\not\models C\sqsubseteq D_1\sqcup\dots\sqcup D_n$$

is equivalent to

$$\varphi(\mathcal{T})\not\models\forall x.(Cx\rightarrow D_ix)\text{ for all }i\ \text{ implies}$$
$$\varphi(\mathcal{T})\not\models\forall x.(Cx\rightarrow D_1x\vee\dots\vee D_nx).$$

The claim of this property can be established easily, consulting the direct product of the n structures witnessing the non-entailments in the hypotheses.

To carry this reasoning over to $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\Diamond}$ and $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\Diamond\mathbf{A}\Box}$, we replace totality in the above argument with reflexivity and transitivity. Consequently, we have to replace the conjunct D in $\varphi(\mathcal{T})$ with the conjunction of the EIDs $\mathsf{T}=\forall x(xR_hx)$ and $\mathsf{4}=\forall xyz(xR_hy\wedge yR_hz\rightarrow xR_hz)$. Unfortunately, $\mathsf{ST}(\mathcal{T})$ now contains translations of axioms containing $\mathbf{A}\Box$, which are not generally equivalent to EIDs. Using additional arguments, however, we can show that $\mathsf{ST}(\mathcal{T})$ for these two

logics is then preserved under direct products *of structures where the relation S representing the temporal successor relation is interpreted as a total relation*. Therefore, the above $\varphi(\mathcal{T})$ remains preserved under direct products of such structures. Since $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\Diamond}$ and $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\Diamond\mathbf{A}\Box}$ are restricted to such structures, the above argument goes through.

It is worth recalling that convexity of both $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\bigcirc}$ and $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\Diamond}$ does not imply that $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\bigcirc,\mathbf{E}\Diamond}$ is convex: in order to translate a TBox using both the $\mathbf{E}\bigcirc$ and the $\mathbf{E}\Diamond$ operator into FO, we would have to use two binary relations $S_{\mathbf{E}\bigcirc}$ and $S_{\mathbf{E}\Diamond}$ and state that $S_{\mathbf{E}\Diamond}$ is the reflexive transitive closure of $S_{\mathbf{E}\bigcirc}$, which is not expressible in FO. ❑

We continue our study by showing that $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\bigcirc}$ lacks the *finite model property (FMP)*: consider the TBox $\mathcal{T}$ consisting of the following concept inclusions

$$A \sqsubseteq \exists r.A, \quad A \sqsubseteq \mathbf{E}\bigcirc B, \quad \exists r.B \sqsubseteq B',$$
$$\exists r.B' \sqsubseteq B', \qquad \mathbf{E}\bigcirc(B \sqcap B') \sqsubseteq C, \qquad \exists r.C \sqsubseteq C,$$

with r a rigid role. It is not hard to see that $\mathcal{T} \not\models A \sqsubseteq C$ but for every finite model $\mathfrak{I}$ of $\mathcal{T}$, $\mathfrak{I} \models A \sqsubseteq C$. In fact, we show that this also holds if the two occurrences of $\mathbf{E}\bigcirc$ in $\mathcal{T}$ are replaced by $\mathbf{E}\Diamond$. Therefore, the following holds.

Theorem 7 *$\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\bigcirc}$ and $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\Diamond}$ lack the FMP.*

Interestingly, in the same way the TBox presented above enforces a temporal tree with infinite branching degree, relying on rigid roles.

We next study the complexity of subsumption relative to general TBoxes in $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\bigcirc}$ and $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\Diamond}$. In Theorem 2, we already showed that the $\mathcal{ALC}$ variant of the latter is undecidable. For the former, observe that the corresponding $\mathcal{ALC}$-version is a notational variant of the product logic $\mathsf{K} \times \mathsf{K}$, for which the global consequence problem (and thus reasoning relative to global TBoxes) is known to be undecidable.

We will prove undecidability for $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\bigcirc}$ and a nonelementary lower bound for $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\Diamond}$, thus showing that even the convex fragments have a high complexity. These high complexity results are surprising because convex logics often exhibit better computational properties. Specifically, the lack of expressiveness prohibits reductions that were previously used to show undecidability particularly for product modal logics, for instance reductions from tiling problems: without disjunction we cannot express that in some point of the grid one of the tile types has to be true. However, we show how to exploit rigidity of the roles for proving these results. Let us remark that the proven lower bounds remain valid when we adopt the *expanding domain assumption* (Gabbay et al. 2003); in particular, the same proofs work.

4.3 Undecidability with the Next Operator

We proceed to show undecidability of the combination of $\mathcal{EL}$ with $\mathbf{E}\bigcirc$.

Theorem 8 *Concept subsumption w.r.t. general $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\bigcirc}$-TBoxes is undecidable.*

We present a reduction from the reachability problem for *two-counter machines (TCM)*. A TCM is a pair (Q, P) with states $Q = \{0, \dots, n\}$, where 0 is the *initial state* and n is the *halting state*, and corresponding instructions $P = \{I_0, \dots, I_{n-1}\}$. Additionally, there are two *registers* 1 and 2. For all $i < n$, we have that

- either $I_i = \mathsf{inc}(c, j)$ is an *incrementation instruction* with $c \in \{1, 2\}$ a register and j the subsequent state;
- or $I_i = \mathsf{dec}(c, j, k)$ is a *decrementation instruction* with $c \in \{1, 2\}$ a register and j the subsequent state if register c contains value 0 and k the subsequent state otherwise.

A *configuration* is a triple (i, n, m) where i is the current state and n and m are the contents of registers 1 and 2, respectively. We write $(i, n_1, n_2) \Rightarrow_M (j, m_1, m_2)$ if one of the following holds:

- $I_i = \mathsf{inc}(c, j)$, $m_c = n_c + 1$ and $m_{\overline{c}} = n_{\overline{c}}$ (where $\overline{c} = 3 - c$);
- $I_i = \mathsf{dec}(c, j, k)$, $m_c = n_c = 0$ and $m_{\overline{c}} = n_{\overline{c}}$;
- $I_i = \mathsf{dec}(c, k, j)$, $n_c > 0$, $m_c = n_c - 1$, and $m_{\overline{c}} = n_{\overline{c}}$.

The *computation of M* is the unique longest configuration sequence $(p_0, n_0, m_0) \Rightarrow_M (p_1, n_1, m_1) \Rightarrow_M \dots$ such that $p_0 = n_0 = m_0 = 0$. The *halting problem for TCM*, i.e., to decide whether a given TCM M reaches state n, is undecidable (Minsky 1967).

For our purposes, it is convenient to define a variant of the halting problem. Fix some TCM $M = (Q, I)$ with $Q = \{0, \dots, n\}$. An *extended state (e-state) x for M* is either $x = q$ for some $q \in Q$ with I_q an increment instruction or a pair $x = (q, f)$ with $f \in \{0, +\}$ and I_q a decrement instruction. Denote with $\overline{x}$ the state q if $x = q \in Q$ or $x = (q, f)$. A finite sequence of e-states $x_0, \dots, x_k$ is called *halting* if $x_k = n$ and there are numbers $n_0, m_0, \dots, n_k, m_k$ such that $x_0 = n_0 = m_0 = 0$ and $(\overline{x_i}, n_i, m_i) \Rightarrow_M (\overline{x_{i+1}}, n_{i+1}, m_{i+1})$ for all i, and additionally, if $x_i = (q, 0)$ and $I_q = \mathsf{dec}(c, \cdot, \cdot)$ then either $c = 1$ and $n_i = 0$ or $c = 2$ and $m_i = 0$, and if $x_i = (q, +)$ and $I_q = \mathsf{dec}(c, \cdot, \cdot)$, then either $c = 1$ and $n_i > 0$ or $c = 2$ and $m_i > 0$. It is easy to verify that M halts iff there is a halting sequence of e-states.

For the reduction let M be as above and assume without loss of generality that I_0 is an inc-instruction. Moreover, define a set of rigid roles, consisting of one role for each e-state:

$$\mathsf{ROL} = \{r_i \mid I_i = \mathsf{inc}(\cdot, \cdot)\} \cup \{r_{i0}, r_{i+} \mid I_i = \mathsf{dec}(\cdot, \cdot, \cdot)\}.$$

Finally, introduce concept names $Q_0, \dots, Q_n$ representing the states of M, for each $c \in \{1, 2\}$ concepts C_c marking elements that contribute to the value in register c and concepts Tail_c and Head_c that mark the bounds of register c.

We construct a $\text{CTL}_{\mathcal{EL}}^{\mathbf{E}\bigcirc}$-TBox $\mathcal{T}_M$ and identify two concept names A, B such that:

Lemma 9 *$\mathcal{T}_M \models A \sqsubseteq B$ iff there is a halting sequence of e-states.*

The idea is (i) to generate all sequences of e-states for M using the roles in ROL and (ii) to check if one of them is halting. Point (i) is done using the concept inclusions

$$A \sqsubseteq \exists r_0.(S \sqcap A), \qquad A \sqsubseteq \exists r.A \text{ for all } r \in \mathsf{ROL} \setminus \{r_0\}$$

where the first inclusion additionally ensures that after creating an r_0 successor, some special concept name S is satisfied. Intuitively, domain elements satisfying A in some world stipulate an infinite tree where the path to each node corresponds to *the reverse of a sequence of e-states*. For example, the branch $r_{3+}r_{20}r_{2+}r_1r_0$ of such a tree corresponds to the sequence $0, 1, (2, +), (2, 0), (3, +)$ of e-states for M.

For achieving Point (ii), we simulate the behavior of M *backwards* over the tree mentioned above. A configuration (i, n_1, n_2) of M will be represented in the temporal dimension by a time point that has a (time) successor for each register: one successor labeled with Head_1 and another with Head_2. Both successors have some (not necessarily direct) successor that is labeled with Tail_c and all worlds between Tail_c and Head_c are labeled with C_c. Further, the distance between Tail_c and Head_c is precisely the value n_c of the register c. Moreover, all these worlds are labeled with the current state Q_i.

Note that a valid computation of M always starts in state 0 and that by the above CI all corresponding nodes are labeled with S. Thus, we can use

$$S \sqsubseteq \mathbf{E}\bigcirc\bigsqcap_{c\in\{1,2\}}\mathbf{E}\bigcirc(\mathsf{Head}_c \sqcap \mathsf{Tail}_c \sqcap Q_0)$$

in order to enforce (the encoding of) an initial configuration of M starting in every node labeled with S. The begin of the counter never changes along a computation:

$$\exists r.\mathsf{Head}_c \sqsubseteq \mathsf{Head}_c \text{ for all } r \in \mathsf{ROL}, c \in \{1, 2\}.$$

It remains to describe how the ends Tail_c, the states Q_i, and the intermediate labels C_c are updated according to the instructions I. For instructions $I_i = \mathsf{inc}(c, j)$, we add the inclusions

$$\begin{aligned}
\exists r_i.(Q_i \sqcap \mathsf{Tail}_c) &\sqsubseteq Q_j \sqcap C_c \sqcap \mathbf{E}\bigcirc(Q_j \sqcap \mathsf{Tail}_c)\\
\exists r_i.(Q_i \sqcap C_c) &\sqsubseteq Q_j \sqcap C_c\\
\exists r_i.(Q_i \sqcap \mathsf{Tail}_{\overline{c}}) &\sqsubseteq Q_j \sqcap \mathsf{Tail}_{\overline{c}}\\
\exists r_i.(Q_i \sqcap C_{\overline{c}}) &\sqsubseteq Q_j \sqcap C_{\overline{c}}
\end{aligned}$$

For instructions $I_i = \mathsf{dec}(c, j, k)$, add the inclusions

$$\begin{aligned}
\exists r_{i0}.(Q_i \sqcap \mathsf{Head}_c \sqcap \mathsf{Tail}_c) &\sqsubseteq Q_j \sqcap \mathsf{Tail}_c\\
\exists r_{i0}.(Q_i \sqcap C_{\overline{c}}) &\sqsubseteq Q_j \sqcap C_{\overline{c}}\\
\exists r_{i0}.(Q_i \sqcap \mathsf{Tail}_{\overline{c}}) &\sqsubseteq Q_j \sqcap \mathsf{Tail}_{\overline{c}}\\
\exists r_{i+}.(Q_i \sqcap C_c \sqcap \mathbf{E}\bigcirc\mathsf{Tail}_c) &\sqsubseteq Q_k \sqcap \mathsf{Tail}_c\\
\exists r_{i+}.(Q_i \sqcap C_c \sqcap \mathbf{E}\bigcirc C_c) &\sqsubseteq Q_k \sqcap C_c\\
\exists r_{i+}.(Q_i \sqcap C_{\overline{c}}) &\sqsubseteq Q_k \sqcap C_{\overline{c}}\\
\exists r_{i+}.(Q_i \sqcap \mathsf{Tail}_{\overline{c}}) &\sqsubseteq Q_k \sqcap \mathsf{Tail}_{\overline{c}}
\end{aligned}$$

Note that in order to correctly update a configuration along some role r_i or r_{if}, $f \in \{0, +\}$, it is required that (1) the state of the configuration is in fact i, i.e., labeled with Q_i, and (2) for decrementation instructions $\mathsf{dec}(c, \cdot, \cdot)$ the mentioned conditions are satisfied. For example, if $f = 0$, then the value currently encoded in register c has to be zero. If this is not the case, none of the above CIs for register c can be applied; thus, no information is propagated for register c and the sequence under consideration does not correspond to a valid computation.

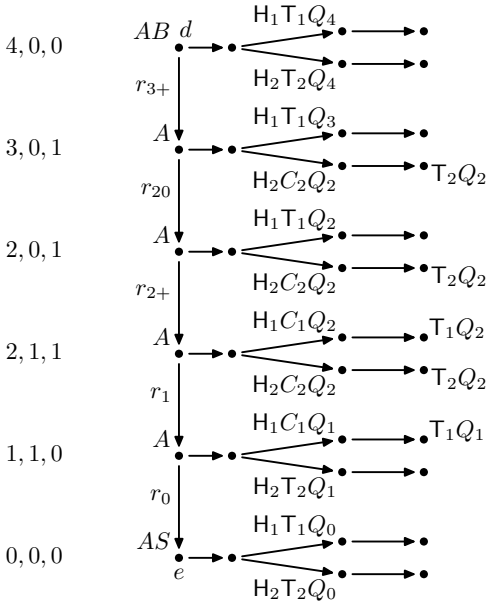

Figure 2: Example computation for $\mathcal{T}_M$.

Finally, a halting configuration can be detected by checking whether the encoding of some configuration has label Q_n in both registers. This is expressed by the CI

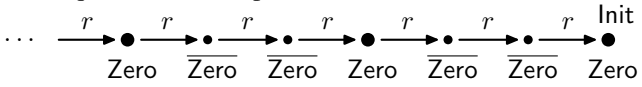
$$\mathbf{E}\bigcirc(\mathbf{E}\bigcirc(\mathsf{Head}_1 \sqcap Q_n) \sqcap \mathbf{E}\bigcirc(\mathsf{Head}_2 \sqcap Q_n)) \sqsubseteq B$$

in order to label accepting configurations with B.

Example 1 *Let $M = (Q, I)$ be a TCM with $Q = \{0, \ldots, 4\}$ and $I_0 = \mathsf{inc}(1, 1)$, $I_1 = \mathsf{inc}(2, 2)$, and $I_2 = \mathsf{dec}(1, 3, 2)$, $I_3 = \mathsf{dec}(2, 2, 4)$. It is easy to check that M halts and that the witnessing sequence of e-states is $0, 1, (2, +), (2, 0), (3, +), 4$. The construction of $\mathcal{T}_M$ implies that for any instance d of A, there is another domain element that is reachable via the sequence of roles $r_{3+}, r_{20}, r_{2+}, r_1, r_0$. This sequence is depicted in Figure 2. Note that by $\mathcal{T}_M$, e is labeled with S and starting from e we find the encoding of the initial configuration of M (the temporal relation is drawn horizontally and H, T abbreviate $\mathsf{Head}, \mathsf{Tail}$). $\mathcal{T}_M$ induces the configurations from bottom to top. The encoding of the configurations is found in the right side of the picture; the corresponding configurations are depicted on the left side. It can be seen that the top-most configuration is actually halting and enforces finally label B in point d. Note that only the consequences of* one *sequence of e-states are depicted. In particular, in a full model, all instances of A are also instances of B.*

4.4 Hardness for Non-Elementary Time with the Transitive Future Operator

We begin by noting that the reduction presented in the previous section does not easily transfer to the case when we consider the transitive future operator $\mathbf{E}\Diamond$ instead of the next



operator $\mathbf{E}\bigcirc$. The main problem is that we cannot update the concept Tail_c for a decrement instruction because the fact *'there is a future with* Tail_c *but no* C_c *until then'* is not expressible. This does not come as a surprise since it is known that the impossibility of talking about next time points brings considerable technical difficulties. For example, for proving lower bounds for products of transitive logics quite intricate techniques are required (Gabelaia et al. 2005).

In this section, we show that also the combination of $\mathbf{E}\Diamond$ with $\mathcal{EL}$ exhibits high computational complexity.

Theorem 10 *Concept subsumption w.r.t. general* $\mathrm{CTL}^{\mathbf{E}\Diamond}_{\mathcal{EL}}$*-TBoxes is inherently nonelementary.*

In order to prove the non-elementary lower bound, we use a technique in the style of (Stockmeyer 1974), which has already been used in the context of many-dimensional modal logics; for instance, for concept satisfiability for $\mathrm{LTL}_{\mathcal{ALC}}$ *without* TBoxes (Gabbay et al. 2003). In a nutshell, this technique consists of two steps: the first step is to find some encoding for numbers and show that arbitrarily big elementary numbers can be 'enforced'. In the second step, a standard reduction is used to show, e.g., k-EXPTIME-hardness of the problem for every $k \geq 1$.

We will proceed along these lines. For step 1, the encoding of a number n, we will provide a TBox $\mathcal{T}$ such that in any model of $\mathcal{T}$ containing a sequence of domain elements connected via a rigid role r the following holds. If some element of the sequence, say d, is an instance of the concept name Init, then every element that can reach d via $k \cdot n$ steps along r is an instance of a concept name Zero, and all other elements are instances of a concept name $\overline{\mathsf{Zero}}$. For $n = 3$, this sequence can be depicted as follows.

Formally, we say that a TBox $\mathcal{T}$ *counts modulo* n if there exist concept names Init, Zero, $\overline{\mathsf{Zero}}$, Fail, and a rigid role r such that for all $i \geq 0$ there are models $\mathfrak{I}$ of $\mathcal{T}$ and $\exists r^i.\mathsf{Init}$[1] with $\mathsf{Fail}^{\mathfrak{I},w} = \emptyset$ for all worlds w, and in all such models $\mathfrak{I}$ it holds for all $i \geq 0$:

(i) $\mathfrak{I} \models \exists r^i.\mathsf{Init} \sqsubseteq \mathsf{Zero}$ iff $i \equiv 0 \bmod n$;

(ii) $\mathfrak{I} \models \exists r^i.\mathsf{Init} \sqsubseteq \overline{\mathsf{Zero}}$ iff $i \not\equiv 0 \bmod n$.

Intuitively, the concept Fail is necessary as negation is not available; it is used to ensure that complementary concept names behave in a complementary way. The use of Fail is straightforward, so in the proof sketches below we will concentrate on points (i) and (ii).

We next show that there are 'small TBoxes that count modulo large numbers'. For making this precise, let us introduce the function $\mathsf{exp} : \mathbb{N} \times \mathbb{N} \to \mathbb{N}$:

$$\mathsf{exp}(1, n) := 2^n; \quad \mathsf{exp}(\ell + 1, n) := \mathsf{exp}(\ell, n) \cdot 2^{\mathsf{exp}(\ell, n)}.$$

Lemma 11 *For each* $k, n \geq 1$*, there is a polynomially sized (in* k, n*)* $\mathrm{CTL}^{\mathbf{E}\Diamond}_{\mathcal{EL}}$*-TBox* $\mathcal{T}_{k,n}$ *that counts modulo* $\mathsf{exp}(k, n)$*.*

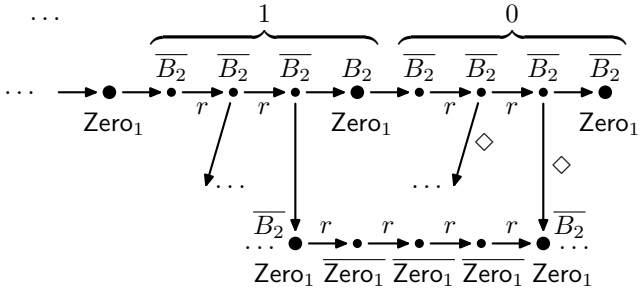
Proof. (sketch) The proof is by induction on k. For $k = 1$, we describe an $\mathcal{EL}$-TBox that counts modulo 2^n. To this aim, we introduce concept names $X_1, \overline{X_1}, \ldots, X_n, \overline{X_n}$, $C_1, \overline{C_1}, \ldots, C_n, \overline{C_n}$ modeling n bits and carry bits (and their negations), respectively, of a counter and take the CIs

$$\exists r.X_1 \sqsubseteq \overline{X_1} \sqcap C_1 \qquad \exists r.\overline{X_1} \sqsubseteq X_1 \sqcap \overline{C_1}$$
$$C_i \sqcap \exists r.X_{i+1} \sqsubseteq \overline{X_{i+1}} \sqcap C_{i+1}$$
$$C_i \sqcap \exists r.\overline{X_{i+1}} \sqsubseteq X_{i+1} \sqcap \overline{C_{i+1}}$$
$$\overline{C_i} \sqcap \exists r.X_{i+1} \sqsubseteq X_{i+1} \sqcap \overline{C_{i+1}}$$
$$\overline{C_i} \sqcap \exists r.\overline{X_{i+1}} \sqsubseteq \overline{X_{i+1}} \sqcap \overline{C_{i+1}}$$

For initializing the counter and for propagating Fail we include the following CIs for $1 \leq i \leq n$:

$$\mathsf{Init}_1 \sqsubseteq \mathsf{Zero}_1, \qquad \mathsf{Zero}_1 \equiv \overline{X_1} \sqcap \ldots \sqcap \overline{X_n},$$
$$X_i \sqsubseteq \overline{\mathsf{Zero}_1}, \qquad X_i \sqcap \overline{X_i} \sqsubseteq \mathsf{Fail}, \qquad C_i \sqcap \overline{C_i} \sqsubseteq \mathsf{Fail}$$

It should be clear that the TBox $\mathcal{T}_{1,n}$ consisting of all these CIs counts modulo 2^n.



For the induction step $k{>}1$, a number is now represented in binary in $\mathsf{exp}(k-1, n)$ consecutive domain elements along the r-chain; we use additional concepts B_k ($\overline{B_k}$) expressing that a bit is set (not set). We proceed 'inductively':

(1) If Init_k is satisfied in some domain element (in some world), then enforce that the next $\mathsf{exp}(k-1, n)$ domain elements satisfy $\overline{B_k}$; this encodes the number 0.

(2) If a sequence of $\mathsf{exp}(k-1, n)$ domain elements encodes some number, say M, then the preceding sequence of $\mathsf{exp}(k-1, n)$ domain elements is enforced to encode the number $M + 1$.

Clearly, for both steps (1) and (2) it is required to determine $\mathsf{exp}(k-1, n)$ consecutive elements, which is possible due to the induction hypothesis. In particular, for step (2) we mark the begin of the encoding of some number using $\mathcal{T}_{k-1,n}$: a new number begins whenever the concept Zero_{k-1} is satisfied. Also by induction hypothesis, we can mark all domain elements that are *not* the begin of some number.

For the actual incrementation necessary in Point (2), it suffices to communicate between domain elements that have distance (again: along r) precisely $\mathsf{exp}(k-1, n)$ as these domain elements represent the same bit positions in two successive numbers. This is realized by enforcing in each element of the chain a possible future where the bit of this element is stored. In the domain element having precisely distance $\mathsf{exp}(k-1, n)$, this bit is accessed and the correct value is enforced, see the following picture ($M = 0, k = 2$).

It remains to mark the elements of the sequence with Zero_k and $\overline{\mathsf{Zero}_k}$, respectively. First, note that Zero_k can hold only

[1] $\exists r^i$ abbreviates sequences of $\exists r$ with length i.

at the begin of the encoding of some number. So in all 'non-begin' elements we imply $\overline{\mathsf{Zero}_\mathsf{k}}$. For distinguishing the begin elements it suffices to detect the encoding of a number where all $\exp(k-1,n)$ bits are set to 1. Then, starting from the next domain element we will find the encoding of a 0, and we mark its begin with Zero_k. ❑

In the second step we employ the TBoxes $\mathcal{T}_{k,n}$ to reduce the word-problem for deterministic Turing machines with k-fold exponential space restriction to subsumption in $\text{CTL}^{\mathbf{E}\Diamond}_{\mathcal{EL}}$. Theorem 10 is then a direct corollary.

Theorem 12 *Concept subsumption w.r.t. general* $\text{CTL}^{\mathbf{E}\Diamond}_{\mathcal{EL}}$*-TBoxes is* k-EXPSPACE*-hard for every* $k \geq 1$.

Proof. (sketch) Fix any $k \geq 1$ and let M be a deterministic Turing machine which runs within $\exp(k, p(n))$ space for inputs of length n for some polynomial $p(n)$. Let w be some input of length n and set $N := p(n)$. By Lemma 11, there is a TBox $\mathcal{T}_{k,N}$ that counts modulo $\exp(k,N)$ and whose size is polynomial in k, N and hence also polynomial in k, n.

For the reduction, we first include the CI $A \sqsubseteq \exists r.A$ that generates an infinite and rigid r-chain. For every domain element satisfying A, we enforce a possible future that simulates M (again backwards) along the r-chain: $A \sqsubseteq \mathbf{E}\Diamond\mathsf{Init}_M$. A configuration of M is represented by a sequence of $\exp(k,N)$ domain elements connected via r using concept names for every symbol from the tape alphabet, for every state, and for the head. The borders between two configurations are marked using $\mathcal{T}_{k,N}$. We proceed inductively along the lines of the proof of Lemma 11:

(1') enforce the initial configuration of M (including w);

(2') if a sequence of $\exp(k,N)$ domain elements between two borders encodes a configuration of M, the preceding sequence of $\exp(k,N)$ domain elements is enforced to encode the successor configuration.

Obviously, step (1') can be done using a polynomial TBox starting from the concept Init_M. For enforcing tape symbols in step (2') it suffices to communicate between domain elements that have an r-distance of precisely $\exp(k,N)$. Finally, for updating the head position, we might have to communicate between elements having distance $\exp(k,N) \pm 1$. The previous ideas can be easily adapted to this case.

It remains to add the CI $\mathbf{E}\Diamond Q_{acc} \sqsubseteq B$ in order to detect an accepting configuration. It is routine to show that M accepts w iff the constructed TBox implies $A \sqsubseteq B$. ❑

5 Decidability of CTL with *DL-Lite*$^{\mathcal{N}}_{bool}$

In this section, we show that the technique developed by (Artale et al. 2012) to prove decidability of TDLs based on *linear-time* temporal logic and *DL-Lite* is robust in the sense that it can be carried over to *some* TDLs based on CTL and *DL-Lite*$^{\mathcal{N}}_{bool}$ (Artale et al. 2009).

CTL-*DL-Lite*$^{\mathcal{N}}_{bool}$ *concepts* C, D are defined by the following grammar:

$$\bot \mid A \mid \geq q\, r \mid \neg C \mid C \sqcap D \mid \mathbf{E}\bigcirc C \mid \mathbf{E}\Box C \mid \mathbf{E}(C\,\mathcal{U}\,D),$$

where q is a positive integer given in binary, A ranges over concept names and r ranges over $\{r, r^- \mid r \in \mathsf{N_R}\}$.

The semantics for Booleans and temporal operators is defined as in Section 2. We interpret *inverse roles* and *number restrictions* in a temporal interpretation $\mathfrak{I}$ as follows:

$$\begin{aligned}(r^-)^{\mathfrak{I},w} &= \{(d',d) \mid (d,d') \in r^{\mathfrak{I},w}\};\\ (\geq q\, r)^{\mathfrak{I},w} &= \{d \mid \sharp\{d' \mid (d,d') \in r^{\mathfrak{I},w}\} \geq q\}.\end{aligned}$$

Our following result shows that three fragments of CTL-*DL-Lite*$^{\mathcal{N}}_{bool}$ behave in a similar way as temporal extensions of *DL-Lite*$^{\mathcal{N}}_{bool}$ based on linear time: reasoning in these fragments is not harder than in the component logics.

Theorem 13 *Concept satisfiability w.r.t. general TBoxes is* EXPTIME*-complete*
1. for CTL-*DL-Lite*$^{\mathcal{N}}_{bool}$ *without local roles,*
2. for $\text{CTL}^{\mathbf{E}\mathcal{U},\mathbf{E}\Box}$-*DL-Lite*$^{\mathcal{N}}_{bool}$*,*
and PSPACE*-complete*
3. for $\text{CTL}^{\mathbf{E}\Diamond}$-*DL-Lite*$^{\mathcal{N}}_{bool}$*.*

The fragments of points 2,3 do not allow the operator $\mathbf{E}\bigcirc$.

Proof. (sketch) For the upper bound, the proof follows the two-step technique proposed by (Artale et al. 2012). First, we reduce from CTL-*DL-Lite*$^{\mathcal{N}}_{bool}$ to the one-variable fragment $\mathcal{QCTL}^1$ of *first-order branching temporal logic* $\mathcal{QCTL}$ (Hodkinson, Wolter, and Zakharyaschev 2002). Then, the result is further reduced to a $\mathcal{QCTL}^1$-formula *without occurrences of existential quantifiers*, which is essentially a CTL-formula. This way we get the same upper bounds as for the propositional CTL fragments. The lower bounds are inherited from the corresponding fragments (Meier et al. 2009).

The elimination of the quantifiers in the second step does not work for full CTL-*DL-Lite*$^{\mathcal{N}}_{bool}$ because the original shifting technique (Artale et al. 2012, Lemma 4.2) relies on the past being unbounded, which is not the case for the standard CTL semantics. However, the problem can be circumvented by (1) disallowing local roles – which makes shifting superfluous – or (2) restricting the temporal operators to $\mathbf{E}\mathcal{U}$ and $\mathbf{E}\Box$ which are tolerant to a certain variant of unravelling into the temporal direction. Unravelling tolerance is related to stutter invariance (Lamport 1983) and does not apply to $\mathbf{E}\bigcirc$ and therefore to the strict variants $\mathbf{E}\Box^<$ and $\mathbf{E}\mathcal{U}^<$.

We note that the only temporal operators used to encode the TBox and rigidity of roles in the first step are $\mathbf{E}\Diamond$ and $\mathbf{A}\Box$, which are available in $\text{CTL}^{\mathbf{E}\Diamond}$-*DL-Lite*$^{\mathcal{N}}_{bool}$. Hence our translation works for $\text{CTL}^{\mathbf{E}\Diamond}$-*DL-Lite*$^{\mathcal{N}}_{bool}$, too. ❑

6 Conclusions and Future Work

In this paper, we have made progress towards understanding the landscape of the computational complexity and expressivity of BTDLs allowing for rigid roles and general TBoxes. In particular, we showed for some BTDLs based on $\mathcal{EL}$ that we cannot easily conclude undecidability via non-convexity, as in the case of similar LTDLs, since they can be shown to be convex. However, we have been able to squelch the hope that these convex logics are practical because we established a non-elementary lower bound and undecidability, respectively.

The problems left open include determining the precise complexity of $\mathrm{CTL}^{\mathbf{E}\Diamond}_{\mathcal{EL}}$ and of unrestricted CTL-*DL-Lite*$^{\mathcal{N}}_{bool}$. For the latter, we plan to pursue an automata-based approach in the style of (Gutiérrez-Basulto, Jung, and Lutz 2012).

Our investigation provides several research directions that are worth exploring in the near future – for example, one could consider reasoning in the presence of *acyclic TBoxes* instead of general ones, as usually the computational properties of DLs over acyclic TBoxes are better. Furthermore, complexity might also drop when assuming *expanding domains* instead of constant domains.

For BTDLs based on *DL-Lite*, the investigation can be broadened in two ways: by considering restrictions such as *DL-Lite*$_{core}$ or by studying the effect of adding role inclusions. In fact, LTDLs based on *DL-Lite*$_{core}$ are less complex than their *DL-Lite*$_{bool}$ counterpart (Artale et al. 2012). Another possibility is the study of BTDLs with the more expressive *temporal roles*; e.g., where $\mathbf{E}\Diamond$ and $\mathbf{A}\Box$ are applied to roles. LTDLs with temporal roles are undecidable (Artale et al. 2012).

Finally, we believe that our results, together with the suggested restriction to acyclic and empty TBoxes, can have an impact on the study of PMLs, given the known correspondence between PMLs and combinations of DLs and modal-like logics with rigid roles and empty TBoxes: it seems that PMLs with good computational properties may be found among their *positive fragments*, some of which are notational variants of $\mathrm{CTL}^{\mathbf{E}\bigcirc}_{\mathcal{EL}}$, $\mathrm{CTL}^{\mathbf{E}\Diamond}_{\mathcal{EL}}$and $\mathrm{CTL}^{\mathbf{E}\Diamond,\mathbf{A}\Box}_{\mathcal{EL}}$. For instance, the satisfiability problems of $\mathsf{K} \times \mathsf{K}$ and $\mathsf{S4} \times \mathsf{K}$ are non-elementary, and there is hope that the complexity of their positive fragments is only elementary.

Abstract

We study finite model reasoning in expressive Horn description logics (DLs), starting with a reduction of finite ABox consistency to unrestricted ABox consistency. The reduction relies on reversing certain cycles in the TBox, an approach that originated in database theory, was later adapted to the inexpressive DL *DL-Lite*$_\mathcal{F}$, and is shown here to extend to the expressive Horn DL Horn-$\mathcal{ALCFI}$. The model construction used to establish correctness makes the structure of finite models more explicit than existing approaches to finite model reasoning in expressive DLs that rely on solving systems of inequations over the integers. Since the reduction incurs an exponential blow-up, we then develop a dedicated consequence-based algorithm for finite ABox consistency in Horn-$\mathcal{ALCFI}$ that implements the reduction on-the-fly rather than executing it up-front. The algorithm has optimal worst-case complexity and provides a promising foundation for implementations. We next show that our approach can be adapted to finite (positive existential) query answering relative to Horn-$\mathcal{ALCFI}$ TBoxes, proving that this problem is EXPTIME-complete in combined complexity and PTIME-complete in data complexity. For finite satisfiability and subsumption, we also show that our techniques extend to Horn-$\mathcal{SHIQ}$.

1 Introduction

Many popular expressive description logics (DLs) include both inverse roles and some form of counting such as functionality restrictions. This combination is well-known to result in a loss of the finite model property (FMP) and, consequently, reasoning w.r.t. the class of finite models (*finite model reasoning*) does not coincide with reasoning w.r.t. the class of all models (*unrestricted reasoning*). On the one hand, this distinction is gaining importance because DLs are increasingly used in database applications, where finiteness of models and databases is a central assumption. On the other hand, finite model reasoning is rarely used when DLs are applied in practice, mainly because for many DLs that lack the FMP, no algorithmic approaches to finite model reasoning are known that lend themselves towards efficient implementation.

Among the most widely-known DLs that include both inverse roles and counting are $\mathcal{ALCFI}$, $\mathcal{ALCQI}$, $\mathcal{SHIF}$, and $\mathcal{SHIQ}$, which are prominent fragments of the OWL2 DL ontology language. While finite model reasoning in these DLs is known to have the same complexity as unrestricted reasoning, namely EXPTIME-complete (Lutz, Sattler, and Tendera 2005), the algorithmic approaches are rather different when only finite models are admitted. For unrestricted reasoning, there is a wide range of applicable algorithms such as tableau and resolution calculi, which often perform rather well in practical implementations. For finite model reasoning, all known approaches rely on the construction of some system of inequations (Calvanese 1996; Lutz, Sattler, and Tendera 2005) and then solve this system over the integers; the crux is that the system of inequations is of exponential size in the best case, and consequently it is far from obvious how to come up with efficient implementations. This is also true for the two-variable fragment of first-order logic with counting quantifiers (C2), into which the mentioned DLs can be embedded (Pacholski, Szwast, and Tendera 2000; Pratt-Hartmann 2005), that is, all known approaches to finite model reasoning in C2 rely on solving (at least) exponentially large systems of inequations.

Interestingly, the situation is quite different on the other end of the expressive power spectrum. While $\mathcal{SHIQ}$ et al. belong to the family of expressive DLs, *DL-Lite*$_\mathcal{F}$ is a comparably inexpressive DL that emerged from database applications, but also includes both inverse roles and functionality restrictions and thus lacks the FMP. Building on a technique that was developed in database theory by Cosmadakis, Kanellakis, and Vardi to decide the implication of inclusion dependencies and functional dependencies over finite databases (1990), Rosati has shown that finite model reasoning in *DL-Lite*$_\mathcal{F}$ can be reduced in polynomial time to unrestricted reasoning in *DL-Lite*$_\mathcal{F}$ (2008). The reduction is conceptually simple and relies on completing the TBox by finding certain cyclic inclusions and then 'reversing' them. For example, the cycle

$$\exists r^- \sqsubseteq \exists s \qquad \exists s^- \sqsubseteq \exists r \qquad (\mathsf{funct}\ r^-) \qquad (\mathsf{funct}\ s^-)$$

that consists of existential restrictions in the 'forward direction' and functionality statements in the 'backwards direction' would lead to the addition of the reversed cycle

$$\exists s \sqsubseteq \exists r^- \qquad \exists r \sqsubseteq \exists s^- \qquad (\mathsf{funct}\ r) \qquad (\mathsf{funct}\ s).$$

As a consequence, finite model reasoning in DL-Lite$_\mathcal{F}$ does not require new algorithmic techniques and can be implemented as efficiently as unrestricted reasoning. The reduction

also makes explicit the *logical consequences of finite models*; in a sense, it can be viewed as an explicit axiomatization of finiteness.

Given that DL-Lite$_\mathcal{F}$ is only a very small fragment of $\mathcal{ALCFI}$ and $\mathcal{SHIQ}$, this situation raises the question whether the cycle reversion technique extends also to larger fragments of these DLs. In particular, *DL-Lite*$_\mathcal{F}$ is a 'Horn DL', and such logics are well-known to be algorithmically much more well-behaved than non-Horn DLs such as $\mathcal{ALCFI}$ (Baader, Brandt, and Lutz 2005; Calvanese et al. 2007). Maybe, then, this is the reason why cycle reversion works for *DL-Lite*$_\mathcal{F}$?

In this paper, we show that the cycle reversion technique of Cosmadakis et al. extends all the way to the expressive DLs Horn-$\mathcal{ALCFI}$ and Horn-$\mathcal{ALCQI}$. These logics, as well as their extensions Horn-$\mathcal{SHIF}$ and Horn-$\mathcal{SHIQ}$, are popular in ontology-based data access (Hustadt, Motik, and Sattler 2007; Ortiz, Rudolph, and Šimkus 2011; Eiter et al. 2012; Bienvenu, Lutz, and Wolter 2013) and properly extend *DL-Lite*$_\mathcal{F}$ and other relevant Horn DLs such as $\mathcal{ELIF}$ (Krisnadhi and Lutz 2007). We start with showing that finite ABox consistency in Horn-$\mathcal{ALCFI}$ can be reduced to unrestricted ABox consistency in Horn-$\mathcal{ALCFI}$ by cycle reversion; it follows that the same is true for finite satisfiability, finite subsumption, and finite instance checking. While the reduction technique is conceptually similar to that for *DL-Lite*$_\mathcal{F}$, the construction of a finite model in the correctness proof is more demanding. In comparison to approaches to finite model reasoning that rely on solving systems of inequations, though, they make the structure of finite models considerably more explicit.

Another crucial difference to the *DL-Lite*$_\mathcal{F}$ case is that, when completing Horn-$\mathcal{ALCFI}$ TBoxes, the cycles that have to be considered can be of exponential length, and thus the reduction is not polynomial. Consequently, when used in a naive way it can neither be expected to perform well in practice nor be used to (re)prove tight complexity bounds. To address these shortcomings, we develop a dedicated calculus for finite ABox consistency in Horn-$\mathcal{ALCFI}$ that implements the reduction on-the-fly rather than executing it up-front. The calculus is an extension of a consequence-based procedure for unrestricted satisfiability in Horn-$\mathcal{SHIQ}$ that was introduced by Kazakov in (2009) and implemented in the highly performant reasoner CB, first to classify the notoriously difficult Galen ontology. Many other state-of-the art reasoners for Horn-DLs are also based on consequence-based procedures, including ELK (Kazakov, Krötzsch, and Simančík 2011a) and CEL (Baader, Lutz, and Suntisrivaraporn 2006). Our algorithm shares the main feature of other consequence-based procedures to carefully avoid considering 'types' (conjunctions of concept names) that are irrelevant for deciding the problem at hand. We therefore believe that it provides a very promising basis for efficient implementations of finite model reasoning in Horn-$\mathcal{ALCFI}$. It also (re)proves the optimal upper ExpTime complexity bound for finite ABox consistency in this DL. Via a reduction, the cycle reversing reduction and the consequence-based algorithm can be applied also to finite satisfiability and subsumption in Horn-$\mathcal{ALCQI}$.

We then consider the paradigm of ontology-based data access (OBDA), extending our results from finite ABox consistency to answering positive existential queries (PEQs), relative to Horn-$\mathcal{ALCFI}$ TBoxes over finite models. In particular, we show that the reduction based on cycle reversion developed for ABox consistency also works in the case of PEQ answering. The construction of (counter)models in the correctness proofs, however, becomes yet more difficult and technical, and proceeds in two stages. First, we carefully modify the models constructed for finite ABox consistency so that there are no unintended matches of acyclic conjunctive queries (CQs). And second, we take a product with a finite group of high girth to eliminate unintended matches of cyclic CQs. Based on this result, we then prove that finite PEQ entailment (the Boolean version of PEQ answering) in Horn-$\mathcal{ALCFI}$ is ExpTime-complete regarding combined complexity and PTime-complete regarding data complexity. Previously, it was only known that finite CQ answering in (non-Horn) $\mathcal{ALCQI}$ is decidable and in coNP regarding data complexity (Pratt-Hartmann 2009).

Some proof details are deferred to the appendix in the long version: http://tinyurl.com/kr14fmr

2 Preliminaries

We introduce the DLs Horn-$\mathcal{ALCFI}$ and Horn-$\mathcal{ALCQI}$, as well as the reasoning tasks studied in this paper. The original definition of these DLs is based on a notion of polarity and somewhat unwieldy (Hustadt, Motik, and Sattler 2007); alternative and more direct definitions have been proposed later, see for example (Lutz and Wolter 2012). For brevity, we directly introduce Horn-$\mathcal{ALCQI}$ TBoxes in a normal form that is convenient for our purposes and disallows syntactic nesting of operators. It is a minor variation of the normal form proposed in (Kazakov 2009).

Let $\mathsf{N_C}$, $\mathsf{N_R}$, and $\mathsf{N_I}$ be countably infinite and disjoint sets of concept names, role names, and individual names. A *role* is either a role name r or an *inverse role* r^-. A *Horn-$\mathcal{ALCQI}$ TBox* $\mathcal{T}$ is a set of *concept inclusions (CIs)* that can take the following forms:

$$K \sqsubseteq A \qquad K \sqsubseteq \bot \qquad K \sqsubseteq \exists r.K'$$
$$K \sqsubseteq \forall r.K' \qquad K \sqsubseteq (\leqslant 1\ r\ K') \qquad K \sqsubseteq (\geqslant n\ r\ K')$$

where K and K' denote a (possibly empty) conjunction of concept names, A a concept name, r a (potentially inverse) role, and $n \geq 2$. Throughout the paper, we will deliberately confuse conjunctions of concept names and sets of concept names. The empty conjunction is abbreviated by $\top$. As usual, we allow to easily switch between role names and their inverse by identifying $(r^-)^-$ and r. A *Horn-$\mathcal{ALCFI}$ TBox* is a Horn-$\mathcal{ALCQI}$ TBox that does not include CIs of the form $K \sqsubseteq (\geqslant n\ r\ K')$.

The semantics of Horn-$\mathcal{ALCQI}$ is based on interpretations as usual, see (Baader et al. 2003) for details. We write $\mathcal{T} \models C \sqsubseteq D$ if the concept inclusion $C \sqsubseteq D$ is satisfied in all models of the TBox $\mathcal{T}$, and $\mathcal{T} \models_{\mathsf{fin}} C \sqsubseteq D$ if the same holds for all finite models. A concept name A is *(finitely) satisfiable* w.r.t. a TBox $\mathcal{T}$ if $\mathcal{T}$ has a (finite) model $\mathcal{I}$ with $A^\mathcal{I} \neq \emptyset$. If $\mathcal{T} \models A \sqsubseteq B$ (resp. $\mathcal{T} \models_{\mathsf{fin}} A \sqsubseteq B$) with A and B concept names, then we say that B is *(finitely) subsumed* by A.

An *ABox* is a finite set of *concept assertions* $A(a)$ and *role assertions* $r(a, b)$ where A is a concept name, r a role name, and a, b are individual names. For simplicity, we make the *standard names assumption*, that is, every interpretation $\mathcal{I}$ interpretes all individuals as themselves; for example $\mathcal{I}$ satisfies $A(a)$ if $a \in A^{\mathcal{I}}$. The standard names assumption implies the unique name assumption (UNA). The results in this paper, however, do not depend on any of these assumptions. Throughout the paper, we sometimes write $r^-(a, b) \in \mathcal{A}$ for $r(b, a) \in \mathcal{A}$ and use $\mathsf{Ind}(\mathcal{A})$ to denote the set of all individual names that occur in $\mathcal{A}$.

We write $\mathcal{A}, \mathcal{T} \models A(a)$ if the ABox assertion $A(a)$ is satisfied in all common models of the ABox $\mathcal{A}$ and the TBox $\mathcal{T}$, and $\mathcal{A}, \mathcal{T} \models_{\mathsf{fin}} A(a)$ if the same holds for all finite models. We then say that a is a *(finite) instance* of A in $\mathcal{A}$ w.r.t. $\mathcal{T}$. An ABox $\mathcal{A}$ is *(finitely) consistent* w.r.t. $\mathcal{T}$ if there is a (finite) model $\mathcal{I}$ of $\mathcal{T}$ that satisfies all assertions in $\mathcal{A}$.

The above notions give rise to four decision problems studied in this paper, which are *finite satisfiability* (of a concept name w.r.t. a TBox), *finite subsumption* (between two concept names w.r.t. a TBox), *finite ABox consistency* (w.r.t. a TBox) and *finite instance checking* (of an ABox individual and a concept name, w.r.t. an ABox and a TBox). There are easy polynomial time reductions from satisfiability to subsumption to instance checking to ABox consistency, which work both in the finite and in the unrestricted case.

The following examples show that, in Horn-$\mathcal{ALCFI}$, finite and unrestricted reasoning do not coincide.

Example 1

$$\mathcal{T} = \{ \quad A \sqsubseteq \exists r.B, \qquad B \sqsubseteq \exists r.B, \\ B \sqsubseteq (\leqslant 1\ r^-\ \top), \quad A \sqcap B \sqsubseteq \bot \qquad \}$$

A is satisfiable w.r.t. $\mathcal{T}$, but not finitely satisfiable. In fact, when $d \in A^{\mathcal{I}}$ in some model $\mathcal{I}$ of $\mathcal{T}$, then there must be an infinite chain $r(d, d_1), r(d_1, d_2), \ldots$ with $d \in A^{\mathcal{I}}$, and $d_2, d_3, \cdots \in B^{\mathcal{I}}$. Since d cannot be in $B^{\mathcal{I}}$ and r is inverse functional, no two elements on the chain can be identified.

$$\mathcal{T}' = \{\ A_1 \sqsubseteq \exists r.A_2, \quad A_2 \sqsubseteq \exists r.(A_1 \sqcap B), \\ \top \sqsubseteq (\leqslant 1\ r^-\ \top) \quad \}$$

The reader might want to verify that $\mathcal{T}' \not\models A_1 \sqsubseteq B$, but $\mathcal{T}' \models_{\mathsf{fin}} A_1 \sqsubseteq B$.

It follows form the observations in (Kazakov 2009) that, for the purposes of deciding satisfiability of concepts in unrestricted models, the normal form for TBoxes introduced above can be assumed without loss of generality because every Horn-$\mathcal{ALCQI}$ TBox $\mathcal{T}$ can be converted in polynomial time into a TBox $\mathcal{T}'$ in the above form such that every model of $\mathcal{T}'$ is a model of $\mathcal{T}$ and, conversely, every model of $\mathcal{T}$ can be converted into a model of $\mathcal{T}'$ by interpreting the concept names that were introduced during normalization. It follows that normal form can be assumed w.l.o.g. both for unrestricted reasoning and for finite model reasoning, and for all reasoning problems considered in this paper.

3 From Finite Models to Unrestricted Models

We show that finite ABox consistency in Horn-$\mathcal{ALCFI}$ can be reduced to unrestricted ABox consistency by reversing certain cycles in the TBox. The reduction exhibited in this section provides a novel decision procedure for finite ABox consistency in Horn-$\mathcal{ALCFI}$ and Horn-$\mathcal{ALCQI}$ (as well as for finite satisfiability, finite subsumption, and finite instance checking) and is the basis for developing a consequence-based procedure in Section 4. It also highlights the logical consequences of finite models in Horn-$\mathcal{ALCFI}$. The material in this section is an extended and improved version of the workshop paper (Ibáñez-García, Lutz, and Schneider 2013).

Reversing Cycles

Let $\mathcal{T}$ be a Horn-$\mathcal{ALCFI}$ TBox. A *finmod cycle in $\mathcal{T}$* is a sequence $K_1, r_1, K_2, r_2, \ldots, r_{n-1}, K_n$, with $K_1, \ldots, K_n$ conjunctions of concept names and $r_1, \ldots, r_{n-1}$ (potentially inverse) roles such that $K_n = K_1$ and, for $1 \leq i < n$:

$$\mathcal{T} \models K_i \sqsubseteq \exists r_i.K_{i+1} \text{ and } \mathcal{T} \models K_{i+1} \sqsubseteq (\leqslant 1\ r_i^-\ K_i).$$

By *reversing* a finmod cycle $K_1, r_1, K_2, r_2, \ldots, r_{n-1}, K_n$ in a TBox $\mathcal{T}$, we mean to extend $\mathcal{T}$ with the following concept inclusions, for $1 \leq i < n$:

$$K_{i+1} \sqsubseteq \exists r_i^-.K_i \text{ and } K_i \sqsubseteq (\leqslant 1\ r_i\ K_{i+1}).$$

The *completion* $\mathcal{T}_{\mathsf{f}}$ of a TBox $\mathcal{T}$ is obtained from $\mathcal{T}$ by exhaustively reversing finmod cycles. Note that, although there may be infinitely many finmod cycles, only finitely many CIs can be added by cycle reversion (exponentially many in the size of the original TBox, in the worst case). For finding these finitely many CIs, it clearly suffices to consider finmod cycles in which all triples (r_i, K_{i+1}, r_{i+1}) are distinct. Also note that finding finmod cycles requires deciding unrestricted subsumption, which is decidable and EXPTIME-complete.

Example 2 *The TBox $\mathcal{T}'$ from Example 1 entails (in unrestricted models)*

$$A_1 \sqcap B \sqsubseteq \exists r.A_2, \qquad A_2 \sqsubseteq \exists r.(A_1 \sqcap B), \\ A_2 \sqsubseteq (\leqslant 1\ r^-\ A_1 \sqcap B), \quad A_2 \sqcap B \sqsubseteq (\leqslant 1\ r^-\ A_1).$$

Thus, A_1, r, A_2, r, A_1, is a finmod cycle in $\mathcal{T}'$, which is reversed to

$$A_2 \sqsubseteq \exists r^-.A_1, \qquad A_1 \sqsubseteq \exists r^-.A_2, \\ A_2 \sqsubseteq (\leqslant 1\ r\ A_1), \qquad A_1 \sqsubseteq (\leqslant 1\ r\ A_2).$$

From $A_1 \sqsubseteq \exists r^-.A_2$, $A_2 \sqsubseteq \exists r.(A_1 \sqcap B)$, and $A_2 \sqsubseteq (\leqslant 1\ r\ A_1)$, we obtain $\mathcal{T}'_{\mathsf{f}} \models A_1 \sqsubseteq B$, in correspondence with $\mathcal{T}' \models_{\mathsf{fin}} A_1 \sqsubseteq B$. Note that $\mathcal{T}'$ also contains another finmod cycle, which is $(A_1 \sqcap B), r, A_2, r, (A_1 \sqcap B)$.

The following result shows that TBox completion provides a reduction from finite ABox consistency to unrestricted ABox consistency.

Theorem 3 *Let $\mathcal{T}$ be a Horn-$\mathcal{ALCFI}$ TBox and $\mathcal{A}$ an ABox. Then $\mathcal{A}$ is finitely consistent w.r.t. $\mathcal{T}$ iff $\mathcal{A}$ is consistent w.r.t. the completion $\mathcal{T}_{\mathsf{f}}$ of $\mathcal{T}$.*

The "only if" direction of Theorem 3 is an immediate consequence of the observation that all CIs added by cycle reversion are entailed by the original TBox in finite models.

Lemma 4 *Let $K_1, r_1, \ldots, r_{n-1}, K_n$ be a finmod cycle in $\mathcal{T}$. Then $\mathcal{T} \models_{\mathsf{fin}} K_{i+1} \sqsubseteq \exists r_i^-.K_i$ and $\mathcal{T} \models_{\mathsf{fin}} K_i \sqsubseteq (\leqslant 1\ r_i\ K_{i+1})$ for $1 \leq i < n$,.*

Proof. We have to show that if $K_1, r_1, \dots, r_{n-1}, K_n$ is a finmod cycle in $\mathcal{T}$ and $\mathcal{I}$ is a finite model of $\mathcal{T}$, then $K_i^{\mathcal{I}} \subseteq (\leqslant 1\ r_i\ K_{i+1})^{\mathcal{I}}$ and $K_{i+1}^{\mathcal{I}} \subseteq (\exists r_i^-.K_i)^{\mathcal{I}}$ for $1 \leq i < n$. We first note that, by the semantics of Horn-$\mathcal{ALCFI}$, we must have $|K_1^{\mathcal{I}}| \leq \cdots \leq |K_n^{\mathcal{I}}|$, thus $K_n = K_1$ yields $|K_1^{\mathcal{I}}| = \cdots = |K_n^{\mathcal{I}}|$. Fix some i with $1 \leq i < n$. Using $|K_i^{\mathcal{I}}| = |K_{i+1}^{\mathcal{I}}|$, $K_i^{\mathcal{I}} \subseteq (\exists r_i.K_{i+1})^{\mathcal{I}}$, and $K_{i+1}^{\mathcal{I}} \subseteq (\leqslant 1\ r_i^-\ K_i)^{\mathcal{I}}$, it is easy to verify that $K_i^{\mathcal{I}} \subseteq (\leqslant 1\ r_i\ K_{i+1})^{\mathcal{I}}$ and $K_{i+1}^{\mathcal{I}} \subseteq (\exists r_i^-.K_i)^{\mathcal{I}}$, as required. ❑

We now prove the "if" direction of Theorem 3, which is much more demanding as it requires to explicitly construct finite models.

Constructing Finite Models

Assume that $\mathcal{A}$ is consistent w.r.t. $\mathcal{T}_\mathsf{f}$. Our aim is to construct a finite model $\mathcal{I}$ of $\mathcal{A}$ and $\mathcal{T}_\mathsf{f}$ (and thus also of $\mathcal{T}$). Before we give details of the construction, we introduce some relevant preliminaries.

Let $\mathsf{CN}(\mathcal{T})$ denote the set of concept names used in $\mathcal{T}$ (or, equivalently, in $\mathcal{T}_\mathsf{f}$). A *type for* $\mathcal{T}_\mathsf{f}$ is a subset $t \subseteq \mathsf{CN}(\mathcal{T})$ such that there is a (potentially infinite) model $\mathcal{I}$ of $\mathcal{T}_\mathsf{f}$ and a $d \in \Delta^{\mathcal{I}}$ such that $\mathsf{tp}_{\mathcal{I}}(d) = t$, where

$$\mathsf{tp}_{\mathcal{I}}(d) := \{A \in \mathsf{CN}(\mathcal{T}) \mid d \in A^{\mathcal{I}}\}$$

is the type *realized* at d in $\mathcal{I}$. We use $\mathsf{TP}(\mathcal{T}_\mathsf{f})$ to denote the set of all types for $\mathcal{T}_\mathsf{f}$. For $t, t' \in \mathsf{TP}(\mathcal{T}_\mathsf{f})$ and r a role, we write

- $t \to_r t'$ if $\mathcal{T}_\mathsf{f} \models t \sqsubseteq \exists r.t'$ and t' is maximal with this property;
- $t \to_r^1 t'$ if $t \to_r t'$ and $\mathcal{T}_\mathsf{f} \models t' \sqsubseteq (\leqslant 1\ r^-\ t)$;
- $t\ {}^1\!\leftrightarrow_r^1 t'$ if $t \to_r^1 t'$ and $t' \to_{r^-}^1 t$.

Note that when

$$t_1 \to_{r_1}^1 t_2 \to_{r_2}^1 \cdots \to_{r_{n-1}}^1 t_n = t_1 \qquad (*)$$

then $t_1, r_1, \dots, r_{n-1}, t_n$ is a finmod cycle in $\mathcal{T}_\mathsf{f}$ and the fact that it has been reversed means that all '$\to^1$' in $(*)$ can be replaced with ${}^1\!\leftrightarrow^1$. Types related by ${}^1\!\leftrightarrow_r^1$ are connected very tightly by the TBox $\mathcal{T}_\mathsf{f}$ and are best considered together when building finite models. This is formalized by the notion of a *type class*, which is a non-empty set $P \subseteq \mathsf{TP}(\mathcal{T}_\mathsf{f})$ such that $t \in P$ and $t\ {}^1\!\leftrightarrow_r^1 t'$ implies $t' \in P$, and P is minimal with this condition. Note that the set of all type classes is a partition of $\mathsf{TP}(\mathcal{T}_\mathsf{f})$. We set $P \prec P'$ if there are $t \in P$ and $t' \in P'$ with $t' \subsetneq t$. Let $\prec^+$ be the transitive closure of $\prec$. A proof of the following observation can be found in the appendix.

Lemma 5 *$\prec^+$ is a strict partial order.*

We construct the desired finite model $\mathcal{I}$ of $\mathcal{A}$ and $\mathcal{T}_\mathsf{f}$ by starting with an initial interpretation that essentially consists of the ABox $\mathcal{A}$ and then exhaustively applying three *completion rules* denoted with $(\mathbf{c1})$ to $(\mathbf{c3})$, where $(\mathbf{c1})$ is given preference over $(\mathbf{c2})$. Completion repeatedly introduces elements whose existence is required by CIs $K \sqsubseteq \exists r.C$, carefully distinguishing several cases to ensure that no functionality restrictions are violated. We will prove that rule application terminates after finitely many steps, producing a finite model.

During the construction of $\mathcal{I}$, we will make sure that the following invariants are satisfied:

(i1) $\mathsf{tp}_{\mathcal{I}}(d) \in \mathsf{TP}(\mathcal{T}_\mathsf{f})$ for all $d \in \Delta^{\mathcal{I}}$;

(i2) if $(d, d') \in r^{\mathcal{I}} \setminus (\mathsf{Ind}(\mathcal{A}) \times \mathsf{Ind}(\mathcal{A}))$, then we have $\mathsf{tp}_{\mathcal{I}}(d) \to_r \mathsf{tp}_{\mathcal{I}}(d')$ or $\mathsf{tp}_{\mathcal{I}}(d') \to_{r^-} \mathsf{tp}_{\mathcal{I}}(d)$;

(i3) if $\mathcal{T}_\mathsf{f} \models K \sqsubseteq (\leqslant 1\ r\ K')$, then $\mathcal{I} \models K \sqsubseteq (\leqslant 1\ r\ K')$.

The initial version of $\mathcal{I}$ is defined by introducing an element for every ABox individual, and an element d_t for each $t \in \mathsf{TP}(\mathcal{T}_\mathsf{f})$. In detail, we set

$$\Delta^{\mathcal{I}} = \mathsf{Ind}(\mathcal{A}) \cup \{\ d_t \mid t \in \mathsf{TP}(\mathcal{T})_\mathsf{f}\ \}$$
$$A^{\mathcal{I}} = \{\ a \in \mathsf{Ind}(\mathcal{A}) \mid A \in \mathsf{tp}_{\mathcal{A}}(a)\ \} \cup \{d_t \mid A \in t\ \}$$
$$r^{\mathcal{I}} = \{\ (a, b) \mid r(a, b) \in \mathcal{A}\ \}$$

where

$$\mathsf{tp}_{\mathcal{A}}(a) := \{A \in \mathsf{CN}(\mathcal{T}) \mid \mathcal{A}, \mathcal{T}_\mathsf{f} \models A(a)\}.$$

The completion rules are described in detail below.

$(\mathbf{c1})$ Choose a $d \in \Delta^{\mathcal{I}}$ such that $\mathsf{tp}_{\mathcal{I}}(d) \to_r^1 t$, $t \not\to_{r^-}^1 \mathsf{tp}_{\mathcal{I}}(d)$, and $d \notin (\exists r.t)^{\mathcal{I}}$. Add a fresh domain element e, and modify the extension of concept and role names such that $\mathsf{tp}_{\mathcal{I}}(e) = t$ and $(d, e) \in r^{\mathcal{I}}$.

$(\mathbf{c2})$ Choose a type class P that is minimal w.r.t. the order $\prec^+$, a $\lambda = s\ {}^1\!\leftrightarrow_r^1 s'$ with $s \in P$, and an element $d \in s^{\mathcal{I}} \setminus (\exists r.s')^{\mathcal{I}}$.

For each $\lambda = s\ {}^1\!\leftrightarrow_r^1 s'$ with $s \in P$, set

$$X_{\lambda,1}^{\mathcal{I}} = s^{\mathcal{I}} \setminus (\exists r.s')^{\mathcal{I}} \qquad X_{\lambda,2}^{\mathcal{I}} = s'^{\mathcal{I}} \setminus (\exists r^-.s)^{\mathcal{I}}.$$

Take (i) a fresh set Δ_s for each $s \in P$ such that $|\biguplus_{s \in P} \Delta_s| \leq 2^{|\mathcal{T}|} \cdot |\Delta^{\mathcal{I}}|$ and (ii) a bijection π_λ between $X_{\lambda,1}^{\mathcal{I}} \cup \Delta_s$ and $X_{\lambda,2}^{\mathcal{I}} \cup \Delta_{s'}$ for each $\lambda = s\ {}^1\!\leftrightarrow_r^1 s'$ with $s, s' \in P$ and r a role name (the concrete construction is detailed below). Now extend $\mathcal{I}$ as follows:

- add all domain elements in $\biguplus_{s \in P} \Delta_s$;
- extend $r^{\mathcal{I}}$ with π_λ, for each $\lambda = s\ {}^1\!\leftrightarrow_r^1 s'$ with $s, s' \in P$ and r a role name;
- interpret concept names so that $\mathsf{tp}_{\mathcal{I}}(d) = s$ for all $d \in \Delta_s$, $s \in P$.

$(\mathbf{c3})$ Choose a $d \in \Delta^{\mathcal{I}}$ such that $\mathsf{tp}_{\mathcal{I}}(d) \to_r t$, $\mathsf{tp}_{\mathcal{I}}(d) \not\to_r^1 t$, and $d \notin (\exists r.t)^{\mathcal{I}}$. Add the edge (d, d_t) to $r^{\mathcal{I}}$, where d_t is the element introduced for type t in the initial version of $\mathcal{I}$.

To complete the description of the rules, we have to show that, in $(\mathbf{c2})$, the sets Δ_s and bijections π_λ indeed exist. Let $n_{\max} = \max\{|s^{\mathcal{I}}| \mid s \in P\}$. For each $s \in P$, set $\Delta_s := \{d_{s,i} \mid |s^{\mathcal{I}}| < i \leq n_{\max}\}$ and define the set of *s-instances* $I_s := s^{\mathcal{I}} \cup \Delta_s$. For each $\lambda = s\ {}^1\!\leftrightarrow_r^1 s'$ with $s, s' \in P$, define

$$R_\lambda := \{(d, e) \in r^{\mathcal{I}} \mid d \in s^{\mathcal{I}} \text{ and } e \in s'^{\mathcal{I}}\}.$$

We first note that it is a consequence of invariant **(i3)** that

$(*)$ the relation R_λ is functional and inverse functional.

In fact, $(d, e_1), (d, e_2) \in R_\lambda$ implies $(d, e_1), (d, e_2) \in r^{\mathcal{I}}$, $d \in s^{\mathcal{I}}$, and $e_1, e_2 \in s'^{\mathcal{I}}$. By λ, $\mathcal{T}_\mathsf{f} \models s \sqsubseteq (\leqslant 1\ r\ s')$. Thus, (**i3**) yields $e_1 = e_2$. Inverse functionality can be shown analogously.

Let R^1_λ be the domain of R_λ, and let R^2_λ be its range. By $(*)$, we have $|R^1_\lambda| = |R^2_\lambda|$. By definition of the sets Δ_s, we have $|I_s| = |I_{s'}|$. Moreover, $R^1_\lambda \subseteq I_s$ and $R^2_\lambda \subseteq I_{s'}$. We can thus choose a bijection π_λ between $I_s \setminus R^1_\lambda$ and $I_{s'} \setminus R^2_\lambda$, which is as required since $I_s \setminus R^1_\lambda = X^{\mathcal{I}}_{\lambda,1} \cup \Delta_s$ and $I_{s'} \setminus R^2_\lambda = X^{\mathcal{I}}_{\lambda,2} \cup \Delta_{s'}$. The construction of the sets Δ_s clearly ensures that their union has the required cardinality.

The following theorem summarizes the statements that remain to be proved in order to show that the construction of $\mathcal{I}$ is well-defined and yields a finite model of $\mathcal{A}$ and $\mathcal{T}_\mathsf{f}$.

Theorem 6

1. *Applying* $(\mathbf{c1})$ *to* $(\mathbf{c3})$ *preserves invariants* $(\mathbf{i1})$ *to* $(\mathbf{i3})$*;*
2. *Application of* $(\mathbf{c1})$ *to* $(\mathbf{c3})$ *terminates;*
3. *$\mathcal{I}$ is a model of $\mathcal{A}$ and $\mathcal{T}_\mathsf{f}$.*

Proof. We refer to the appendix for full proofs and only sketch the central idea in the proof of Point 2 here, going back to (Cosmadakis, Kanellakis, and Vardi 1990). The main issue in the termination proof is to show that no infinite role chain $r_0(d_0, d_1), r_1(d_1, d_2), \dots$ is generated in which all the elements d_i are pairwise distinct. Since every application of a completion rule generates only finitely many elements, any such chain must be generated by infinitely many rule applications. As there are only finitely many types, we must find elements d_i and d_j with $\mathtt{tp}_\mathcal{I}(d_i) = \mathtt{tp}_\mathcal{I}(d_j)$ and such that d_i and d_j were generated by different rule applications. It can be shown that, w.l.o.g., we can assume that the elements on the chain are ordered so that if $j > i$, then d_j was not generated by an earlier rule application than d_i. Analysing the completion rules, it is easy to see that this implies $\mathtt{tp}_\mathcal{I}(d_i) \to^1_{r_i} \mathtt{tp}_\mathcal{I}(d_{i+1}) \to^1_{r_{i+1}} \cdots \to^1_{r_{j-1}} \mathtt{tp}_\mathcal{I}(d_j)$. Since $\mathtt{tp}_\mathcal{I}(d_i) = \mathtt{tp}_\mathcal{I}(d_j)$, this is a finmod cycle, which has been reversed when constructing $\mathcal{T}_\mathsf{f}$, and thus all arrows $\to^1_{r_{i+\ell}}$ can be replaced with ${}^1{\leftrightarrow}^1_{r_{i+\ell}}$. By definition of the completion rules, this means that all of $d_i, \dots, d_j$ were introduced in the same application of (**c2**), which is a contradiction to d_i and d_j being generated by different rule applications. ❑

4 Consequence-Driven Procedure

While completing TBoxes with reversed cycles yields a reduction of finite model reasoning to infinite model reasoning, it blows up the TBox exponentially and is thus not suited for direct implementation. In this section, we build on the results from the previous section to devise a calculus for ABox consistency in Horn-$\mathcal{ALCFI}$ that does not require TBox completion to be carried out up-front, but instead reverses cycles 'on the fly'; moreover, the calculus implicitly groups together cycles that are closely related, potentially reversing a very large number of cycles in only a few steps (see Example 7 below). Our calculus belongs to a family of algorithms that are known as consequence-driven procedures and underly modern and highly efficient reasoners for Horn DLs such as

$$\textbf{R1}\ \frac{}{K \sqcap A \sqsubseteq A} \qquad \textbf{R2}\ \frac{}{K \sqsubseteq \top}$$

$$\textbf{R3}\ \frac{K \sqsubseteq A_i \quad \bigsqcap A_i \sqsubseteq C}{K \sqsubseteq C} \qquad \textbf{R4}\ \frac{K \sqsubseteq \exists r.K' \quad K' \sqsubseteq \forall r^-.A}{K \sqsubseteq A}$$

$$\textbf{R5}\ \frac{K \sqsubseteq \exists r.K' \quad K \sqsubseteq \forall r.A}{K \sqsubseteq \exists r.(K' \sqcap A)} \qquad \textbf{R6}\ \frac{K \sqsubseteq \exists r.K' \quad K' \sqsubseteq \bot}{K \sqsubseteq \bot}$$

$$\textbf{R7}\ \frac{\begin{array}{lll} K \sqsubseteq \exists r.K_1 & K \sqsubseteq \exists r.K_2 & K_1 \sqsubseteq A \\ K \sqsubseteq (\leqslant 1\ r\ A) & & K_2 \sqsubseteq A \end{array}}{K \sqsubseteq \exists r.(K_1 \sqcap K_2)}$$

$$\textbf{R8}\ \frac{\begin{array}{lll} K \sqsubseteq \exists r.K' & K' \sqsubseteq \exists r^-.K_1 & K \sqsubseteq A \\ K' \sqsubseteq (\leqslant 1\ r^-\ A) & & K_1 \sqsubseteq A \end{array}}{K \sqsubseteq A_1 \quad \text{for any } A_1 \in K_1}$$

$$\textbf{R9}\ \frac{\begin{array}{ll} K_i \sqsubseteq \exists r_i.K_{i \oplus_n 1} & \\ K_{i \oplus_n 1} \sqsubseteq (\leqslant 1\ r_i^-\ A_i) & K_i \sqsubseteq A_i \qquad i < n \end{array}}{K_1 \sqsubseteq \exists r_0^-.K_0 \qquad K_0 \sqsubseteq (\leqslant 1\ r_0\ A_1)}$$

Figure 1: Inference Rules

CEL, CB, and ELK (Baader, Lutz, and Suntisrivaraporn 2006; Kazakov 2009; Kazakov, Krötzsch, and Simančík 2011b). It thus establishes a promising foundation for actual implementations of finite-model reasoning in Horn-$\mathcal{ALCFI}$ and, via the reduction in Section 6, in Horn-$\mathcal{ALCQI}$. For simplicity, we start with a calculus for finite satisfiability and finite subsumption. An expansion to finite ABox consistency (and thus to finite instance checking) is sketched afterwards.

The calculus starts with a given TBox $\mathcal{T}$ and then exhaustively applies a set of inference rules. To ease their presentation, we assume that $\mathcal{T}$ is in a normal form that is slightly stricter than the one introduced in Section 2: in CIs $K \sqsubseteq \forall r.K'$ and $K \sqsubseteq (\leqslant 1\ r\ K)'$, K' must be a concept name A. The inference rules are displayed in Figure 1. They preserve the normal form and are applied in the sense that, if the concept inclusions in the precondition (above the line) are already present, then those in the postcondition (below the line) are added. Recall that K stands for a conjunction of concept names, which we read here modulo commutativity. Rule **R1** is applied only if $K \sqcap A$ *occurs* in the current (partially completed) TBox, that is, there is a CI of the form $K \sqcap A \sqsubseteq C$ or $K' \sqsubseteq \exists r.(K \sqcap A)$. The same is true for rule **R2** with K in place of $K \sqcap A$. In rule **R9**, $\oplus_n$ means addition modulo n.

We point out that rules **R1** to **R8** are minor variations of the corresponding rules in the calculus presented by Kazakov (2009), the main difference being that our language does not include role hierarchies. Rule **R9** is novel and deals with reversing cycles on the fly. Note that only the 'first edge' of each cycle is reversed, and that this is sufficient because the cycle can be rotated to make any edge the 'first' one.

Example 7 *Consider the TBox*

$$\mathcal{T} = \{A \sqsubseteq \exists r.(A \sqcap A_1 \sqcap \cdots \sqcap A_n), \quad (1)$$
$$A \sqsubseteq (\leqslant 1\ r^-\ A)\}. \quad (2)$$

Cycle reversion from Section 3 reverses all of the exponentially many cycles K, r, K with $K \subseteq S := \{A, A_1, \ldots, A_n\}$ and $A \in K$, adding $K \sqsubseteq \exists r^-.K$ and $K \sqsubseteq (\leqslant 1\ r\ K)$ for all such K. In contrast, the calculus avoids introducing 'irrelevant' conjunctions K and instead jointly reverses all these cycles by generating $A \sqsubseteq \exists r^-.S$ and $A \sqsubseteq (\leqslant 1\ r\ A)$:

$S \sqsubseteq A$	*from* **R1**	(3)
$A \sqsubseteq A$	*from* **R1**	(4)
$S \sqsubseteq \exists r.S$	*from* (1), (3), **R3**	(5)
$S \sqsubseteq (\leqslant 1\ r^-\ A)$	*from* (2), (3), **R3**	(6)
$S \sqsubseteq \exists r^-.S$	*and*	(7)
$S \sqsubseteq (\leqslant 1\ r\ A)$	*from* (3), (5), (6), **R9**	(8)
$A \sqsubseteq A_i$	*from* (1), (3), (4), (6), (7), **R8**	(9)
$A \sqsubseteq \exists r^-.S$	*from* (7), (9), **R3**	(10)
$A \sqsubseteq (\leqslant 1\ r\ A)$	*from* (8), (9), **R3**	(11)

Note that avoiding to introduce 'irrelevant' conjunctions K as illustrated by Example 7 is a main feature of consequence-based procedures which enables the excellent practical performance typically observed for this class of calculi.

The algorithm terminates after at most exponentially many rule applications since there are only exponentially many different concept inclusions that use the concept and role names of the original TBox. Each rule application can be performed in polynomial time, which is easy to see for the rules **R1**–**R8**. For **R9**, the crucial observation is that it suffices to consider all conjunctions K_0, K_1 and to check whether they are involved in *any* cycle. The latter can easily be done by a variation of directed graph reachability, where the nodes of the graph are the conjunctions that occur in the current TBox and the edges come from inclusions $K \sqsubseteq \exists r.K'$.

The following theorem, which is the main result of this section, states that the calculus is sound and complete.

Theorem 8 *Let $\mathcal{T}$ be a Horn-$\mathcal{ALCFI}$ TBox, $\widehat{\mathcal{T}}$ be obtained by exhaustively applying Rules* **R1**–**R9***, and let A_0 be a concept name. Then A_0 is finitely satisfiable w.r.t. $\mathcal{T}$ iff $A_0 \sqsubseteq \bot \notin \widehat{\mathcal{T}}$.*

While Theorem 8 is formulated only for finite satisfiability, the algorithm can of course also be used to decide finite subsumption via the usual reduction to finite satisfiability. The following continues Example 7.

Example 9 *Let $\mathcal{T}$ be the TBox from Example 7 and*

$$\mathcal{T}' = \mathcal{T} \cup \{ \quad A \sqsubseteq \exists r.(A \sqcap X_1), \quad (12)$$
$$A \sqsubseteq \exists r.(A \sqcap X_2), \quad (13)$$
$$X_1 \sqcap X_2 \sqsubseteq \bot \quad \} \quad (14)$$

The calculus derives $A \sqsubseteq \bot$, thus A is finitely unsatisfiable w.r.t. $\mathcal{T}'$:[1]

$A \sqcap X_i \sqsubseteq A$	*from* **R1**	(15)
$A \sqsubseteq \exists r.(A \sqcap X_1 \sqcap X_2)$	*from* (11)–(13), (15), **R7**	(16)
$A \sqsubseteq \bot$	*from* (14), (16), **R6**	(17)

[1] A is obviously satisfiable w.r.t. $\mathcal{T}'$ in unrestricted models.

We now prove Theorem 8. The "only if" direction (soundness) is straightforward by verifying that each rule is sound in finite models. In contrast, the "if" direction (completeness) turns out to be surprisingly subtle to establish. The proof strategy is as follows. Assume that $A_0 \sqsubseteq \bot \notin \widehat{\mathcal{T}}$. We construct a (possibly infinite) model $\widehat{\mathcal{I}}$ of $\widehat{\mathcal{T}}$ with $A_0^{\widehat{\mathcal{I}}} \neq \emptyset$ and show that $\widehat{\mathcal{I}}$ is actually a model of $\mathcal{T}_\mathsf{f}$. By Theorem 3, it follows that A_0 is finitely satisfiable w.r.t. $\mathcal{T}$. From now on, assume w.l.o.g. that A_0 actually occurs in $\mathcal{T}$.

To construct $\widehat{\mathcal{I}}$, let $\mathsf{KON}(\widehat{\mathcal{T}})$ denote the set of all conjunctions K such that K occurs in $\widehat{\mathcal{T}}$ (in the sense explained above) and $K \sqsubseteq \bot \notin \widehat{\mathcal{T}}$. The domain $\Delta^{\widehat{\mathcal{I}}}$ consists of finite words $d = K_1 K_2 \cdots K_n \in \mathsf{KON}(\widehat{\mathcal{T}})^*$, and we use $\mathsf{tail}(d)$ to denote K_n. Define $\widehat{\mathcal{I}}$ by starting with

$$\Delta^{\widehat{\mathcal{I}}} = \mathsf{KON}(\widehat{\mathcal{T}})$$
$$A^{\widehat{\mathcal{I}}} = \{K \in \mathsf{KON}(\widehat{\mathcal{T}}) \mid K \sqsubseteq A \in \widehat{\mathcal{T}}\}$$
$$r^{\widehat{\mathcal{I}}} = \emptyset$$

Observe that since A_0 occurs in $\widehat{\mathcal{T}}$ and $A_0 \sqsubseteq \bot \notin \widehat{\mathcal{T}}$, $\Delta^{\widehat{\mathcal{I}}}$ contains the conjunction $K = A_0$ and thus $A_0^{\widehat{\mathcal{I}}} \neq \emptyset$. We finish the construction of $\widehat{\mathcal{I}}$ by exhaustively applying the following rule: if there is some $d \in \Delta^{\widehat{\mathcal{I}}}$ with $\mathsf{tail}(d) \sqsubseteq \exists r.K' \in \widehat{\mathcal{T}}$, K' maximal with this property, and $d \notin (\exists r.K')^{\widehat{\mathcal{I}}}$, then add a fresh element $e = dK'$ to $\Delta^{\widehat{\mathcal{I}}}$, add (d, K') to $r^{\widehat{\mathcal{I}}}$, and add dK' to $A^{\widehat{\mathcal{I}}}$ whenever $K' \sqsubseteq A \in \widehat{\mathcal{T}}$.

We first show that $\widehat{\mathcal{I}}$ is a model of $\widehat{\mathcal{T}}$, which amounts to a case distinction over the forms of CIs that can be present in $\widehat{\mathcal{T}}$, in each case relying on the fact that $\widehat{\mathcal{T}}$ is closed under the rules of the calculus. Details are provided in the appendix.

Lemma 10 $\widehat{\mathcal{I}} \models \widehat{\mathcal{T}}$.

It remains to show that $\widehat{\mathcal{I}}$ is a model of $\mathcal{T}_\mathsf{f}$, which is significantly more difficult to prove than Lemma 10 due to the fact that $\mathcal{T}_\mathsf{f}$ is obtained by reversing all cycles in $\mathcal{T}$ whereas the calculus is more careful to reverse only the 'relevant' ones, as explained above. We start with the observation that, when constructing $\mathcal{T}_\mathsf{f}$, it suffices to close only maximal cycles. More precisely, a cycle $K_1, r_1, K_2, \ldots, K_n$ in a TBox $\mathcal{T}$ is *maximal* if K_{j+1} is maximal with $\mathcal{T} \models K_j \sqsubseteq \exists r_j.K_{j+1}$, for $1 \leq j < n$. Let $\mathcal{T}_\mathsf{f}^{\max}$ be the variation of $\mathcal{T}_\mathsf{f}$ that is obtained by reversing only maximal cycles.

Lemma 11 *$\mathcal{T}_\mathsf{f}$ is equivalent to $\mathcal{T}_\mathsf{f}^{max}$.*

To finish the proof of Theorem 8, let $\mathcal{T}_\mathsf{f}^0, \mathcal{T}_\mathsf{f}^1, \ldots$ be the sequence of TBoxes obtained by starting with $\mathcal{T}_\mathsf{f}^0 = \mathcal{T}$ and then exhaustively closing maximal cycles, that is, $\mathcal{T}_\mathsf{f}^{\max}$ is the limit of this sequence. In the appendix, we prove by induction on i that $\widehat{\mathcal{I}}$ is a model of each $\mathcal{T}_\mathsf{f}^i$, thus of $\mathcal{T}_\mathsf{f}$.

We now briefly consider an extension of our algorithm to ABox consistency, with Figure 2 showing the additional rules. Instead of starting with only a TBox $\mathcal{T}$, the algorithm now begins with a set $\mathcal{T} \cup \mathcal{A}$, where $\mathcal{T}$ is a TBox and $\mathcal{A}$ an ABox, and then exhaustively applies rules **R1** to **R12**. In rules **R10**

R10 $\dfrac{K(a) \quad K \sqsubseteq A}{A(a)}$ **R11** $\dfrac{K(a) \quad r(a,b) \quad K \sqsubseteq \forall r.K'}{K'(b)}$

R12 $\dfrac{K_1(a) \quad K_2(a) \quad r(a,b) \quad K(b) \quad K_1 \sqsubseteq (\leqslant 1\ r\ A) \quad K_2 \sqsubseteq \exists r.K' \quad K \sqsubseteq A \quad K' \sqsubseteq A}{K'(b)}$

Figure 2: Additional Inference Rules

to **R12**, $K(a)$ is an abbreviation for $A_1(a) \cdots A_k(a)$ when $K = \{A_1, \ldots, A_k\}$. Recall that rules **R1** and **R2** only apply when the conjunction in their precondition occurs in the partially completed TBox. For the extension with ABoxes, an additional way for K to *occur* is that, for some ABox individual a, $K = \{A \mid A(a)$ is in the partial completion$\}$. It is easy to see that rule application still terminates after exponentially many steps. Let Γ be the set of concept inclusions and ABox assertions finally generated. The algorithm is sound and complete in the sense that $\mathcal{A}$ is finitely inconsistent w.r.t. $\mathcal{T}$ iff there is an ABox individual a and a conjunction K such that Γ contains both $K(a)$ and $K \sqsubseteq \bot$. To prove this, one updates the construction of $\widehat{\mathcal{I}}$ by starting with an initial interpretation defined by setting $\Delta^{\widehat{\mathcal{I}}} = \mathsf{Ind}(\mathcal{A})$, $r^{\widehat{\mathcal{I}}} = \{(a,b) \mid r(a,b) \in \mathcal{A}\}$, and $A^{\widehat{\mathcal{I}}} = \{a \in \mathsf{Ind}(\mathcal{A}) \mid A(a) \in \Gamma\}$. The rest of the construction of $\widehat{\mathcal{I}}$ is as before. It is not hard to adapt the proof of Lemma 10 to show that $\widehat{\mathcal{I}}$ satisfies all inclusions and assertions in Γ. As in the case of finite satisfiability, it thus remains to prove that $\widehat{\mathcal{I}}$ is a model of $\mathcal{T}_\mathsf{f}$. Fortunately, the proof of goes through without modification.

Apart from providing a basis for practical implementations, our algorithm also yields an EXPTIME upper bound for finite ABox consistency in Horn-$\mathcal{ALCFI}$. This result is known from (Lutz, Sattler, and Tendera 2005), where it is shown that ABox consistency in the non-Horn version of $\mathcal{ALCQI}$ is in EXPTIME. A matching lower bound can be derived from (Baader, Brandt, and Lutz 2008) where an EXPTIME lower bound is established for unrestricted subsumption in (the $\mathcal{ELI}$ fragment of) Horn-$\mathcal{ALCFI}$; the proof can easily be adapted to finite satisfiability.

Theorem 12 *Finite satisfiability and finite ABox consistency in Horn-$\mathcal{ALCQI}$ are* EXPTIME*-complete.*

5 Query Answering in the Finite

In the ontology-based data access (OBDA) paradigm, the central reasoning problem is answering database-style queries over ABoxes in the presence of a DL TBox. In this section, we study the finite model version of this problem, assuming that queries are positive existential queries (PEQs) and that TBoxes are formulated in Horn-$\mathcal{ALCFI}$. We show that, as in the case of ABox consistency, finite PEQ answering can be reduced to unrestricted PEQ answering by reversing finmod cycles in the TBox. This result enables the use of algorithms for unrestricted PEQ answering also in the finite case. It also allows us to show that finite PEQ answering w.r.t. Horn-$\mathcal{ALCFI}$ TBoxes is EXPTIME-complete regarding combined complexity, and PTIME-complete regarding data complexity.

We start with a brief introduction of positive existential queries and of query answering. For simplicity, we concentrate on Boolean queries, that is, queries without answer variables. It is, however, easy to adapt all techniques established in this section to the case of queries with answer variables. A *(Boolean) positive existential query (PEQ)* q takes the form $\exists \mathbf{x}\, \varphi(\mathbf{x})$ where φ is built from atoms of the form $A(x)$ and $r(x,y)$ using conjunction and disjunction, with x, y variables from $\mathbf{x}$, A a concept name, and r a role name. Let $\mathcal{I}$ be an interpretation and $q = \exists \mathbf{x}\, \varphi$ a PEQ. A *match* of q in $\mathcal{I}$ is a mapping $\pi : \mathbf{x} \to \Delta^{\mathcal{I}}$ such that φ evaluates to true unter the valuation that assigns true to an atom $A(x)$ in φ iff $\pi(x) \in A^{\mathcal{I}}$ and true to an atom $r(x,y)$ in φ iff $(\pi(x), \pi(y)) \in r^{\mathcal{I}}$. We write $\mathcal{I} \models q$ if there is a match of q in $\mathcal{I}$. For an ABox $\mathcal{A}$ and a TBox $\mathcal{T}$, we write $\mathcal{A}, \mathcal{T} \models q$ (resp. $\mathcal{A}, \mathcal{T} \models_{\mathsf{fin}} q$) if $\mathcal{I} \models q$ for all models (resp. finite models) $\mathcal{I}$ of $\mathcal{T}$ and $\mathcal{A}$. We then say that $\mathcal{A}, \mathcal{T}$ *entails* (resp. *finitely entails*) q. The problem that we are interested in is *finite query entailment*, that is, given an ABox $\mathcal{A}$, a TBox $\mathcal{T}$, and a query q, to decide whether $\mathcal{A}, \mathcal{T} \models_{\mathsf{fin}} q$. We will study both the combined complexity and the data complexity of this problem. When studying combined complexity, all of $\mathcal{A}$, $\mathcal{T}$, and q are considered an input. In the case of data complexity, $\mathcal{T}$ and q are assumed to be fixed and q is the only input.

The main result of this section is the following theorem, where $\mathcal{T}_\mathsf{f}$ is the TBox obtained from $\mathcal{T}$ by exhaustively reversing finmod cycles, exactly as in Section 3.

Theorem 13 *Let $\mathcal{T}$ be a Horn-$\mathcal{ALCFI}$ TBox and $\mathcal{A}$ an ABox that is finitely consistent w.r.t. $\mathcal{T}$. For any PEQ q,*

$$\mathcal{A}, \mathcal{T} \models_{\mathsf{fin}} q \text{ iff } \mathcal{A}, \mathcal{T}_\mathsf{f} \models q$$

The proof of the "$\Leftarrow$" direction is trivial. Indeed, if $\mathcal{A}, \mathcal{T} \not\models_{\mathsf{fin}} q$, then there is a finite model $\mathcal{I}$ of $\mathcal{A}$ and $\mathcal{T}$ such that $\mathcal{I} \not\models q$. Since every finite model of $\mathcal{T}$ is also a model of $\mathcal{T}_\mathsf{f}$ by Lemma 4, it follows that $\mathcal{A}, \mathcal{T}_\mathsf{f} \not\models q$.

For the proof of the "$\Rightarrow$" direction, we use a well-known (infinite) canonical model $\mathcal{U}$ of $\mathcal{A}$ and $\mathcal{T}_\mathsf{f}$, constructed by starting with the following initial interpretation

$$\begin{aligned} \Delta^{\mathcal{U}} &= \mathsf{Ind}(\mathcal{A}) \\ A^{\mathcal{U}} &= \{a \in \mathsf{Ind}(\mathcal{A}) \mid \mathcal{A}, \mathcal{T}_\mathsf{f} \models A(a)\} \\ r^{\mathcal{U}} &= \{(a,b) \mid r(a,b) \in \mathcal{A}\} \end{aligned}$$

and then exhaustively applying the following completion rule: for all $d \in \Delta^{\mathcal{U}}$ such that $\mathcal{T}_\mathsf{f} \models \mathsf{tp}_{\mathcal{U}}(d) \sqsubseteq \exists r.t'$, where t' is maximal with this property and $d \notin (\exists r.t')^{\mathcal{U}}$, add a fresh element d' to $\Delta^{\mathcal{U}}$, the edge (d,d') to $r^{\mathcal{U}}$, and d' to the interpretation $A^{\mathcal{U}}$ of all concept names $A \in t'$.

The following properties of $\mathcal{U}$ are well-known and the reason for why $\mathcal{U}$ is called canonical (Krisnadhi and Lutz 2007; Eiter et al. 2008; Ortiz, Rudolph, and Šimkus 2011).

Lemma 14

1. *$\mathcal{U}$ is a model of $\mathcal{A}$ and of $\mathcal{T}_\mathsf{f}$;*
2. *For any PEQ q, we have that $\mathcal{A}, \mathcal{T}_\mathsf{f} \models q$ iff $\mathcal{U} \models q$.*

By Point 2 of Lemma 14, we can establish the "⇒" direction of Theorem 13 by showing that $\mathcal{A}, \mathcal{T} \models_{\mathsf{fin}} q$ implies $\mathcal{U} \models q$. The proof makes intense use of homomorphisms. For interpretations $\mathcal{I}_1, \mathcal{I}_2$, a *homomorphism from $\mathcal{I}_1$ to $\mathcal{I}_2$* is a function $h : \Delta^{\mathcal{I}_1} \to \Delta^{\mathcal{I}_2}$ such that

1. $h(a) = a$ for all $a \in \mathsf{N_I}$;
2. $d \in A^{\mathcal{I}_1}$ implies $h(d) \in A^{\mathcal{I}_2}$ for all concept names A;
3. $(d, e) \in r^{\mathcal{I}_1}$ implies $(h(d), h(e)) \in r^{\mathcal{I}_2}$ for all (possibly inverse) roles r.

For $n > 0$, an *n-substructure* of an interpretation $\mathcal{I}$ is an interpretation $\mathcal{I}'$ obtained from $\mathcal{I}$ by selecting a domain $\Delta^{\mathcal{I}'} \subseteq \Delta^{\mathcal{I}}$ with at most n elements and restricting $\mathcal{I}$ to $\Delta^{\mathcal{I}'}$. To show that $\mathcal{A}, \mathcal{T} \models_{\mathsf{fin}} q$ implies $\mathcal{U} \models q$, it suffices to establish the following.

Proposition 15 *For every $n_0 > 0$, there is a finite model $\mathcal{J}_{n_0}$ of $\mathcal{A}$ and $\mathcal{T}$ such that there is a homomorphism from any n_0-substructure of $\mathcal{J}_{n_0}$ to $\mathcal{U}$.*

In fact, $\mathcal{A}, \mathcal{T} \models_{\mathsf{fin}} q$ implies $\mathcal{J}_{n_0} \models q$ and thus there is an n_0-substructure $\mathcal{J}$ of $\mathcal{J}_{n_0}$ with $\mathcal{J} \models q$, where n_0 is the number of variables in q. The latter is witnessed by a match π. By Proposition 15, there is a homomorphism h from $\mathcal{J}$ to $\mathcal{U}$ and thus a match of q in $\mathcal{U}$ can be found by composing π with h.

We construct the model $\mathcal{J}$ from Proposition 15 by modifying the finite model $\mathcal{I}$ constructed in Section 3. For two reasons, the finite model $\mathcal{I}$ constructed in Section 3 need not satisfy the condition formulated for $\mathcal{J}_{n_0}$ in Proposition 15.

1. $\mathcal{I}$ can contain paths of length $\leq n_0$ that do not exist in $\mathcal{U}$.
2. $\mathcal{I}$ can contain cycles that do not exclusively consist of ABox elements, while no such cycles are present in $\mathcal{U}$.

Let us start with Problem 1 above. There are, in turn, two sources for paths in $\mathcal{I}$ that we cannot reproduce in $\mathcal{U}$.

(i) Application of $(\mathbf{c3})$ can generate a path $(d_1, d) \in r^{\mathcal{I}}$, $(d, d_2) \in s^{\mathcal{I}}$ such that $\mathsf{tp}_{\mathcal{I}}(d_1) \to_r \mathsf{tp}_{\mathcal{I}}(d) \ {}_s\!\leftarrow \mathsf{tp}_{\mathcal{I}}(d_2)$ and d is not identified by an ABox element. Such situations are not necessarily reproducible in $\mathcal{U}$. As a concrete example, consider

$$\mathcal{A} = \{\ B_1(a), B_2(b)\ \}$$
$$\mathcal{T} = \{\ B_1 \sqsubseteq \exists r.A,\ B_2 \sqsubseteq \exists r.A\ \}.$$

The problematic path is $(a, d_t) \in r^{\mathcal{I}}, (d_t, b) \in (r^-)^{\mathcal{I}}$ with $t = \{A\}$.

(ii) Application of $(\mathbf{c2})$ can result in similar a situation as above, but where the middle element d is replaced with a sequence of elements $e_0, \dots, e_k$ such that $(e_i, e_{i+1}) \in r_i^{\mathcal{I}}$ for all $i < k$ (for some roles $r_0, \dots, r_{k-1}$) and

$$\mathsf{tp}_{\mathcal{I}}(e_0) \ {}^1\!\leftrightarrow^1_{r_1} \cdots {}^1\!\leftrightarrow^1_{r_{k-1}} \mathsf{tp}_{\mathcal{I}}(e_k). \tag{18}$$

For a very simple example, take

$$\mathcal{A} = \{\ B_1(a),\ B_2(b)\ \}$$

and assume that $\mathcal{T}$ is such that $B_1 \ {}^1\!\leftrightarrow^1_r \ B_2$. Then an application of $(\mathbf{c2})$ will simply add $r(a, b)$, an edge that does not exist in $\mathcal{U}$.

To obtain the desired model $\mathcal{J}_{n_0}$ from Proposition 15, we first solve Problems (i) and (ii) above, and then Problem 2. To make precise what we mean by this, we introduce bounded simulations, a weakening of homomorphisms. A *bounded simulation of $\mathcal{I}_1$ in $\mathcal{I}_2$* is a relation $\rho \subseteq \Delta^{\mathcal{I}_1} \times \mathbb{N} \times \Delta^{\mathcal{I}_2}$ such that for all $(d, i, e) \in \rho$, the following conditions are satisfied:

1. if $d \in A^{\mathcal{I}_1}$, then $e \in A^{\mathcal{I}_2}$;
2. if $i > 0$ and $(d, d') \in r^{\mathcal{I}_1}$ for some (possibly inverse) role r, then there is an $e' \in \Delta^{\mathcal{I}_2}$ with $(e, e') \in r^{\mathcal{I}_2}$ and $(d', i-1, e') \in \rho$.

We write $(\mathcal{I}_1, d) \preceq_k (\mathcal{I}_2, e)$, for $d \in \Delta^{\mathcal{I}_1}$ and $e \in \Delta^{\mathcal{I}_2}$, if there is a bounded simulation of $\mathcal{I}_1$ in $\mathcal{I}_2$ such that $(d, k, e) \in \rho$ and for all $a \in \mathsf{N_I} \cap \Delta^{\mathcal{I}_1}$, we have $(a, k, a) \in \rho$. Then $\mathcal{I}_1 \preceq_k \mathcal{I}_2$ denotes that for every $d \in \Delta^{\mathcal{I}_1}$, there is an $e \in \Delta^{\mathcal{I}_2}$ with $(\mathcal{I}_1, d) \preceq_k (\mathcal{I}_2, e)$. We write $(\mathcal{I}_1, d) \sim_k (\mathcal{I}_2, e)$ if $(\mathcal{I}_1, d) \preceq_k (\mathcal{I}_2, e)$ and vice versa.

With solving Problems (i) and (ii), we mean to establish the following intermediate result.

Proposition 16 *For every $n_0 > 0$, there is a finite model $\mathcal{I}_{n_0}$ of $\mathcal{A}$ and $\mathcal{T}$ such that $\mathcal{I}_{n_0} \preceq_{n_0} \mathcal{U}$.*

To remove the undesired paths illustrated in (i) above, we modify the construction of $\mathcal{I}$ by replacing the elements d_t, $t \in \mathsf{TP}(\mathcal{T}_{\mathsf{f}})$, that are introduced at the beginning of the construction of $\mathcal{I}$ and used as 'targets' for role edges introduced by applications of $(\mathbf{c3})$. In the modified construction, we instead introduce one $(\mathbf{c3})$-target for each *n_0-bounded simulation type*, which is an equivalence class of $\sim_{n_0}$ on the set of all pointed interpretations $(\mathcal{I}_1, d)$. In the example given in (i) above, the result is that the two existential restrictions would no longer be witnessed by the same d_t because the 1-simulation type of the witnesses are different (one has an r-predecessor in B_1, the other in B_2). Since simulations need only to consider symbols that occur in the (fixed) ABox $\mathcal{A}$ and (fixed) TBox $\mathcal{T}$, there are only finitely many n_0-simulation types and thus finiteness of $\mathcal{I}$ is not compromised.

Undesired paths of type (ii) are avoided by modifying the $(\mathbf{c2})$ rule so that the sequences (18) are of length exceeding n_0 and thus the highlighted problem which involves both ends of the sequence is not 'visible' in n_0-substructures. We also include an initial piece of the canonical model $\mathcal{U}$ for $\mathcal{A}$ and $\mathcal{T}_{\mathsf{f}}$ of depth n_0 in the initial version of $\mathcal{I}$ to avoid the undesired 'shortcuts' between ABox elements illustrated by the example given in (ii) above.

The construction is spelled out in full detail in the appendix. We have actually omitted some aspects in the overview above for the sake of a clearer exposition, such as the fact that we first exhaustively apply rules $(\mathbf{c1})$ and $(\mathbf{c2})$, followed by exhaustive application of $(\mathbf{c3})$ (the latter two in their modified versions), and that we actually cannot include in the initial $\mathcal{I}$ *all* n_0-bounded simulation types, but must select only the 'relevant' ones. This finishes the proof of Proposition 16.

To solve Problem 2 above and thus obtain the model $\mathcal{J}_{n_0}$ stipulated by Proposition 15, we have to eliminate all non-ABox-cycles of size at most n_0 in the model $\mathcal{I}_{n_0}$ delivered by Proposition 16. This is achieved by taking the product with a suitable finite group of high girth, a technique championed

by Otto (2012). Details are provided in the appendix. This finishes the proof of Theorem 13.

Apart from enabling the use of algorithms for unrestricted PEQ answering also in the finite case, Theorem 13 yields tight complexity bounds for finite PEQ entailment.

Theorem 17 *Finite PEQ entailment in Horn-$\mathcal{ALCFI}$ is decidable,* EXPTIME*-complete in combined complexity, and* PTIME*-complete in data complexity.*

Proof.(sketch) For the unrestricted case, an EXPTIME lower bound is in (Baader, Brandt, and Lutz 2008) and a PTIME one in (Calvanese et al. 2006). Both results can easily be adapted to the finite case. The upper bounds can be proved using the following straightforward algorithm for PEQ entailment, which resembles existing algorithms such as those presented in (Krisnadhi and Lutz 2007; Eiter et al. 2008; Calì, Gottlob, and Lukasiewicz 2009; Ortiz, Rudolph, and Šimkus 2011). Assume that an input ABox $\mathcal{A}$, TBox $\mathcal{T}$, and PEQ q are given, and let n_0 be the number of variables in q. As a consequence of Theorem 3, finite satisfiability w.r.t. $\mathcal{T}$ coincides with unrestricted satisfiability w.r.t. $\mathcal{T}_\mathsf{f}$. Using our algorithm for computing finite satisfiability in Horn-$\mathcal{ALCFI}$ in EXPTIME, we can thus compute the set $\mathsf{TP}(\mathcal{T}_\mathsf{f})$ of types for $\mathcal{T}_\mathsf{f}$ without computing $\mathcal{T}_\mathsf{f}$ or explicitly reasoning w.r.t. this exponentially large TBox. Let $\mathcal{A}'$ be the extension of $\mathcal{A}$ with assertions $\{A(a_t) \mid A \in t\}$ for each $t \in \mathsf{TP}(\mathcal{A})$. Now compute an initial piece $\mathcal{U}'$ of the canonical model $\mathcal{U}$ of $\mathcal{A}'$ and $\mathcal{T}_\mathsf{f}$, namely its restriction to depth n_0. Similar to the computation of $\mathsf{TP}(\mathcal{T}_\mathsf{f})$ above, we can do this by using finite subsumption w.r.t. $\mathcal{T}$ instead of unrestricted subsumption w.r.t. $\mathcal{T}_\mathsf{f}$. It is not difficult to prove that $\mathcal{U}' \models q$ iff $\mathcal{U} \models q$. To check whether $\mathcal{U}' \models q$ within the desired time bounds, we can simply enumerate all possible maps of variables in q to elements of $\mathcal{U}'$ and check whether any such map is a match. ❑

Note that decidability of PEQ entailment in Horn-$\mathcal{ALCFI}$ was expected given a result by Pratt-Hartmann which states that finite CQ answering for the two-variable guarded fragment of first-order logic extended with counting quantifiers is decidable (Pratt-Hartmann 2009). We assume that his proof can be extended to unions of conjunctive queries (UCQs), thus to PEQs. Pratt-Hartmann also analyses the data complexity of finite CQ answering in his logic, but finds it to be CONP-complete. He does not analyse combined complexity. Theorem 17 suggests that PEQ entailment in Horn-$\mathcal{ALCFI}$ has the same complexity in finite and in unrestricted models. For the unrestricted case, PTIME-completeness in data complexity follows from the results in (Hustadt, Motik, and Sattler 2007), and EXPTIME-completeness in combined complexity is proved in (Eiter et al. 2008) for UCQs. We assume that the techniques in that paper extend to PEQs.

6 From Horn-$\mathcal{ALCFI}$ to Horn-$\mathcal{ALCQI}$

Our results for finite satisfiability and finite subsumption (the reasoning tasks that do not involve ABoxes) extend in a straightforward way from Horn-$\mathcal{ALCFI}$ to Horn-$\mathcal{ALCQI}$. In particular, we can convert a Horn-$\mathcal{ALCQI}$ TBox $\mathcal{T}$ into a Horn-$\mathcal{ALCFI}$ TBox $\mathcal{T}'$ such that finite (un)satisfiability is preserved by replacing each CI $K \sqsubseteq (\geqslant n\ r\ K')$ in $\mathcal{T}$ with the following inclusions, for $1 \leq i < j \leq n$:

$$K \sqsubseteq \exists r.B_i, \quad B_i \sqsubseteq K', \quad B_i \sqcap B_j \sqsubseteq \bot \qquad (*)$$

While an easy unraveling argument can be used to prove that this reduction is correct in the presence of infinite models, more care is required in the finite case (see appendix).

Proposition 18 *$\mathcal{T}$ is finitely satisfiable iff $\mathcal{T}'$ is finitely satisfiable.*

It follows from Proposition 18 and Theorem 3 that a Horn-$\mathcal{ALCQI}$ TBox $\mathcal{T}$ is finitely satisfiable iff $(\mathcal{T}')_\mathsf{f}$ is satisfiable. Actually, it is not hard to see that this is the case iff $\mathcal{T}_\mathsf{f}$ (the result of applying cycle reversion directly to the Horn-$\mathcal{ALCQI}$ TBox, ignoring all inclusions $A \sqsubseteq (\geqslant n\ r\ C)$) is satisfiable because if any of the existential restrictions in $\mathcal{T}' \setminus \mathcal{T}$ is involved in a finmod cycle, then a simple semantic argument shows that both $\mathcal{T}_\mathsf{f}$ and $(\mathcal{T}')_\mathsf{f}$ are unsatisfiable. Proposition 18 also enables the use of our consequence-based procedure for deciding finite satisfiability in Horn-$\mathcal{ALCQI}$.

It is not immediately obious how to extend $(*)$ and Proposition 18 to ABox consistency and instance checking. We believe, though, that it is not too hard to modify the proof of Theorem 3 for Horn-$\mathcal{ALCQI}$, to adapt the consequence-based procedure to allow a direct treatment of Horn-$\mathcal{ALCQI}$ TBoxes without prior reduction to Horn-$\mathcal{ALCFI}$, and to extend all model constructions underlying our results about PEQ entailment to Horn-$\mathcal{ALCQI}$. In particular, such a direct approach should yield EXPTIME/ PTIME upper bounds for PEQ entailment in Horn-$\mathcal{ALCQI}$ even when the numbers in at least restrictions are coded in binary (note that, in this case, the translation $(*)$ incurs an exponential blowup).

7 Future Work

As future research, it would be interesting to extend the results in this paper to Horn-$\mathcal{SHIQ}$, that is, to add role hierarchies and transitive roles. Reducing out role hierarchies does not seem easily possible in the finite,[2] so they would have to be built directly into all constructions. For query entailment, we expect transitive roles to cause significant additional challenges, see for example (Eiter et al. 2009; Mosurovic et al. 2013). In particular, transitive roles result in an additional way in which the finite model property is lost, illustrated by the TBox $\mathcal{T} = \{A \sqsubseteq \exists r.A, \mathsf{trans}(r)\}$ and the conjunctive query $q = \exists x\, r(x,x)$. We have $\{A(a)\}, \mathcal{T} \not\models q$, but $\{A(a)\}, \mathcal{T} \models_\mathsf{fin} q$ although neither counting nor inverse roles are present (the TBox $\mathcal{T}$ is formulated in the DL $\mathcal{EL}_\mathsf{trans}$). Finite model reasoning in versions of Datalog$^\pm$ that extend $\mathcal{EL}_\mathsf{trans}$ has recently been studied in (Gogacz and Marcinkowski 2013b; 2013a).

In this paper, we have not analyzed the size of finite models. It is, however, easy to prove a double exponential lower bound on the size of finite models for satisfiability in Horn-$\mathcal{ALCFI}$ by enforcing a tree of exponential depth in which no two elements can be identical. A matching upper bound follows from Pratt-Hartmann's result that every finitely satisfiable formula in first-order logic with two variables and

[2] In contrast to what we have claimed in the workshop predecessor of this paper (Ibáñez-García, Lutz, and Schneider 2013).

counting quantifiers has a model of at most double exponential size (Pratt-Hartmann 2005). Analyzing the size of finite (counter)models for query entailment is left as future work.

Abstract

We study learning of description logic TBoxes in Angluin et al.'s framework of exact learning via queries. We admit entailment queries ("is a given subsumption entailed by the target TBox?") and equivalence queries ("is a given TBox equivalent to the target TBox?"), assuming that the signature and logic of the target TBox are known. We present three main results: (1) TBoxes formulated in DL-Lite with role inclusions and composite concepts on the right-hand side of concept inclusions can be learned in polynomial time; (2) $\mathcal{EL}$ TBoxes with only concept names on the right-hand side of concept inclusions can be learned in polynomial time; and (3) $\mathcal{EL}$ TBoxes cannot be learned in polynomial time. It follows that non-polynomial time learnability of $\mathcal{EL}$ TBoxes is caused by the interaction between existential restrictions on the right- and left-hand sides of concept inclusions. We also show that neither entailment nor equivalence queries alone are sufficient in cases (1) and (2) above.

Successfully deploying a description logic (DL) in a concrete application requires to carefully capture the relevant domain knowledge in a DL ontology. This is a subtle, error-prone, and time consuming task, which is further hindered by the fact that domain experts are rarely experts in ontology engineering and, conversely, ontology engineers are often not sufficiently familiar with the domain to be modeled. From its beginnings, DL research was driven by the aim to provide various forms of support for ontology engineers, assisting them in the design of high-quality ontologies. Examples include the ubiquitous task of ontology classification (Baader et al. 2003), bootstrapping ontology design from examples, data, or text (Baader and Molitor 2000; Borchmann and Distel 2011; Ma and Distel 2013) and checking the completeness of the modeling in a systematic way (Baader et al. 2007).

Machine learning (ML) techniques are natural candidates to support ontology engineering by partly automatizing the design process, and in fact ML approaches have been proposed for ontology engineering in non-DL-contexts. There, the main focus is on mining the relevant terms of the application domain from bodies of text and semi-structured data with the aim of including them in the ontology. Some approaches also support learning of subsumptions between the identified terms, but not between compound logical expressions based on these terms (Cimiano, Hotho, and Staab 2005; Buitelaar, Cimiano, and Magnini 2005). In the context of DL ontologies, though, the main objective is to develop a detailed modeling of the relevant concepts of the domain using the logical operators provided by the DL at hand (Voelker 2009). In this paper, we thus concentrate on learning the full logical structure of a DL TBox. In particular, we study the foundations of learning ontologies that are formulated in several DLs which underly the three tractable *profiles* of the OWL2 ontology language.

We adopt Angluin et al.'s framework of exact learning via queries (Angluin 1987c). In particular, we are interested in learning a target TBox $\mathcal{T}$ that is formulated in a given DL and whose signature Σ (the concept and role names that occur in $\mathcal{T}$) is also known, by posing queries to an oracle. Intuitively, the oracle can be thought of as a domain expert who interacts with the learning algorithm. We consider two forms of oracle queries:

- *entailment queries*: does $\mathcal{T}$ entail a given Σ concept inclusion $C \sqsubseteq D$? These queries are answered by the oracle with 'yes' or 'no'.
- *equivalence queries*: is a given Σ-TBox $\mathcal{H}$ (the hypothesis) equivalent to $\mathcal{T}$? The oracle answers 'yes' if $\mathcal{H}$ and $\mathcal{T}$ are logically equivalent and 'no' otherwise. It then returns a Σ-inclusion $C \sqsubseteq D$ such that $\mathcal{T} \models C \sqsubseteq D$ and $\mathcal{H} \not\models C \sqsubseteq D$ (a *positive counterexample*), or vice versa (a *negative counterexample*).

We generally assume that the inclusions used in entailment queries and returned by equivalence queries are of the same form as the inclusions allowed in the target TBox. While, in general, answering an equivalence query of the above form can be expected to be rather challenging also for a domain expert and an ontology engineer, we emphasize that the actual algorithms developed in this paper use equivalence queries only in a very restricted way. In particular, our algorithms always ensure that the hypothesis TBox $\mathcal{H}$ that they maintain is a logical consequence of the target TBox $\mathcal{T}$, and then use equivalence queries only to ask 'is the TBox $\mathcal{H}$ learned so far complete and if not, please give me a missing inclusion $C \sqsubseteq D$'.

Copyright © 2014, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

Following Angluin, our aim is to find (deterministic) learning algorithms that run in polynomial time and consequently also make only polynomially many oracle queries. More precisely, we require that there is a two-variable polynomial $p(n, m)$ such that at every point of the algorithm execution, the time spent up to that point is bounded by $p(n, m)$, where n is the size of the target TBox $\mathcal{T}$ to be learned and m is the size of the largest (positive or negative) counterexample that was returned by the oracle until the considered point of the execution. If such an algorithm exists, then $\mathcal{L}$ TBoxes are *polynomial time learnable*.

Within the setup laid out above, we study three different DLs, which are significant fragments of the three profiles of OWL2 (Motik et al. 2009). The popular description logic $\mathcal{EL}$ can be viewed as a logical core of the OWL2 EL profile of OWL2. It is known that propositional Horn formulas, which correspond to $\mathcal{EL}$ TBoxes without existential restrictions, can be learned in polynomial time when both entailment and equivalence queries are available, but not when one of these types of queries is disallowed (Frazier and Pitt 1993; Angluin, Frazier, and Pitt 1992; Angluin 1987a), see also (Arias and Balcázar 2011). We show that, in contrast, $\mathcal{EL}$ TBoxes are not polynomial time learnable. The results for the other two DLs that we study will shed some light on the reasons for this behaviour.

The DL-Lite family of DLs underlies the OWL2 QL profile of OWL2 (Calvanese et al. 2007). In many versions of DL-Lite such as in DL-Lite$_\mathcal{R}$ (DL-Lite with role inclusions), the number of Σ-concept inclusions is polynomial in the size of Σ. In this case, TBoxes are trivially learnable in polynomial time, even when only entailment queries (but no equivalence queries) are available or vice versa. We thus consider the more interesting DL-Lite$_\mathcal{R}^\exists$ dialect, that is, the extension of DL-Lite$_\mathcal{R}$ that allows any $\mathcal{ELI}$ concept on the right-hand side of concept inclusions. Note that DL-Lite$_\mathcal{R}^\exists$ can be viewed as a logical core of OWL2 QL. Here, the number of Σ-concept inclusions is infinite, but we are nevertheless able to establish that DL-Lite$_\mathcal{R}^\exists$ TBoxes are polynomial time learnable. In practice, many $\mathcal{EL}$ TBoxes actually fall within (the intersection of $\mathcal{EL}$ and) DL-Lite$_\mathcal{R}^\exists$. We also show that DL-Lite$_\mathcal{R}^\exists$ TBoxes cannot be learned in polynomial time with entailment queries alone or with equivalence queries alone.

We then consider the fragment $\mathcal{EL}_\mathsf{lhs}$ of $\mathcal{EL}$ where only concept names (but no compound concepts) are admitted on the right-hand side of concept inclusions. $\mathcal{EL}_\mathsf{lhs}$ is a significant fragment of the OWL2 RL profile of OWL2, and also a fragment of datalog. We prove that $\mathcal{EL}_\mathsf{lhs}$ TBoxes can be learned in polynomial time using a non-trivial extension of Angluin's polynomial time algorithm for learning propositional Horn theories (1992). Note that the symmetric fragment $\mathcal{EL}_\mathsf{rhs}$ that allows only concept names on the *left*-hand side of concept inclusions is a fragment of DL-Lite$_\mathcal{R}^\exists$. Together, our results for DL-Lite$_\mathcal{R}^\exists$ and $\mathcal{EL}_\mathsf{lhs}$ thus show that non-polynomial time learnability of $\mathcal{EL}$ TBoxes is caused by the interaction between existential restrictions on the right- and left-hand sides of concept inclusions.

To improve readability, we first present the upper bounds (polynomial time learnability for DL-Lite$_\mathcal{R}^\exists$ and $\mathcal{EL}_\mathsf{lhs}$) and then the lower bounds. Proof details are provided in an appendix (Konev et al. 2013).

Related Work. In the terminology of the learning literature, entailment queries are a kind of membership queries, which can take many different forms (Raedt 1997). Learning using membership and equivalence queries appears to be the most successful protocol for exact learning in Angluin's framework. Apart from propositional Horn formulas, polynomial time learnable classes for this protocol include regular sets (Angluin 1987b) and monotone DNF (Angluin 1987c). Exploring the possibilities of extending the learning algorithm for propositional Horn formulas to (fragments) of first-order Horn logic has been a major topic in exact learning (Reddy and Tadepalli 1999; Arias and Khardon 2002; Arias, Khardon, and Maloberti 2007; Selman and Fern 2011). Note that $\mathcal{EL}_\mathsf{lhs}$ can be regarded as a fragment of first-order (FO) Horn logic. Existing approaches to polynomial time learning of FO Horn formulas either disallow recursion, bound the number of individual variables per Horn clause, or admit additional queries in the learning protocol. None of this is the case in our setup. Also related to our work is exact learning of schema mappings in data exchange, as recently studied in (ten Cate, Dalmau, and Kolaitis 2012). In this and some other studies mentioned above, membership queries take the form of interpretations ("is a given interpretation a model of the target theory?"). In DL, exact learning has been studied for CLASSIC in (Frazier and Pitt 1996) where it is shown that single CLASSIC concepts (but not TBoxes) can be learned in polynomial time (here membership queries are concepts). Learning single concepts using refinement operators has been studied in (Lehmann and Hitzler 2010).

Preliminaries

Let $\mathsf{N_C}$ be a countably infinite set of *concept names* and $\mathsf{N_R}$ a countably infinite set of *role names*. The dialect DL-Lite$_\mathcal{R}^\exists$ of DL-Lite is defined as follows (Calvanese et al. 2007). A *role* is a role name or an inverse role r^- with $r \in \mathsf{N_R}$. A *role inclusion (RI)* is of the form $r \sqsubseteq s$, where r and s are roles. A *basic concept* is either a concept name or of the form $\exists r.\top$, with r a role. A DL-Lite$_\mathcal{R}^\exists$ concept inclusion (CI) is of the form $B \sqsubseteq C$, where B is a basic concept and C is an $\mathcal{ELI}$ concept, that is, C is formed according to the rule

$$C, D \quad := \quad A \quad | \quad \top \quad | \quad C \sqcap D \quad | \quad \exists r.C \quad | \quad \exists r^-.C$$

where A ranges over $\mathsf{N_C}$ and r ranges over $\mathsf{N_R}$. A DL-Lite$_\mathcal{R}^\exists$ TBox is a finite set of DL-Lite$_\mathcal{R}^\exists$ CIs and RIs.[1]

As usual, an $\mathcal{EL}$ *concept* is an $\mathcal{ELI}$ concept that does not use inverse roles, an $\mathcal{EL}$ *concept inclusion* has the form $C \sqsubseteq D$ with C and D $\mathcal{EL}$ concepts, and a *(general) $\mathcal{EL}$ TBox* is a finite set of $\mathcal{EL}$ concept inclusions (Baader, Brandt, and Lutz 2005). We use $C \equiv D$ as an abbreviation for the inclusions $C \sqsubseteq D$ and $D \sqsubseteq C$. An $\mathcal{EL}$ TBox $\mathcal{T}$ is *acyclic* if it consists of inclusions $A \sqsubseteq C$ and

[1] For simplicity, we consider DL-Lite without disjointness axioms. All our results also hold for the extension of DL-Lite$_\mathcal{R}^\exists$ with disjointness.

$A \equiv C$ such that A is a concept name, no concept names occurs more than once on the left hand side of an inclusion in $\mathcal{T}$, and $\mathcal{T}$ contains no cycles (Baader et al. 2003; Konev et al. 2012). The semantics of concepts and TBoxes is defined as usual in terms of interpretations (Baader et al. 2003). For a TBox $\mathcal{T}$ and concept inclusion $C \sqsubseteq D$, we write $\mathcal{T} \models C \sqsubseteq D$ if every model $\mathcal{I}$ of $\mathcal{T}$ also satisfies $C \sqsubseteq D$. $\mathcal{T}$ is omitted if it is empty, that is, we then simply write $\models C \sqsubseteq D$. We say that concepts C and D are *equivalent w.r.t.* $\mathcal{T}$ and write $C \equiv_{\mathcal{T}} D$ if both $\mathcal{T} \models C \sqsubseteq D$ and $\mathcal{T} \models D \sqsubseteq C$; if r, s are roles, $r \equiv_{\mathcal{T}} s$ is defined analogously. A *signature* Σ is a finite set of concept and role names. The *size* of a concept C, denoted with $|C|$, is the length of the string that represents it, where concept names and role names are considered to be of length one. The *size* of a TBox $\mathcal{T}$, denoted with $|\mathcal{T}|$, is $\sum_{C \sqsubseteq D \in \mathcal{T}} |C| + |D|$.

Learning DL-Lite$_{\mathcal{R}}^{\exists}$ TBoxes in Polynomial Time

We prove that DL-Lite$_{\mathcal{R}}^{\exists}$ TBoxes can be learned in polynomial time. The signature Σ of the target TBox $\mathcal{T}$ is known to the learner. To simplify presentation, we assume that the target TBox is in *named form*, that is, it contains for each role r a concept name A_r such that $A_r \equiv \exists r.\top \in \mathcal{T}$. This assumption is without loss of generality since any (polynomial time) learning algorithm for TBoxes in named form can be transformed into one for unrestricted TBoxes: the algorithm still uses the concept names A_r in its internal representations (although they are no longer included in the target signature Σ), and replaces each A_r with $\exists r.\top$ in queries to the oracle and when ultimately returning the TBox that it has learned.

In an initial phase, the learning algorithm for DL-Lite$_{\mathcal{R}}^{\exists}$ TBoxes determines, using at most $\mathcal{O}(|\Sigma|^2)$ entailment queries, all CIs $B_1 \sqsubseteq B_2$ with $\mathcal{T} \models B_1 \sqsubseteq B_2$ and B_1, B_2 basic concepts and the set of all RIs $r \sqsubseteq s$ with $\mathcal{T} \models r \sqsubseteq s$. A concept or role inclusion is in *reduced form* if all basic concepts that occur in it are concept names. We assume without further notice that all concept inclusions considered by the learner, except those that have been determined in the initial phase, are in reduced form. In particular, counterexamples returned by the oracle are immediately converted into this form.

To formulate the learning algorithm, it is useful to identify each $\mathcal{ELI}$ concept C with a finite tree T_C whose nodes are labeled with sets of concept names and whose edges are labeled with roles. In detail, if A is a concept name, then T_A has a single node d with label $l(d) = \{A\}$; if $C = \exists r.D$, then T_C is obtained from T_D by adding a new root d_0 and an edge from d_0 to the root d of T_D with label $l(d_0, d) = r$ (we then call d an *r-successor* of d_0); if $C = D_1 \sqcap D_2$, then T_C is obtained by identifying the roots of T_{D_1} and T_{D_2}. Conversely, every tree T of the described form gives rise to an $\mathcal{ELI}$ concept C_T in the obvious way. We will not always distinguish explicitly between C and its tree representation T_C which allows us to speak, for example, about the nodes and subtrees of an $\mathcal{ELI}$ concept.

The following notion plays a central role in the learning algorithm. Let $\mathcal{T}$ be a DL-Lite$_{\mathcal{R}}^{\exists}$ TBox. A DL-Lite$_{\mathcal{R}}^{\exists}$ inclusion $A \sqsubseteq C$ is *$\mathcal{T}$-essential* if it is in reduced form, $\mathcal{T} \models A \sqsubseteq C$, and the following conditions are satisfied:

1. $A \sqsubseteq C$ is *concept saturated for* $\mathcal{T}$: if C' results from C by adding a concept name A' to the label of some node, then $\mathcal{T} \not\models A \sqsubseteq C'$.
2. $A \sqsubseteq C$ is *role saturated for* $\mathcal{T}$: if C' results from C by replacing a role r by a role r' with $r' \not\equiv_{\mathcal{T}} r$ and $\mathcal{T} \models r' \sqsubseteq r$, then $\mathcal{T} \not\models A \sqsubseteq C'$.
3. $A \sqsubseteq C$ is *sibling-merged for* $\mathcal{T}$: if C' is the result of identifying in C an r-successor and an s-successor of the same node where $r \equiv_{\mathcal{T}} s$, then $\mathcal{T} \not\models A \sqsubseteq C'$.[2]
4. $A \sqsubseteq C$ is *parent/child-merged for* $\mathcal{T}$: if d' is an r-successor of d in C and d'' is an s-successor of d' with $r^- \equiv_{\mathcal{T}} s$, then $\mathcal{T} \not\models A \sqsubseteq C'$ where C' results from C by identifying d and d''.
5. $A \sqsubseteq C$ is *minimal for* $\mathcal{T}$: if d' is an r-successor of d in C and A' is in the node label of d, then $\mathcal{T} \not\models A' \sqsubseteq \exists r.C'$ where C' corresponds to the subtree rooted at d' (where $A' \not\equiv_{\mathcal{T}} A$ if d is the root of C).

Note that Points 1 to 5 carefully mix conditions that 'maximize' (Points 1 and 2) and 'minimize' (Point 5) the concept C. Points 3 and 4 are a form of maximization.

Algorithm 1 The learning algorithm for DL-Lite$_{\mathcal{R}}^{\exists}$

```
1: Compute                                              (entailment queries)
     H_basic = {r ⊑ s | T ⊨ r ⊑ s} ∪
               {B1 ⊑ B2 | T ⊨ B1 ⊑ B2, B1, B2 basic}
2: Set H_add = ∅
3: while Equivalent (H_basic ∪ H_add)? returns "no" do
4:     Let A ⊑ C be the returned positive counterexample
           for T relative to H_basic ∪ H_add
5:     Find a T-essential inclusion A' ⊑ C' with
           H_basic ∪ H_add ⊭ A' ⊑ C'                    (entailment queries)
6:     if there is A' ⊑ C'' ∈ H_add then
7:         Find T-essential inclusion A' ⊑ C* such that
           H_basic ⊨ C* ⊑ C'' ⊓ C'                      (entailment queries)
8:         Replace A' ⊑ C'' by A' ⊑ C* in H_add
9:     else
10:        add A' ⊑ C' to H_add
11:    end if
12: end while
13: Set H = H_basic ∪ H_add.
```

The algorithm for learning DL-Lite$_{\mathcal{R}}^{\exists}$ TBoxes in named form is given as Algorithm 1, where the implementation of the lines marked with "(entailment queries)" requires the execution of entailment queries as detailed below. Observe that, in Line 4, the assumption that a positive counterexample is returned by the oracle (i.e., CI entailed by $\mathcal{T}$ but not by $\mathcal{H}_{basic} \cup \mathcal{H}_{add}$) is justified by the construction of $\mathcal{H}_{basic}$ and $\mathcal{H}_{add}$, that is, we only include inclusions entailed by the target TBox $\mathcal{T}$ in our hypothesis TBox $\mathcal{H}_{basic} \cup \mathcal{H}_{add}$ and thus, at all times, $\mathcal{T} \models \mathcal{H}_{basic} \cup \mathcal{H}_{add}$. We now show in

[2] The node that results from the identification is then either an r-successor or an s-successor of its parent, which is equivalent.

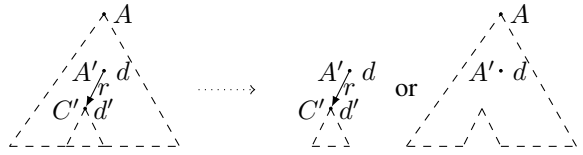

Figure 1: Minimization.

more detail how Lines 5 and 7 can be implemented, and that only polynomially many entailment queries are required. The next lemma addresses Line 5.

Lemma 1 *Given a positive counterexample $A \sqsubseteq C$ for $\mathcal{T}$ relative to $\mathcal{H}_{basic} \cup \mathcal{H}_{add}$, one can construct a $\mathcal{T}$-essential such counterexample using only polynomially many entailment queries in $|C| + |\mathcal{T}|$.*

Proof. Let $A \sqsubseteq C$ be a positive counterexample for $\mathcal{T}$ relative to $\mathcal{H}_{basic} \cup \mathcal{H}_{add}$. We may assume that $A \sqsubseteq C$ is in reduced form and exhaustively apply the following rules, which rely on posing entailment queries to the oracle:

(Concept saturation) if $\mathcal{T} \models A \sqsubseteq C'$ and C' results from C by adding a concept name A' to the label of some node, then replace $A \sqsubseteq C$ by $A \sqsubseteq C'$.

(Role saturation) if $\mathcal{T} \models A \sqsubseteq C'$ and C' results from C by replacing a role r by a r' with $r \not\equiv_{\mathcal{T}} r'$ and $\mathcal{T} \models r' \sqsubseteq r$, then replace $A \sqsubseteq C$ by $A \sqsubseteq C'$.

(Sibling merging) if $\mathcal{T} \models A \sqsubseteq C'$ and C' is the result of identifying in C an r-successor and an s-successor of the same node where $r \equiv_{\mathcal{T}} s$, then replace $A \sqsubseteq C$ by $A \sqsubseteq C'$.

(Parent/child merging) if d' is an r-successor of d in C, d'' is an s-successor of d' with $r^- \equiv_{\mathcal{T}} s$, and $\mathcal{T} \models A \sqsubseteq C'$ where C' results from C by identifying d and d'', then replace $A \sqsubseteq C$ by $A \sqsubseteq C'$.

(Minimization) if d' is an r-successor of d in C, A' is in the node label of d, and C' corresponds to the subtree rooted at d', $\mathcal{T} \models A' \sqsubseteq \exists r.C'$ (plus $A' \not\equiv_{\mathcal{T}} A$ if d is the root of C), then replace $A \sqsubseteq C$ by

(a) $A' \sqsubseteq \exists r.C'$ if $\mathcal{H}_{basic} \cup \mathcal{H}_{add} \not\models A' \sqsubseteq \exists r.C'$; or

(b) $A \sqsubseteq C|^-_{d'\downarrow}$, where $C|^-_{d'\downarrow}$ is obtained from C by removing the subtree generated by d' from C, otherwise.

The last rule is illustrated in Figure 1. It follows directly from the definition of the rules that the final concept inclusion is $\mathcal{T}$-essential. Let us verify that it is also a positive counterexample for $\mathcal{T}$ relative to $\mathcal{H}_{basic} \cup \mathcal{H}_{add}$. It suffices to show that the CI resulting from each rule application is entailed by $\mathcal{T}$, but not by $\mathcal{H}_{basic} \cup \mathcal{H}_{add}$. The former is straightforward for all five rules. Regarding the latter, in the first four rules we have $\mathcal{H}_{basic} \models C' \sqsubseteq C$ if $A \sqsubseteq C$ is replaced by $A \sqsubseteq C'$. Hence $\mathcal{H}_{basic} \cup \mathcal{H}_{add} \not\models A \sqsubseteq C'$. In the last rule, we have $\{A \sqsubseteq C|^-_{d'\downarrow}, A' \sqsubseteq \exists r.C'\} \models A \sqsubseteq C$. Thus, one of the inclusions $A \sqsubseteq C|^-_{d'\downarrow}$ and $A' \sqsubseteq \exists r.C'$ is not entailed by $\mathcal{H}_{basic} \cup \mathcal{H}_{add}$, and this is the CI resulting from the rule application.

It is not hard to see that the number of rule applications is bounded by $|C|^2 \cdot |\Sigma|$. Note that termination of the algorithm requires the condition in the last rule that $A' \not\equiv_{\mathcal{T}} A$ if d is the root of C. Otherwise, this rule could 'replace' $A \sqsubseteq C$ by any $A' \sqsubseteq C$ with A equivalent to A' w.r.t. $\mathcal{T}$. With the mentioned condition and since all CIs are in reduced form, each time when d is the root of C and $A \sqsubseteq C$ is replaced by $A' \sqsubseteq \exists r.C'$, then we strictly descend in subsumption order, that is, $\mathcal{T} \models A \sqsubseteq A'$ and $\mathcal{T} \not\models A' \sqsubseteq A$. ❑

The following lemma addresses Line 7.

Lemma 2 *Assume that $A \sqsubseteq C_1$ and $A \sqsubseteq C_2$ are $\mathcal{T}$-essential. Then one can construct a $\mathcal{T}$-essential $A \sqsubseteq C$ such that $\mathcal{H}_{basic} \models C \sqsubseteq C_1 \sqcap C_2$ using polynomially many entailment queries in $|C_1| + |C_2|$.*

Proof. Starting with $A \sqsubseteq C_1 \sqcap C_2$, we exhaustively apply the rule for sibling merging from Lemma 1 and denote the result by $A \sqsubseteq C$. Observe that since $A \sqsubseteq C_1$ and $A \sqsubseteq C_2$ are both $\mathcal{T}$-essential, the concept inclusion $A \sqsubseteq C_1 \sqcap C_2$ is (i) concept-saturated for $\mathcal{T}$, (ii) role saturated for $\mathcal{T}$, (iii) parent/child-merged for $\mathcal{T}$, and (iv) minimal for $\mathcal{T}$. The only property of $\mathcal{T}$-essential inclusions that can fail for $A \sqsubseteq C_1 \sqcap C_2$ is being sibling-merged for $\mathcal{T}$. Now one can show that an inclusion with properties (i)–(iv) still has those properties after applying the rule (sibling merging) above. Thus $A \sqsubseteq C$ is $\mathcal{T}$-essential, as required. ❑

Example 3 *Suppose the target TBox $\mathcal{T}$ is*[3]

$$\begin{aligned} \mathsf{Prof} &\sqsubseteq \mathsf{Academic} \sqcap \\ &\quad \exists \mathsf{worksFor}.(\exists \mathsf{supports.Teaching} \sqcap \\ &\qquad \exists \mathsf{supports.Research}) \\ \mathsf{Academic} &\sqsubseteq \exists \mathsf{advisor.Academic} \end{aligned}$$

The algorithm first computes $\mathcal{H}_{\mathsf{basic}}$ as

$$\begin{aligned} \mathsf{Prof} &\sqsubseteq \mathsf{Academic} & \mathsf{Prof} &\sqsubseteq \exists \mathsf{worksFor}.\top \\ \mathsf{Prof} &\sqsubseteq \exists \mathsf{advisor}.\top & \mathsf{Academic} &\sqsubseteq \exists \mathsf{advisor}.\top \end{aligned}$$

and then poses $\mathcal{H}_{\mathsf{basic}}$ as the first equivalence query. Assume that the oracle returns the positive counterexample

$$\mathsf{Prof} \sqsubseteq \exists \mathsf{advisor.Academic}.$$

which is not concept saturated for $\mathcal{T}$; saturating it yields

$$\mathsf{Prof} \sqsubseteq \mathsf{Academic} \sqcap \exists \mathsf{advisor.Academic}$$

which is not minimal for $\mathcal{T}$; minimizing it yields

$$\mathsf{Academic} \sqsubseteq \exists \mathsf{advisor.Academic}.$$

The above CI constitutes the new $\mathcal{H}_{\mathsf{add}}$ and the algorithm asks $\mathcal{H}_{\mathsf{basic}} \cup \mathcal{H}_{\mathsf{add}}$ as an equivalence query. Assume the oracle returns the positive counterexample

$$\begin{aligned} \mathsf{Prof} &\sqsubseteq \exists \mathsf{worksFor}.(\exists \mathsf{supports.Teaching} \sqcap \\ &\qquad \exists \mathsf{worksFor}^-.\mathsf{Academic}) \end{aligned}$$

[3]To facilitate presentation, we use a TBox $\mathcal{T}$ that is not in named form; for this concrete example, however, named form does not make any difference.

which is not parent/child-merged for $\mathcal{T}$; merging it results in the following CI, which is added to $\mathcal{H}_{\mathsf{add}}$:

$$\mathsf{Prof} \sqsubseteq \mathsf{Academic} \sqcap \exists \mathsf{worksFor}.\exists \mathsf{supports}.\mathsf{Teaching}.$$

For the next equivalence query, the oracle returns the positive counterexample

$$\mathsf{Prof} \sqsubseteq \exists \mathsf{worksFor}.\exists \mathsf{supports}.\mathsf{Research}.$$

Following Lines 6 and 7 of Algorithm 1, we conjoin the right-hand side of this CI with that of the existing CI for Prof *in $\mathcal{H}_{\mathsf{add}}$. Applying sibling merging yields the first CI from $\mathcal{T}$, and the algorithm has succeeded to learn $\mathcal{T}$.*

If Algorithm 1 terminates, then it obviously has found a TBox $\mathcal{H}_{basic} \cup \mathcal{H}_{add}$ that is logically equivalent to $\mathcal{T}$. It thus remains to show that the algorithm terminates in polynomially time. Observe that $\mathcal{H}_{add}$ contains at most one concept inclusion $A \sqsubseteq C$ for each concept name A. At each step in the while loop, either some $A \sqsubseteq C$ is added to $\mathcal{H}_{add}$ such that no inclusion with A on the left-hand side existed in $\mathcal{H}_{add}$ before or an existing inclusion $A \sqsubseteq C$ in $\mathcal{H}_{add}$ is replaced by a fresh $A \sqsubseteq C'$ with $\models C' \sqsubseteq C$ and $\not\models C \sqsubseteq C'$. It is thus not hard to see that we can prove termination in polynomial time by establishing the following lemma.

Lemma 4 *The number of replacements of an existing CI $A \sqsubseteq C$ in $\mathcal{H}_{add}$ is bounded polynomially in $|\mathcal{T}|$.*

Proof.(sketch) We first observe that, as a consequence of the fact that $A \sqsubseteq C$ and its replacement $A \sqsubseteq C'$ are both $\mathcal{T}$-essential, the tree that corresponds to C is obtained from the tree that corresponds to C' by removing subtrees (and possibly replacing roles). Let n_C denote the number of nodes in the tree representation of C and let $A^{\mathcal{T}} = \{B \mid A \sqsubseteq B \in \mathcal{H}_{basic}\} \cup \{D \mid A \equiv_{\mathcal{T}} B, B \sqsubseteq D \in \mathcal{T}\}$. Then it suffices to prove the following

Claim. If $A \sqsubseteq C$ is $\mathcal{T}$-essential, then $n_C \leq \sum_{D \in A^{\mathcal{T}}} n_D$.

The claim is proved in the appendix using canonical models for DL-Lite$^{\exists}_{\mathcal{R}}$ TBoxes. ❑

We have obtained the following main result of this section.

Theorem 5 *DL-Lite$^{\exists}_{\mathcal{R}}$ TBoxes are polynomial time learnable using entailment and equivalence queries.*

In the appendix, we provide additional examples showing that if any of the five conditions for being $\mathcal{T}$-essential is removed, then Algorithm 1 no longer runs in polynomial time or does not even terminate. As an example, assume that minimality is omitted from the definition of being $\mathcal{T}$-essential and let $\mathcal{T} = \{A \sqsubseteq B, B \sqsubseteq \exists r.B\}$. Then the oracle can provide for the n-th equivalence query the positive counterexample $A \sqsubseteq \exists r^n.B$, $n \geq 1$. The algorithm does not terminate.

Learning $\mathcal{EL}_{\mathsf{lhs}}$ TBoxes in Polynomial Time

We consider the restriction $\mathcal{EL}_{\mathsf{lhs}}$ of general $\mathcal{EL}$ TBoxes where only concept names are allowed on the right-hand side of concept inclusions. We assume that CIs used in entailment queries and in equivalence queries and those returned as counterexamples are also of this restricted form. Our learning algorithm is a non-trivial extension of the polynomial time algorithm for learning propositional Horn theories presented in (Angluin, Frazier, and Pitt 1992; Arias and Balcázar 2011).

We first introduce some notation. An interpretation $\mathcal{I}$ is a *tree interpretation* if the directed graph $(\Delta^{\mathcal{I}}, \bigcup_{r \in \mathsf{N_R}} r^{\mathcal{I}})$ is a tree and $r^{\mathcal{I}} \cap s^{\mathcal{I}} = \emptyset$ for all distinct $r, s \in \mathsf{N_R}$. We generally denote the root of a tree interpretation $\mathcal{I}$ with $\rho_{\mathcal{I}}$. The *product* of two interpretations $\mathcal{I}$ and $\mathcal{J}$ is the interpretation $\mathcal{I} \times \mathcal{J}$ with $\Delta^{\mathcal{I}\times\mathcal{J}} = \Delta^{\mathcal{I}} \times \Delta^{\mathcal{J}}$, $(d, e) \in A^{\mathcal{I}\times\mathcal{J}}$ if $d \in A^{\mathcal{I}}$ and $e \in A^{\mathcal{J}}$, and $((d, e), (d', e')) \in r^{\mathcal{I}\times\mathcal{J}}$ if $(d, d') \in r^{\mathcal{I}}$ and $(e, e') \in r^{\mathcal{J}}$, for any concept name A and role name r. Products preserve the truth of $\mathcal{EL}$ concept inclusions (Lutz, Piro, and Wolter 2011):

Lemma 6 *For all $\mathcal{EL}$ concepts C: $d \in C^{\mathcal{I}}$ and $e \in C^{\mathcal{J}}$ iff $(d, e) \in C^{\mathcal{I}\times\mathcal{J}}$.*

One can show that the product of tree interpretations is a disjoint union of tree interpretations. If $\mathcal{I}$ and $\mathcal{J}$ are tree interpretations, we denote by $\mathcal{I} \times_{\mathsf{r}} \mathcal{J}$ the tree interpretation that is contained in $\mathcal{I} \times \mathcal{J}$ with root $(\rho_{\mathcal{I}}, \rho_{\mathcal{J}})$.

Let $\mathcal{I}, \mathcal{J}$ be interpretations, $d \in \Delta^{\mathcal{I}}$ and $e \in \Delta^{\mathcal{J}}$. A relation $\sim \subseteq \Delta^{\mathcal{I}} \times \Delta^{\mathcal{J}}$ is a *simulation from $(\mathcal{I}, d)$ to $(\mathcal{J}, e)$* if the following conditions are satisfied: (i) $d \sim e$; (ii) $d \in A^{\mathcal{I}}$ and $d \sim e$ implies $e \in A^{\mathcal{J}}$; (iii) $(d, d') \in r^{\mathcal{I}}$ and $d \sim e$ implies $d' \sim e'$ for some $e' \in \Delta^{\mathcal{J}}$ with $(e, e') \in r^{\mathcal{J}}$. We write $(\mathcal{I}, d) \Rightarrow (\mathcal{J}, e)$ if there is a simulation from $(\mathcal{I}, d)$ to $(\mathcal{J}, e)$ and if $\mathcal{I}$ and $\mathcal{J}$ are tree interpretations then we write $\mathcal{I} \Rightarrow \mathcal{J}$ as a shorthand for $(\mathcal{I}, \rho_{\mathcal{I}}) \Rightarrow (\mathcal{J}, \rho_{\mathcal{J}})$. Simulations preserve the membership of $\mathcal{EL}$-concepts (Lutz, Piro, and Wolter 2011):

Lemma 7 *For all $\mathcal{EL}$ concepts C: if $d \in C^{\mathcal{I}}$ and $(\mathcal{I}, d) \Rightarrow (\mathcal{J}, e)$, then $e \in C^{\mathcal{J}}$.*

For an $\mathcal{EL}$ concept C, we write $\mathcal{I}_C$ to denote the tree interpretation that is obtained by viewing C as an interpretation in the natural way, that is, $\mathcal{I}_C$ is the tree T_C introduced in the context of our learning algorithm for DL-Lite$^{\exists}_{\mathcal{R}}$, represented as an interpretation. Conversely, every tree interpretation $\mathcal{I}$ can be viewed as an $\mathcal{EL}$ concept $C_{\mathcal{I}}$ in a straightforward way.

Let $\mathcal{T}$ be the target TBox to be learned, and assume again that its signature Σ is known to the learner. An interpretation $\mathcal{I}$ is a *$\mathcal{T}$-countermodel* if $\mathcal{I} \not\models \mathcal{T}$. We will now describe a class of $\mathcal{T}$-countermodels that are in a sense minimal and central to our learning algorithm. For a tree interpretation $\mathcal{I}$, we use $\mathcal{I}|^{-}_{\mathsf{root}}$ to denote the interpretation obtained from $\mathcal{I}$ by removing the root $\rho_{\mathcal{I}}$ of $\mathcal{I}$. For any element d of $\Delta^{\mathcal{I}}$, we use $\mathcal{I}|^{-}_{d\downarrow}$ to denote $\mathcal{I}$ with the subtree rooted at d removed. A $\mathcal{T}$-countermodel is *essential* if the following conditions are satisfied:

Algorithm 2 The learning algorithm for $\mathcal{EL}_{\mathsf{lhs}}$ TBoxes

1: Set $\mathfrak{I}$ to the empty sequence (of tree interpretations)
2: Set $\mathcal{H} = \emptyset$
3: **while** Equivalent($\mathcal{H}$)? returns "no" **do**
4: Let $C \sqsubseteq A$ be the returned positive counterexample for $\mathcal{T}$ relative to $\mathcal{H}$
5: Find an essential $\mathcal{T}$-countermodel $\mathcal{I}$ with $\mathcal{I} \models \mathcal{H}$ (entailment queries)
6: **if** there is a $\mathcal{J} \in \mathfrak{I}$ such that $\mathcal{J} \not\to (\mathcal{I} \times_{\mathsf{r}} \mathcal{J})$ and $\mathcal{I} \times_{\mathsf{r}} \mathcal{J} \not\models \mathcal{T}$ **then**
7: Let $\mathcal{J}$ be the first such element of $\mathfrak{I}$
8: Find an essential $\mathcal{T}$-countermodel $\mathcal{J}' \subseteq \mathcal{I} \times_{\mathsf{r}} \mathcal{J}$ (entailment queries)
9: replace $\mathcal{J}$ in $\mathfrak{I}$ with $\mathcal{J}'$
10: **else**
11: append $\mathcal{I}$ to $\mathfrak{I}$
12: **end if**
13: Construct $\mathcal{H} = \{C_{\mathcal{I}} \sqsubseteq A \mid \mathcal{I} \in \mathfrak{I}, \mathcal{T} \models C_{\mathcal{I}} \sqsubseteq A\}$ (entailment queries)
14: **end while**

1. $\mathcal{I}|^{-}_{\mathsf{root}} \models \mathcal{T}$;
2. $\mathcal{I}|^{-}_{d\downarrow} \models \mathcal{T}$ for all $d \in \Delta^{\mathcal{I}} \setminus \{\rho_{\mathcal{I}}\}$.

Intuitively, Condition 1 states that $\mathcal{I}$ contradicts $\mathcal{T}$ only at the root, that is, the only reason for why $\mathcal{I}$ does not satisfy $\mathcal{T}$ is that for at least one CI $C \sqsubseteq A \in \mathcal{T}$, we have that $\rho_{\mathcal{I}} \in C^{\mathcal{I}}$ and $\rho_{\mathcal{I}} \notin A^{\mathcal{I}}$. Condition 2 is a minimality condition which states that for any such $C \sqsubseteq A$ (which needs not be unique), $\rho_{\mathcal{I}}$ is no longer in $C^{\mathcal{I}}$ if we remove any node from $\mathcal{I}$.

The algorithm for learning $\mathcal{EL}_{\mathsf{lhs}}$ TBoxes is given as Algorithm 2, where the implementation of the lines marked with "(entailment queries)" requires the execution of entailment queries as detailed below. It maintains a sequence $\mathfrak{I}$ of tree interpretations that intuitively represents the TBox $\mathcal{H}$ constructed in Line 13; however, tree interpretations are easier to work with for our purposes than the $\mathcal{EL}$ concepts that they represent. In Line 8, we write $\mathcal{J}' \subseteq \mathcal{I} \times_{\mathsf{r}} \mathcal{J}$ as shorthand for: $\mathcal{J}'$ is a subinterpretation of $\mathcal{I} \times_{\mathsf{r}} \mathcal{J}$ that is obtained from $\mathcal{I} \times_{\mathsf{r}} \mathcal{J}$ by removing subtrees. Note that the assumption in Line 4 that a *positive* counterexample is returned is justified by the construction of $\mathcal{H}$ in Lines 2 and 13, which ensures that, at all times, $\mathcal{T} \models \mathcal{H}$.

We now provide additional details on how to realize the three lines marked with "(entailment queries)". Line 13 is easiest: We simply use entailment queries to find all CIs $C_{\mathcal{I}} \sqsubseteq A$ with $\mathcal{I} \in \mathfrak{I}$ and A a concept name from Σ. We will later show that the length of $\mathfrak{I}$ is bounded polynomially in $|\mathcal{T}|$, therefore polynomially many entailment queries suffice. Lines 5 and 8 are addressed by Lemmas 8 and 9 below.

Lemma 8 *Given a positive counterexample $C \sqsubseteq A$ for $\mathcal{T}$ relative to $\mathcal{H}$, one can construct an essential $\mathcal{T}$-countermodel $\mathcal{I}$ with $\mathcal{I} \models \mathcal{H}$ using only polynomially many entailment queries in $|\mathcal{T}| + |C|$.*

Proof. $\mathcal{I}$ is constructed by applying the following rules to $\mathcal{I} := \mathcal{I}_C$.

1. Saturate $\mathcal{I}$ by exhaustively applying the CIs from $\mathcal{H}$ as rules: if $D \sqsubseteq B \in \mathcal{H}$ and $d \in D^{\mathcal{I}}$, then add d to $B^{\mathcal{I}}$.
2. Replace $\mathcal{I}$ by a minimal subtree of $\mathcal{I}$ refuting $\mathcal{T}$ to address Condition 1 of essential $\mathcal{T}$-countermodels: replace $\mathcal{I}$ by $\mathcal{I}|_d$ if $\mathcal{I}|_d$ is minimal with $\mathcal{I}|_d \not\models \mathcal{T}$ (checked using entailment queries), where $\mathcal{I}|_d$ denotes the subtree of $\mathcal{I}$ rooted at d.
3. Exhaustively remove subtrees from $\mathcal{I}$ until Condition 2 of essential $\mathcal{T}$-countermodels is also satisfied: if $\mathcal{I}|^{-}_{d\downarrow} \not\models \mathcal{T}$ (checked using entailment queries), then replace $\mathcal{I}$ by $\mathcal{I}|^{-}_{d\downarrow}$.

The resulting interpretation $\mathcal{I}$ is as required. Details are presented in the appendix. ❏

Lemma 9 *Given essential $\mathcal{T}$-countermodels $\mathcal{I}$ and $\mathcal{J}$ with $\mathcal{I} \times \mathcal{J} \not\models \mathcal{T}$, one can construct an essential $\mathcal{T}$-countermodel $\mathcal{J}' \subseteq \mathcal{I} \times_{\mathsf{r}} \mathcal{J}$ using only polynomially many entailment queries in $|\mathcal{T}| + |\mathcal{I}| + |\mathcal{J}|$.*

Proof. Let $\mathcal{I}$ and $\mathcal{J}$ be essential $\mathcal{T}$-countermodels with $\mathcal{I} \times_{\mathsf{r}} \mathcal{J} \not\models \mathcal{T}$. Set $\mathcal{J}' = \mathcal{I} \times_{\mathsf{r}} \mathcal{J}$ and then exhaustively apply Rule 3 from the proof of Lemma 8 to $\mathcal{J}'$. Clearly, the new $\mathcal{J}'$ is a $\mathcal{T}$-countermodel. Moreover, it is essential:

(1) $\mathcal{J}'|^{-}_{\mathsf{root}} \models \mathcal{T}$: by Lemma 6, $\mathcal{I}|^{-}_{\mathsf{root}} \models \mathcal{T}$ and $\mathcal{J}|^{-}_{\mathsf{root}} \models \mathcal{T}$ imply $\mathcal{I}|^{-}_{\mathsf{root}} \times \mathcal{J}|^{-}_{\mathsf{root}} \models \mathcal{T}$. Now $\mathcal{J}'|^{-}_{\mathsf{root}}$ can be obtained from $\mathcal{I}|^{-}_{\mathsf{root}} \times \mathcal{J}|^{-}_{\mathsf{root}}$ by removing subtrees, and removing subtrees clearly preserves being a model of an $\mathcal{EL}_{\mathsf{lhs}}$ TBox.

(2) $\mathcal{J}'|^{-}_{d\downarrow} \models \mathcal{T}$ for all $d \in \Delta^{\mathcal{J}'} \setminus \{\rho_{\mathcal{J}'}\}$: otherwise, the subtree rooted at d would have been removed during the construction of $\mathcal{J}'$. ❏

Example 10 *Suppose that the target TBox is*

$$\exists \mathsf{parent}.\mathsf{Mouse} \sqsubseteq \mathsf{Mouse}$$
$$\exists \mathsf{parent}.\mathsf{Rabbit} \sqsubseteq \mathsf{Rabbit}$$
$$\exists \mathsf{parent}.\top \sqsubseteq \mathsf{Living}$$

and assume that the oracle returns to the first equivalence query the positive counterexample $C \sqsubseteq \mathsf{Living}$ with

$$C = \exists \mathsf{parent}.\mathsf{Mouse} \sqcap \exists \mathsf{parent}.\mathsf{Rabbit}$$

$\mathcal{I}_C$ is a $\mathcal{T}$-countermodel that violates Condition 2 of being essential which leads to its rewriting into $\mathcal{I}_{C'}$ with

$$C' = \exists \mathsf{parent}.\mathsf{Mouse}$$

(Alternatively, it could also lead to $C' = \exists \mathsf{parent}.\mathsf{Rabbit}$.) The algorithm inserts $\mathcal{I}_{C'}$ into $\mathfrak{I}$ and asks the next equivalence query, to which the oracle returns $D \sqsubseteq \mathsf{Living}$ with

$$D = \exists \mathsf{parent}.\mathsf{Rabbit}.$$

$\mathcal{I}_D$ is an essential $\mathcal{T}$-countermodel and we have $\mathcal{I}_{C'} \not\to (\mathcal{I}_D \times_{\mathsf{r}} \mathcal{I}_{C'})$, where $\mathcal{I}_D \times_{\mathsf{r}} \mathcal{I}_{C'}$ corresponds to the concept

$$D' = \exists \mathsf{parent}.\top.$$

$\mathcal{I}_{D'}$ is $\mathcal{T}$-essential and thus it is inserted into $\mathfrak{I}$ in place of $\mathcal{I}_{C'}$. At this point, the algorithm has learnt $\mathcal{H} = \{\exists \mathsf{parent}.\top \sqsubseteq \mathsf{Living}\}$. The algorithm asks the next equivalence query, to which the oracle returns $E \sqsubseteq \mathsf{Rabbit}$ with

$$E = \exists \mathsf{parent}.\exists \mathsf{parent}.\mathsf{Rabbit}$$

$\mathcal{I}_E$ violates Conditions 1 and 2 of being essential, which leads to its rewriting into $\mathcal{I}_{E'}$ with

$$E' = \mathsf{Living} \sqcap \exists \mathsf{parent}.\mathsf{Rabbit}.$$

We have $\mathcal{I}_{D'} \Rightarrow \mathcal{I}_{E'} \times_{\mathsf{r}} \mathcal{I}_{D'}$ and so $\mathcal{I}_{E'}$ is appended to the list $\mathfrak{I}$. At this point, the algorithm has learnt $\mathcal{H} = \{\mathsf{Living} \sqcap \exists \mathsf{parent}.\mathsf{Rabbit} \sqsubseteq \mathsf{Rabbit}, \exists \mathsf{parent}.\top \sqsubseteq \mathsf{Living}\}$, which is equivalent to the TBox that consists of the second and third CI in $\mathcal{T}$. The algorithm can now proceed to learn $\mathsf{Living} \sqcap \exists \mathsf{parent}.\mathsf{Mouse} \sqsubseteq \mathsf{Mouse}$.

If the algorithm terminates, then it obviously returns a TBox $\mathcal{H}$ that is equivalent to the target TBox $\mathcal{T}$. It thus remains to prove that the algorithm terminates after polynomially many steps, which is a consequence of the following lemma.

Lemma 11 *Let $\mathfrak{I}$ be a sequence computed at some point of an execution of Algorithm 2. Then (i) the length of $\mathfrak{I}$ is bounded by the number of CIs in $\mathcal{T}$ and (ii) each interpretation in each position of $\mathfrak{I}$ is replaced only $|\mathcal{T}| + |\mathcal{T}|^2$ often with a new interpretation.*

Proof.(sketch) Assume that at each point of the execution of the algorithm, $\mathfrak{I}$ has the form $\mathcal{I}_0, \dots, \mathcal{I}_k$ for some $k \geq 0$. To establish Point (i), we closely follow (Angluin, Frazier, and Pitt 1992) and show that (iii) for every $\mathcal{I}_i$, there is a $D_i \sqsubseteq A_i \in \mathcal{T}$ with $\mathcal{I}_i \not\models D_i \sqsubseteq A_i$ and (iv) if $i \neq j$, then $D_i \sqsubseteq A_i$ and $D_j \sqsubseteq A_j$ are not identical.

The proof of Points (iii) and (iv), in turn requires a careful analysis of the concept inclusions in the target TBox that are violated at the root of the $\mathcal{T}$-countermodels $\mathcal{I}_0, \dots, \mathcal{I}_k$.

For the proof of Point (ii), we show that $|\Delta^{\mathcal{I}}| \leq |\mathcal{T}|$ for any essential $\mathcal{T}$-countermodel $\mathcal{I}$ and analyze the relationship between the essential $\mathcal{T}$-countermodels produced from $\mathcal{I} \times_{\mathsf{r}} \mathcal{J}$ when $\mathcal{J} \not\Rightarrow (\mathcal{I} \times_{\mathsf{r}} \mathcal{J})$ (using Lemma 6 and 7). ❑

We have thus established the main result of this section.

Theorem 12 *$\mathcal{EL}_{\mathsf{lhs}}$ TBoxes are polynomial time learnable using entailment and equivalence queries.*

It can again be shown that all adopted conditions are indeed necessary. Consider for example the first condition of being $\mathcal{T}$-essential. Without it, for the target TBox $\mathcal{T} = \{\exists r.A \sqsubseteq A\}$ the oracle can return the infinite set of positive counterexamples $\exists r^n.A \sqsubseteq A$, n a prime number. Then the learning algorithm does not terminate.

Limits of Polynomial Time Learnability

The main result of this section is that $\mathcal{EL}$ TBoxes cannot be learned in polynomial time using entailment and equivalence queries. We also show that DL-Lite$^{\exists}_{\mathcal{R}}$ TBoxes cannot be learned in polynomial time using entailment or equivalence queries alone. This holds for $\mathcal{EL}_{\mathsf{lhs}}$ TBoxes as well and follows from the fact that propositional Horn theories cannot be learned in polynomial time using entailment or equivalence queries alone (Frazier and Pitt 1993; Angluin, Frazier, and Pitt 1992; Angluin 1987a).

We start by proving the non-learnability result for $\mathcal{EL}$ TBoxes. Our proof shows that even *acyclic* target TBoxes cannot be learned in polynomial time when general $\mathcal{EL}$ concept inclusions are admitted in entailment queries, as counterexamples returned by the oracle, and in TBoxes used as equivalence queries. On our way, we also prove non-learnability of DL-Lite$^{\exists}_{\mathcal{R}}$ TBoxes using entailment queries only. The proof is inspired by Angluin's lower bound for the following abstract learning problem (1987c): a learner aims to identify one of N distinct sets $L_1, \dots, L_N$ which have the property that there exists a set $L_\cap$ for which $L_i \cap L_j = L_\cap$, for any $i \neq j$. It is assumed that $L_\cap$ is not a valid argument to an equivalence query. The learner can pose membership queries "$x \in L$?" and equivalence queries "$H = L$?". Then in the worst case it takes at least $N - 1$ membership and equivalence queries to exactly identify a hypothesis L_i from $L_1, \dots, L_N$. The proof proceeds as follows. At every stage of computation, the oracle (which here should be viewed as an adversary) maintains a set of hypotheses S, which the learner is not able to distinguish based on the answers given so far. Initially, $S = \{L_1, \dots, L_N\}$. When the learner asks a membership query x, the oracle returns 'Yes' if $x \in L_\cap$ and 'No' otherwise. In the latter case, the (unique) L_i such that $x \in L_i$ is removed from S. When the learner asks an equivalence query H, the oracle returns 'No' and a counterexample $x \in L_\cap \oplus H$ (the symmetric difference of $L_\cap$ and H). This always exists as $L_\cap$ is not a valid query. If the counterexample x is not a member of $L_\cap$, (at most one) $L_i \in S$ such that $x \in L_i$ is eliminated from S. In the worst case, the learner has to reduce the cardinality of S to one to exactly identify a hypothesis, which takes $N - 1$ queries.

Similarly to the method outlined above, in our proof we maintain a set of acyclic $\mathcal{EL}$ TBoxes S whose members the learning algorithm is not able to distinguish based on the answers obtained so far. We start with $S = \{\mathcal{T}_1, \dots, \mathcal{T}_N\}$, where N is superpolynomial in the size of every TBox $\mathcal{T}_i$, and describe an oracle that responds to entailment and equivalence queries. For didactic purposes, we first present a set of acyclic TBoxes $\mathcal{T}_1, \dots, \mathcal{T}_N$, for which the oracle can respond to entailment queries in the way described above but which is polynomial time learnable when equivalence queries are also allowed. We then show how the TBoxes can be modified to obtain a family of acyclic TBoxes that is not polynomial time learnable using entailment and equivalence queries.

To present the TBoxes in S, fix two role names r and s. For any sequence $\sigma = \sigma^1\sigma^2 \dots \sigma^n$ with $\sigma^i \in \{r, s\}$, the expression $\exists \boldsymbol{\sigma}.C$ stands for $\exists \sigma^1.\exists \sigma^2 \dots \exists \sigma^n.C$. For every such sequence $\boldsymbol{\sigma}$, of which there are $N = 2^n$ many, consider the acyclic $\mathcal{EL}$ TBox $\mathcal{T}_\sigma$ defined as

$$\begin{aligned} \mathcal{T}_{\boldsymbol{\sigma}} &= \{A \sqsubseteq \exists \boldsymbol{\sigma}.M \sqcap X_0\} \cup \mathcal{T}_0 \text{ with} \\ \mathcal{T}_0 &= \{X_i \sqsubseteq \exists r.X_{i+1} \sqcap \exists s.X_{i+1} \mid 0 \leq i < n\} \end{aligned}$$

where $\mathcal{T}_0$ generates a full binary tree whose edges are la-

belled with the role names r and s and with X_0 at the root, X_1 at level 1 and so on. M is a concept name that 'marks' a particular path in this tree given by the sequence $\boldsymbol{\sigma}$. One can use Angluin's strategy to show that TBoxes from the set S of all such TBoxes $\mathcal{T}_{\boldsymbol{\sigma}}$ cannot be learned in polynomial time using entailment queries only: notice that for no sequence $\boldsymbol{\sigma}' \neq \boldsymbol{\sigma}$ of length n, we have $\mathcal{T}_{\boldsymbol{\sigma}} \models A \sqsubseteq \exists \boldsymbol{\sigma}'.M$. Thus an entailment query of the form $A \sqsubseteq \exists \boldsymbol{\sigma}.M$ eliminates at most one TBox from the set of TBoxes that the learner cannot distinguish. This observation can be generalized to arbitrary entailment queries $C \sqsubseteq D$ in $\mathcal{EL}$ since one can prove, similarly to the proof of Lemma 14 below, that for any $\mathcal{EL}$ concept inclusion $C \sqsubseteq D$ either $\{A \sqsubseteq X_0\} \cup \mathcal{T}_0 \models C \sqsubseteq D$ (thus $C \sqsubseteq D$ is entailed by all TBoxes in S) or at most one TBox from S entails $C \sqsubseteq D$. It follows that acyclic $\mathcal{EL}$ TBoxes are not polynomial time learnable using entailment queries, only. Observe that the TBoxes $\mathcal{T}_{\boldsymbol{\sigma}}$ are actually formulated in DL-Lite$^{\exists}_{\mathcal{R}}$. We show in the appendix that all arguments above are true also when entailment queries are formulated in DL-Lite$^{\exists}_{\mathcal{R}}$ (which include inverse roles) and thus obtain the following result.

Theorem 13 *DL-Lite$^{\exists}_{\mathcal{R}}$ TBoxes are not polynomial time learnable using entailment queries, only.*

Interestingly, a single equivalence query is sufficient to learn any TBox from S in two steps: given the equivalence query $\{A \sqsubseteq X_0\} \cup \mathcal{T}_0$, the oracle has no other option but to reveal the target TBox $\mathcal{T}_{\boldsymbol{\sigma}}$ as $A \sqsubseteq \exists \boldsymbol{\sigma}.M$ can be found 'inside' every counterexample. Our strategy to rule out this option for the oracle is to modify $\mathcal{T}_1, \dots, \mathcal{T}_N$ in such a way that although a TBox $\mathcal{T}_\cap$ axiomatizing the intersection over the set of consequences of each $\mathcal{T}_i$, $i \leq N$, exists, its size is superpolynomial and so cannot be used as an equivalence query by a polynomial time learning algorithm.

For every $n > 0$ and every n-tuple $L = (\boldsymbol{\sigma}_1, \dots, \boldsymbol{\sigma}_n)$, where every $\boldsymbol{\sigma}_i$ is a role sequence of length n as above, we define an acyclic $\mathcal{EL}$ TBox $\mathcal{T}_L$ as the union of $\mathcal{T}_0$ and the following inclusions:[4]

$$\begin{array}{ccc} A_1 \sqsubseteq \exists \boldsymbol{\sigma}_1.M \sqcap X_0 & & A_n \sqsubseteq \exists \boldsymbol{\sigma}_n.M \sqcap X_0 \\ B_1 \sqsubseteq \exists \boldsymbol{\sigma}_1.M \sqcap X_0 & \cdots & B_n \sqsubseteq \exists \boldsymbol{\sigma}_n.M \sqcap X_0 \end{array}$$

$$A \equiv X_0 \sqcap \exists \boldsymbol{\sigma}_1.M \sqcap \dots \sqcap \exists \boldsymbol{\sigma}_n.M.$$

Let $\mathfrak{L}_n$ be a set of n-tuples such that for $1 \leq i \leq n$ and every $L, L' \in \mathfrak{L}_n$ with $L = (\boldsymbol{\sigma}_1, \dots, \boldsymbol{\sigma}_n)$, $L' = (\boldsymbol{\sigma}'_1, \dots, \boldsymbol{\sigma}'_n)$, if $\boldsymbol{\sigma}_i = \boldsymbol{\sigma}'_j$ then $L = L'$ and $i = j$. Then for any sequence $\boldsymbol{\sigma}$ of length n there exists at most one $L \in \mathfrak{L}_n$ and at most one $i \leq n$ such that $\mathcal{T}_L \models A_i \sqsubseteq \exists \boldsymbol{\sigma}.M$ and $\mathcal{T}_L \models B_i \sqsubseteq \exists \boldsymbol{\sigma}.M$. We can choose $\mathfrak{L}_n$ such that there are $N = \lfloor 2^n/n \rfloor$ different tuples in $\mathfrak{L}_n$. Notice that the size of each $\mathcal{T}_L$ with $L \in \mathfrak{L}_n$ is polynomial in n and so N is superpolynomial in the size of each $\mathcal{T}_L$ with $L \in \mathfrak{L}_n$.

Every $\mathcal{T}_L$, for $L \in \mathfrak{L}_n$, entails, among other inclusions, $\bigsqcap_{i=1}^n C_i \sqsubseteq A$, where every C_i is either A_i or B_i. There are 2^n different such inclusions, which indicates that every representation of the 'intersection TBox' requires superpolynomially many axioms. It follows from Lemma 15 below that this is indeed the case.

The following lemma (proved in the appendix) enables us to respond to entailment queries without eliminating too many TBoxes from the list S of TBoxes that the learner cannot distinguish. We use Σ_n to denote the signature of $\mathcal{T}_L$.

Lemma 14 *For all $\mathcal{EL}$ concept inclusions $C \sqsubseteq D$ over Σ_n:*

- *either $\mathcal{T}_L \models C \sqsubseteq D$ for every $L \in \mathfrak{L}_n$ or*
- *the number of different $L \in \mathfrak{L}_n$ such that $\mathcal{T}_L \models C \sqsubseteq D$ does not exceed $|C|$.*

To illustrate the result, consider two TBoxes $\mathcal{T}_L$ and $\mathcal{T}_{L'}$, where $L = (\boldsymbol{\sigma}_1, \dots, \boldsymbol{\sigma}_n)$ and $L' = (\boldsymbol{\sigma}'_1, \dots, \boldsymbol{\sigma}'_n)$. Then the inclusion $X_0 \sqcap \exists \boldsymbol{\sigma}_1.M \sqcap \exists \boldsymbol{\sigma}'_1.M \sqcap A_2 \sqcap \dots \sqcap A_n \sqsubseteq A$ is entailed by both $\mathcal{T}_L$ and $\mathcal{T}_{L'}$ but not by any other $\mathcal{T}_{L''}$ with $L \in \mathfrak{L}_n$.

We now show how the oracle can answer equivalence queries, aiming to show that for any polynomial size equivalence query $\mathcal{H}$, the oracle can return a counterexample $C \sqsubseteq D$ such that either (i) $\mathcal{H} \models C \sqsubseteq D$ and $\mathcal{T}_L \models C \sqsubseteq D$ for at most one $L \in \mathfrak{L}_n$ or (ii) $\mathcal{H} \not\models C \sqsubseteq D$ and for every $L \in \mathfrak{L}_n$ we have $\mathcal{T}_L \models C \sqsubseteq D$. Thus, such a counterexample eliminates at most one $\mathcal{T}_L$ from the set S of TBoxes that the learner cannot distinguish. In addition, however, we have to take extra care of the size of counterexamples as the learning algorithm is allowed to run in time polynomial not only in the size of the target TBox but also in the size of the counterexamples returned by the oracle. For instance, if the hypothesis TBox $\mathcal{H}$ contains an inclusion $C \sqsubseteq D$ which is not entailed by any $\mathcal{T}_L$, one cannot simply return $C \sqsubseteq D$ as a counterexample since the learner will be able to 'pump up' its running time by asking for equivalence of the target TBox a sequence of hypotheses $\mathcal{H}_i = \{C_i \sqsubseteq D_i\}$ such that the size of $C_{i+1} \sqsubseteq D_{i+1}$ is twice the size of $C_i \sqsubseteq D_i$. Then at every stage in a run of the learning algorithm, the running time will be polynomial in the size of the input and the size of the largest counterexample received so far, but the overall running time will be exponential in the size of input. The following lemma addresses this issue.

Lemma 15 *For any $n > 1$ and any $\mathcal{EL}$ TBox $\mathcal{H}$ in Σ_n with $|\mathcal{H}| < 2^n$, there exists an $\mathcal{EL}$ CI $C \sqsubseteq D$ over Σ_n such that (i) the size of $C \sqsubseteq D$ does not exceed $6n$ and (ii) if $\mathcal{H} \models C \sqsubseteq D$ then $\mathcal{T}_L \models C \sqsubseteq D$ for at most one $L \in \mathfrak{L}_n$ and if $\mathcal{H} \not\models C \sqsubseteq D$ then for every $L \in \mathfrak{L}_n$ we have $\mathcal{T}_L \models C \sqsubseteq D$.*

Then we have the following.

Theorem 16 *$\mathcal{EL}$ TBoxes are not polynomial time learnable using entailment and equivalence queries.*

[4] In fact, to prove non-polynomial learnability, it suffices to consider $\exists \boldsymbol{\sigma}_1.M \sqcap \dots \sqcap \exists \boldsymbol{\sigma}_n.M \sqsubseteq A$ in place of the concept equality; however, inclusions of this form are not allowed in acyclic TBoxes.

Proof. Assume that TBoxes are polynomial time learnable. Then there exists a learning algorithm whose running time is bounded at any stage by a polynomial $p(n, m)$. Choose n such that $\lfloor 2^n/n \rfloor > (p(n, 6n))^2$ and let $S = \{\mathcal{T}_L \mid L \in \mathfrak{L}_n\}$. We follow Angluin's strategy of letting the oracle remove TBoxes from S in such a way that the learner cannot distinguish between any of the remaining TBoxes. Given an entailment query $C \sqsubseteq D$, if $\mathcal{T}_L \models C \sqsubseteq D$ for every $L \in \mathfrak{L}_n$, then the answer is 'yes'; otherwise the answer is 'no' and all $\mathcal{T}_L$ with $\mathcal{T}_L \models C \sqsubseteq D$ are removed from S (by Lemma 14, there are at most $|C|$ such TBoxes). Given an equivalence query $\mathcal{H}$, the answer is 'no', a counterexample $C \sqsubseteq D$ guaranteed by Lemma 15 is produced, and (at most one) $\mathcal{T}_L$ such that $\mathcal{T}_L \models C \sqsubseteq D$ is removed from S.

As all counterexamples produced are smaller than $6n$, the overall running time of the algorithm is bounded by $p(n, 6n)$. Hence, the learner asks no more than $p(n, 6n)$ queries and the size of every query does not exceed $p(n, 6n)$. By Lemmas 14 and 15, at most $(p(n, 6n))^2$ TBoxes are removed from S during the run of the algorithm. But then, the algorithm cannot distinguish between any remaining TBoxes and we have derived a contradiction. ❑

We now show that DL-Lite$^{\exists}_{\mathcal{R}}$ TBoxes cannot be learnt in polynomial time using equivalence queries only. We use the following result on non-learnability of monotone DNF formulas using equivalence queries due to Angluin (1990). Here, equivalence queries take a hypothesis ψ in the form of a monotone DNF formula and return as a counterexample either a truth assignment that satisfies ψ but not the target formula ϕ or vice versa. Let $M(n, t, s)$ denote the set of all monotone DNF formulas whose variables are $x_1, \dots, x_n$, that have exactly t conjunctions, and where each conjunction contains exactly s variables.
